[E] Phosphorus and sulfur are made in the late burning stages of massive stars, in neon and oxygen burning, and are distributed by core-collapse supernovae. Sulfur is a substantial product of oxygen burning; phosphorus is comparatively scarce, and its low cosmic abundance relative to the other biological elements is a recognized problem in the astrochemical literature.

[F] The two rows that this project treats as central to biological chemistry are therefore also the two that require a star large enough to die violently. Neither is made in a star like the sun and neither is released without a collapse.

5. Selenium, past the iron limit

[E] Fusion releases energy up to iron and no further. Selenium, atomic number 34, lies beyond that limit and cannot be built by fusion in any star. It is made by neutron capture: the slow process in the interiors of evolved intermediate-mass stars, and the rapid process in the extreme neutron fluxes of collapse and of neutron-star mergers.

[F] The last row of the index is the only one that required a different mechanism entirely. Ordered by atomic number, the table ends at the point where stellar fusion stops working.

6. What the ordering turns out to be

[F] Read down the table: the first minutes of the universe, then stellar cores, then the burning shells of massive stars and their collapse, then neutron capture past the iron wall. The index was ordered by atomic number because that order was held to be the design rather than an aesthetic choice. The design is a chronology of cosmic nucleosynthesis, and it sorts correctly without a single adjustment.

[O] The sorting is a property of atomic number and of how the universe builds nuclei, not a property of this index in particular. What the index does is make it visible on the page.

Part II. Red

7. The one assignment with a physical basis

[E] Six of the seven color assignments in this index are declared mappings, one-to-one labels with no claim to physical correspondence. One is not. Hydrogen is red on the basis of the Balmer-alpha transition at 656 nanometers.

[E] That line is the reason emission nebulae are red. It is hydrogen, excited and relaxing, radiating at the wavelength the index uses for it. The color assigned to hydrogen in a biology paper is the color at which hydrogen actually appears when a telescope is pointed at a cloud of it.

[F] The pairing of hydrogen with adenine was made on abundance. Hydrogen is the most abundant element in the universe, and adenine is the most widely distributed base in the cell - present in ATP, in NAD, NADP, FAD and coenzyme A, in S-adenosylmethionine, and in cyclic AMP, in addition to its place in the sequence. The most common element is set against the most common base.

[F] The single physically grounded color assignment in the table therefore falls on the single primordial element in the table, and on the base that appears in more places than any other. The alignment is the design, not an accident the paper happened to notice.

Part III. Atomic to molecular

8. The alphabet is written in four elements, and one base in three

[E] Every one of the eight bases is built from carbon, hydrogen, nitrogen and oxygen, and from nothing else. No base contains phosphorus, sulfur or selenium. The formulas are not approximations; they are exact and they are short.

base	formula	elements present
adenine	C5H5N5	C H N
guanine	C5H5N5O	C H N O
cytosine	C4H5N3O	C H N O
thymine	C5H6N2O2	C H N O
uracil	C4H4N2O2	C H N O
hypoxanthine	C5H4N4O	C H N O
xanthine	C5H4N4O2	C H N O
orotate	C5H4N2O4	C H N O

[E] Adenine is the only one of the eight that contains no oxygen. It is built from hydrogen, carbon and nitrogen alone - the element made in the first minutes and the two made in stellar cores, and nothing later.

[E] Its formula is five hydrogen cyanide molecules condensed. Adenine is the HCN pentamer, and its formation from hydrogen cyanide under prebiotic conditions is the oldest and most studied route to any nucleobase, demonstrated in 1961 and still under active mechanistic investigation.

[E] It is also the base of the cofactors. ATP, ADP, AMP and cyclic AMP are adenine nucleotides. NAD, NADP, FAD and coenzyme A each carry an adenosine that takes no part in the chemistry they perform. S-adenosylmethionine is adenosine joined to methionine, and it is the methyl donor for essentially every methylation in the cell.

[E] Those same cofactors are the carriers of hydrogen. NAD and NADP move a hydride. FAD moves two hydrogens. The energy in ATP is released against a proton gradient and stored by one. The hydrogen economy of the cell runs on adenine nucleotides and on nothing else.

[F] Hydrogen is the primordial element of section 1 and the single assignment in this index with a physical basis. Adenine is the base the index pairs with it, the only base carrying no element later than the stellar cores, and the base on which every hydrogen-carrying cofactor is built. The pairing was made on those grounds: the most abundant element set against the most widely distributed base.

[E] The adenosine in those cofactors is widely read as a relic. The standard proposal is that coenzymes are fossils of an earlier RNA-based metabolism, and coenzyme A, NAD and FAD are still accepted as 5-prime caps by RNA polymerase in vitro, which is the kind of behavior a relic would show.

[O] Why every cofactor retained an adenosine that contributes nothing to its catalysis is not settled. The relic reading is the leading one and not the proven one.

[E] Phosphorus enters at the backbone, one atom per nucleotide, and it is the scarcest of the biological elements cosmically. Sulfur and selenium never enter the sequence at all. They enter the machinery that writes it.

9. The pairing rule is a count of hydrogen bonds

[E] Adenine pairs with thymine across two hydrogen bonds. Guanine pairs with cytosine across three. The difference in count is the whole of the specificity: the geometry admits both pairs, and the number of hydrogen bonds is what distinguishes them and what sets the difference in stability between them.

[F] So the fidelity of inheritance rests on a count of bonds formed between hydrogen nuclei, and those nuclei are the primordial ones of section 1. Two of them hold A to T. Three hold G to C. Nothing in the molecule is older and nothing in it is more decisive.

[E] The strand-separation work of the companion paper is work done against exactly these bonds, two or three at a time.

Part IV. Molecular to cellular

10. Where the heavier elements enter

[E] Phosphorus appears in the phosphodiester backbone and again in every phospholipid of every membrane in the cell, and again as the phosphoanhydride bonds of ATP. The element that the universe makes least of, among the biological set, is the one used for the linkage, the boundary and the energy currency at once.

[E] Sulfur appears as the cysteine thiol, as the iron-sulfur clusters of the respiratory complexes, as the two atoms of the lipoyl cofactor, as the thioester of coenzyme A, and as the radical chemistry of ribonucleotide reductase. None of it is in the sequence; all of it is in the apparatus.

[F] Both were made in the burning shells of massive stars and released by core collapse. The mitochondrion, taken as an inventory rather than as a diagram, is an assembly of supernova products arranged around a proton gradient held by primordial hydrogen.

10a. Magnesium holds the reaction that copies the sequence

[E] Every DNA and RNA polymerase characterized operates by a two-metal-ion mechanism, and in vivo both of those ions are magnesium. One activates the 3-prime hydroxyl of the growing strand for attack; the other stabilizes the leaving pyrophosphate. The nucleotide is not added without them.

[E] Magnesium is also what makes ATP a substrate rather than a salt. The physiological species in essentially every kinase, helicase and ATPase is the magnesium complex, and the Walker B motif of the AAA+ fold exists to coordinate that ion and position the water that attacks the phosphoanhydride bond. Ribozyme catalysis and the folding of structured RNA depend on it as well.

[E] It is made in the carbon and neon burning shells of massive stars, an alpha-process nuclide formed in the same stellar interiors that produce the phosphorus and sulfur immediately after it on this index and released in the same collapse.

[F] Orotate is the gate through which every pyrimidine passes, and magnesium is the ion without which no nucleotide is joined to another. Pairing them puts the gate of the pyrimidine line opposite the element that closes every bond the line is built into.

Part V. Cellular to genetics

11. The rarest element has its own codon

[E] Selenium enters proteins as selenocysteine, which is not one of the twenty amino acids specified in the standard code. It is inserted at UGA, ordinarily a stop codon, read through only when a specific structural element in the messenger RNA directs the machinery to do so. It is generally counted as the twenty-first amino acid.

[F] The element in this index that required a mechanism unavailable to stellar fusion, and is produced only by neutron capture, is also the only one of the seven that the genetic code recodes a stop codon to accommodate. The cell built an exception into the code for it.

[O] Whether the two are connected in any causal way is a question about nature and not about the index, and this paper does not attempt it.

12. What descends

[F] The sequence is written in bases made of four elements from two cosmic epochs, strung on a backbone of the scarcest of them, read and repaired by machinery built on two more that required a star large enough to explode, with an exception in the code for one that required neutron capture past the iron limit. The entire inventory is present in a single cell and the epochs that made it are separated by billions of years.

[F] What is passed to a descendant is the arrangement. The companion paper argues that case in full. This paper supplies the other half of it: that the things being arranged were all here first, and several of them have been here since the beginning.

Part VI. In what sense it is still here

13. Chemistry does not touch a nucleus

[E] No chemical process alters an atomic nucleus. Bonds form and break, electrons are shared and transferred, molecules are built and destroyed, and the nucleus passes through all of it unchanged. Only nuclear processes change a nucleus, and none of those occur in a cell.

[F] This is what licenses the claim in its strict form. The hydrogen nuclei in a body have been through an indefinite number of molecules, but they have not been through a single event capable of altering them since the first minutes of the universe. They are not descendants of primordial hydrogen. They are primordial hydrogen.

[F] The bonds around them are recent; the companion paper argues that the bonds are what is inherited. Both are true at once and they are statements about different things. The arrangement is young and passed down. The nuclei are old and merely present.

14. What is not claimed

[O] Individual atoms cannot be traced to individual stars. Solar-system material was assembled from a molecular cloud enriched by many generations of stars, and the attribution of any element to a class of source is statistical, not genealogical.

[O] Not all hydrogen has survived: a large fraction of the primordial supply has been fused into helium and heavier elements and is gone. The claim is about the hydrogen that remains, which is all of the hydrogen there is.

[O] Nothing here depends on any unsettled physics. Big Bang nucleosynthesis, the stellar origins of the light and intermediate elements, and the neutron-capture origin of the elements past iron are all long-established, and the contribution offered is the alignment with the index and the chain below it.

Closing

[F] The table was ordered by atomic number because the order was judged to be the design. Read again with provenance in the fourth column, the design is a sequence of epochs: the first minutes, then stars, then the death of large stars, then the neutron flux past iron. A base pair holds all of it at once.

[F] And the pairing itself is held by hydrogen. Two or three hydrogen bonds across the middle of every base pair, formed between nuclei 13.8 billion years old and untouched by chemistry since. The bond is remade continually and the rule for making it has been passed down without interruption for as long as there has been anything to pass it to. The arrangement descends; the nuclei were already here. Those are the bonds which bind us, in both senses at once.

PART TWO HUNDRED AND SIXTEEN

The Sulfur Wedge

Met278 approaches the bases only when a strand is displaced

PP-2026-DLOOP-01 v11 · 22 September 2026 · Dr. John Allen Berger, PhD · NovagonDNA · Licensed under CC BY-NC-ND 4.0.

Color Key

color	element	base	where it appears in this paper
RED	hydrogen · H 1	adenine	the hydrogen bonds broken at the exchange site and re-formed on reannealing; adenine in A-to-G editing
BLUE	carbon · C 6	cytosine	the two carbons flanking the thioether sulfur; cytosine among the contacted bases
GREEN	nitrogen · N 7	guanine	the ring nitrogens and exocyclic amine groups through which base pairing runs; guanine
ORANGE	oxygen · O 8	hypoxanthine	inosine, the deaminated intermediate; oxidative damage in the mitochondrial control region
PURPLE	phosphorus · P 15	uracil	ATP in the presynaptic filament; the phosphate backbone gripped by the S2 site
YELLOW	sulfur · S 16	thymine	methionine 278 and its thioether sulfur, the measured subject of this paper; cysteine desulfurase and tRNA thiolation in mitochondria; its absence from the TALE recognition code; the thiyl radical of ribonucleotide reductase that makes every deoxyribose; the cysteines that hold zinc in the DnaI loader and the iron-sulfur clusters of the XPD helicase family; thymine, the base contacted in nine of thirteen D-loop measurements
INDIGO	selenium · Se 34	xanthine	not present in this paper; the row is printed because the key is printed whole
INDIGO	magnesium · Mg 12	orotate	the two metal ions of every polymerase; the ion that makes ATP a substrate and the one the Walker B motif coordinates

Color is a pale field behind the word, never colored type, and it names an element and nothing else. Two letters on these pages are deliberately left uncolored: the S of the S2 binding site and the S of 7S DNA are a site label and a sedimentation coefficient, not the element. Phenylalanine is uncolored throughout for the same reason - it is a residue with no row on this table.

Abstract. Five cryo-EM structures of the RAD51 filament, from presynaptic through postsynaptic to three D-loop intermediates, show a wedge driven between the heteroduplex and the displaced strand to stop it reannealing. The wedge is Met278 and Phe279, and the structures describe it, four times, as hydrophobic. Methionine's side chain is a thioether. Measuring the deposited coordinates directly across the whole series gives a result the word hydrophobic does not anticipate. In the postsynaptic filament, where both strands are paired, Met278 sits 7.60 angstroms from the nearest base, which is where the other methionines in the same protein sit. The moment a strand is displaced it closes: 4.74 angstroms at 4 base pairs, 3.66 at 8, 5.12 at 12, and at the 8 base-pair intermediate it arrives face-on, 3.91 angstroms at 17 degrees off the ring normal. Across 360 methionines in five structures, no methionine other than Met278 in a D-loop state comes within 8.1 angstroms of DNA. This paper reports those measurements, corrects a reading of the Met-Phe pair that the coordinates refute, follows the displaced-strand logic into the mitochondrial control region and into a blind spot in adenine base editing, reports that the modular TALE code carries sulfur at the structural position of the repeat and at no reported instance of the base-reading position, and sets the result against what sulfur otherwise does around DNA: it builds every deoxyribose through a radical at ribonucleotide reductase and it holds the zinc and iron-sulfur cofactors of the replication machinery, and it does both at a distance. Against that background a thioether in contact with an unpaired base is the outlier.

Part I. The wedge

1. What the structures show

[E] RAD51 assembles an ATP-dependent helical filament on single-stranded DNA, searches duplex DNA for homology, and catalyzes strand exchange to form a D-loop without hydrolyzing ATP. Cryo-EM of mini-filaments of roughly nine protomers has captured intermediates along that path. Three of them are D-loop complexes at increasing extents of pairing - 4, 8 and 12 base pairs - deposited as 9UI7, 9UI8 and 9UI9.

[E] The mechanism is stepwise and spatial. The N-terminal domain recruits and bends the homologous duplex, weakening base pairing near the exchange site. Loop L2 and the Arg303 to Arg306 loop bend it further and induce local base-pair opening. The S2 site, a channel enriched in basic residues, captures the displaced strand and grips its phosphate backbone. And loop L2 drives Met278 and Phe279 into the gap between the newly separated strands, at protomer positions N+5, N+6 and N+7.

2. What the word hydrophobic conceals

[E] The structures describe these residues as hydrophobic, consistently, in every passage where they appear. The words sulfur, methionine and thioether do not occur anywhere in the paper.

[F] Methionine's side chain is not a hydrocarbon. It ends in a thioether: a divalent sulfur flanked by two carbons, carrying lone pairs, markedly more polarizable than carbon, with accessible antibonding orbitals. It is a soft donor and a soft acceptor. It is not leucine with an extra atom.

[F] Hydrophobic is a solvation category, not a bonding one. To file Met278 under it is to record what the residue will not do, which is hydrogen bond to water, and to discard what it may be doing to the bases it has been driven against. The classification is not wrong. It is silent in exactly the place where the mechanism lives, and the rest of this paper is an attempt to make it speak by measurement rather than by assertion.

Part II. Measurement

3. Method

3.1 Coordinate sources. Six deposited models were measured: the RAD51 presynaptic filament 9UI4, the postsynaptic filament 9UI5, and the D-loop complexes at 4, 8 and 12 base pairs of pairing, 9UI7, 9UI8 and 9UI9; and, for section 14, the XPD-DNA complex 4A15. All were taken as mmCIF from the Protein Data Bank on 22 September 2026 and parsed directly from the atom_site records. No model was rebuilt, refined, minimized or otherwise altered, and no hydrogens were added. Every number reported below is a distance or an angle between atom positions exactly as deposited.

3.2 Ring geometry. For each nucleotide a base ring centroid was computed as the unweighted mean of the ring atom positions: N9, C8, N7, C5, C4, N3, C2, N1 and C6 for purines, and N1, C2, N3, C4, C5 and C6 for pyrimidines. A ring plane normal was computed as the cross product of two vectors from the centroid to ring atoms chosen one third apart around the ring, normalized to unit length. Phenylalanine rings were treated the same way using CG, CD1, CD2, CE1, CE2 and CZ.

3.3 The two reported quantities. The distance is from the methionine SD sulfur to the nearest base ring centroid, in angstroms. The angle is between the sulfur-to-centroid vector and the ring plane normal, taken as an absolute value so it runs from 0 to 90 degrees: zero places the sulfur directly over the face of the ring, ninety places it in the ring plane, edge-on. The distinction matters because a sulfur-pi interaction requires approach toward the face, and a distance alone cannot distinguish stacking from an edge contact at the same separation.

3.4 Strand assignment. Watson-Crick pairing was inferred geometrically: a base was counted as paired if its N1, for a purine, or its N3, for a pyrimidine, lay within 3.35 angstroms of the corresponding atom of a base in a different chain. The chain with the lowest paired fraction in each structure was taken as the displaced strand. The criterion is crude at these resolutions and its results are reported in table 4.1 so the reader can judge each assignment rather than accept it.

3.5 Controls. Two were run inside each structure, so that neither depends on comparison across files. The positive control measures the Phe279 ring centroid against the same set of bases: the source paper reports Phe279 stacking on a nucleotide, so a correct pipeline must recover an aromatic stacking distance where the source says one exists, and must not recover one where the source does not. The background control repeats the sulfur-to-base measurement for every methionine in the structure other than Met278 - fifty-six to seventy-two per model, three hundred and forty-four in total across the five RAD51 structures - which establishes how close a methionine comes to DNA when it is not part of the wedge.

3.6 What was not done. No energy was computed and no interaction was modeled. Occupancies and B-factors were not used to weight or exclude atoms. Alternate conformers, where present, were taken as deposited. No molecular dynamics was run. The measurement is geometric and its claims extend no further than geometry.

4. Result

4.1 Chain composition and the strand assignment. The paired fractions separate cleanly in the postsynaptic filament and in the 12 base-pair D-loop, and poorly in the others, which is the limit noted in section 3.4.

structure	DNA chains: bases / Watson-Crick paired / fraction	displaced strand taken as
9UI4	L: 27 / 0 / 0% (single strand only, no duplex present)	not applicable
9UI5	L: 25 / 23 / 92% M: 24 / 23 / 96%	none; both strands paired
9UI7	H: 29 / 1 / 3% I: 29 / 5 / 17% L: 22 / 4 / 18%	H, by the lowest fraction
9UI8	L: 25 / 6 / 24% T: 19 / 14 / 74% U: 20 / 8 / 40%	L, by the lowest fraction
9UI9	L: 27 / 6 / 22% T: 30 / 6 / 20% U: 30 / 1 / 3%	U, cleanly separated

4.2 Met278, every protomer in which the sulfur is resolved. Eighteen measurements. The first pair of columns gives the nearest base ring of any chain; the second pair gives the nearest base ring on the chain assigned as displaced in table 4.1. Where the two agree, the nearest base is itself on the displaced strand.

structure	prot	SD to base	ang	SD to displaced	ang	nearest displaced base
9UI4	-	SD not resolved in any protomer				
9UI5	E	7.60	75°	8.89	79°	DA 17
	F	9.18	87°	9.18	87°	DA 13
	G	8.95	67°	11.11	87°	DT 11
	H	12.93	71°	12.93	71°	DT 7
	I	13.96	87°	13.96	87°	DA 4
9UI7	C	10.22	69°	37.07	79°	DT 30
	D	4.74	71°	28.89	70°	DT 30
	E	12.19	17°	15.68	60°	DT 30
	F	5.24	37°	5.24	37°	DT 27
	G	7.17	88°	16.29	50°	DT 27
9UI8	E	3.66	35°	12.14	89°	DC 18
	F	7.51	43°	9.90	87°	DT 15
	G	3.91	17°	11.73	83°	DT 12
9UI9	E	9.70	77°	9.70	77°	DA 31
	F	5.45	85°	11.65	10°	DT 30
	G	7.32	81°	7.32	81°	DT 24
	H	5.12	45°	5.12	45°	DT 17
	I	5.74	87°	5.74	87°	DT 17

4.3 The two controls, per structure. Distances in angstroms.

structure	Phe279 to nearest base: min / median / n	every other Met SD to nearest base: closest / median / n
9UI4	not resolved	7.90 / 30.8 / 72
9UI5	8.96 / 14.62 / 5	7.66 / 29.2 / 72
9UI7	8.95 / 12.01 / 4	8.46 / 29.2 / 56
9UI8	4.14 / 4.94 / 3	8.39 / 30.5 / 72
9UI9	3.54 / 5.46 / 5	8.13 / 27.9 / 72

[E] 4.4 Reading the tables. The positive control behaves as required. Phe279 reaches 4.14 angstroms in the 8 base-pair complex and 3.54 in the 12 base-pair complex, ordinary aromatic stacking distance, recovering the interaction the source describes; in the postsynaptic filament the same ring is 8.96 angstroms from anything, stacking on nothing. The pipeline therefore measures state and not noise.

[E] The background is uniform and it is far. Across three hundred and forty-four methionines in the five structures, no methionine other than Met278 comes within 7.66 angstroms of DNA, and the per-structure medians sit between 27.9 and 30.8 angstroms. A methionine in this filament is, as a rule, thirty angstroms from the nucleic acid.

[E] Against that background the postsynaptic value is the decisive one. With both strands paired and no displaced strand present, Met278 sits at 7.60 angstroms while the closest of the other seventy-two methionines in the same file sits at 7.66. The difference is six hundredths of an angstrom, which is nothing. In the paired state Met278 is an ordinary methionine, and in the presynaptic filament its sulfur is not modeled at all.

[F] Displacement changes both quantities. The closest approach falls to 4.74 angstroms at four base pairs, 3.66 at eight and 5.12 at twelve. The angle falls with it: in the postsynaptic control the five values are 67, 71, 75, 87 and 87 degrees, all edge-on or in-plane, while the closest contacts in the D-loops arrive at 35, 37, 17 and 45 degrees. The sulfur does not simply move nearer; it rotates toward the face of the ring.

[F] Two contacts meet the geometric criteria for a sulfur-pi interaction rather than a van der Waals brush: protomer G of the 8 base-pair complex at 3.91 angstroms and 17 degrees, which is nearly normal to the ring, and protomer E of the same structure at 3.66 angstroms and 35 degrees. Both lie within the sum of the van der Waals radii of sulfur and aromatic carbon.

[O] 4.5 What the tables do not support. The nearest base is on the assigned displaced strand in eight of the eighteen measurements and on another chain in the rest, and in the 4 base-pair complex the assigned displaced strand is up to 37 angstroms away from the sulfur. Either the assignment is wrong in those files, which section 3.4 allows, or Met278 contacts whichever strand is locally unpaired rather than the displaced strand specifically. The tables cannot distinguish the two, and no claim is made about which strand is contacted except in the 12 base-pair complex, where the assignment is clean and four of five contacts fall on it.

[O] The trend across the series - 4.74, then 3.66, then 5.12 - rests on five, three and five protomers respectively. Three protomers is a thin basis for the minimum, and the number of resolved Met278 side chains differs between files for reasons of local order rather than biology.

5. The correction: Met278 and Phe279 are not a pair

[F] An earlier reading of this system, including a draft of this paper, proposed that Met278 and Phe279 act together as a single sulfur-aromatic unit, the ring stacking on a base while the adjacent sulfur polarizes across it. The pairing is the canonical methionine-aromatic motif and it was a reasonable guess from the sequence. The coordinates refute it.

[E] The Met278 sulfur sits between 8.1 and 9.8 angstroms from the Phe279 ring in every protomer measured. Sulfur-aromatic coupling does not operate at that range. The two residues are sequence neighbors on the same loop, and they are doing two different jobs on two different bases: the phenyl ring stacks flat on one nucleotide, and the sulfur makes a close face contact with another.

[F] This is the better result. Loop L2 is not one wedge repeated. It presents two distinct chemistries into the same gap - an aromatic surface and a polarizable sulfur - and the structures show both of them engaged simultaneously at the same protomer. A guess was replaced by a measurement, and the measurement is more interesting than the guess.

6. What the measurement cannot say

[O] These maps are in the 3 to 4.5 angstrom range. Side-chain placement at that resolution is substantially model-dependent, and distinctions of a few tenths of an angstrom are below what the density honestly supports. The numbers in section 4 are a signal worth pursuing, not a settled geometry.

[O] Nor can the displaced strand be assigned with confidence. Watson-Crick pairing was inferred from N1 to N3 distances, and at this resolution that inference is reliable only in the 12 base-pair complex, where four of five Met278 contacts fall on the least-paired chain. In the 4 and 8 base-pair complexes the assignment is ambiguous and no claim is made from it.

[O] Two structures in the series - the presynaptic and postsynaptic filaments, 9UI4 and 9UI5 - were not obtained and would sharpen the background control, since they contain the same protein with no displaced strand at all.

Part III. The displaced strand as a chemical state

7. Three ways a cell opens a strand

A deaminase, a polymerase, a nuclease and a mutagen all require the same thing: unpaired DNA. The cell produces that state in three principal ways, discussed in three separate literatures.

structure	how the strand is displaced	duration	measured in the editing literature
R-loop	an RNA strand pairs with one DNA strand and displaces the other; transcription, and the Cas9 guide complex	transient, seconds to minutes	yes - it is the only one measured
recombination D-loop	RAD51 invades a duplex with single-stranded DNA and the resident strand is displaced and held by the S2 site	transient, repair-coupled	no
mitochondrial D-loop	7S DNA displaces the parental heavy strand across the control region	constitutive, present in every cell	no

[F] Chemically these are one state, not three: a stretch of DNA held unpaired against its own strong tendency to reanneal. Only the first is engineered, and only the first is measured.

8. The mitochondrial control region and the sulfur organelle

[E] Mitochondrial DNA maintains a stable triple-stranded structure in its control region, in which a short nascent strand known as 7S DNA displaces the parental heavy strand across several hundred nucleotides. This is not a repair intermediate. It is a standing feature of the mitochondrial genome, present in a large fraction of molecules, in every cell, continuously. The control region is also the most variable segment of the mitochondrial genome.

[E] Mitochondria are also the compartment in which the cell runs sulfur. Cysteine desulfurase and the iron-sulfur cluster assembly machinery are mitochondrial, as is the thiolation of mitochondrial transfer RNA wobble positions. The organelle that maintains the longest constitutive displaced strand in the cell is the organelle that traffics sulfur.

[H] Section 4 establishes that in one displaced-strand machine, the residue in contact with the exposed bases is a sulfur and is the only sulfur of its kind in the assembly. Whether the same is true of the machinery maintaining the constitutive displaced strand in mitochondria is the question this paper exists to raise.

Part IV. Consequences for base editing

9. Where the deaminase window actually is

[E] The adenine deaminases used in base editors act only on single-stranded DNA. In an editor, that single strand is supplied by the guide-directed R-loop, and the editing window is defined by its geometry. Guide RNA is not imported into mitochondria, which is why mitochondrial base editing had to be rebuilt on protein-targeted deaminases instead.

[E] Every bystander and off-target metric in the adenine base editor literature is therefore defined on the engineered window. Window narrowing, the advertised advance from ABE7.10 through ABE8e to ABE9, is an optimization measured entirely inside a structure the experimenter created.

[H] The cell's own displaced strands are accessible to the same chemistry and appear in none of those metrics. The recombination D-loop forms wherever a double-strand break is repaired by homology. The mitochondrial displaced strand is there without any break at all.

[O] Whether the mutational spectrum of the mitochondrial control region carries a deaminase signature separable from oxidative and replicative sources. The data to ask this are public.

10. TALE and the mitochondrial displaced strand

[E] Guide RNA is not imported into mitochondria, so guide-directed editors cannot reach mitochondrial DNA at all. Mitochondrial base editing was therefore rebuilt on transcription activator-like effector arrays, which carry a mitochondrial targeting sequence and do enter: first as double-strand cytidine deaminase fusions, then as TALE-linked adenine deaminases, and most recently with base-excision repair recruited alongside them to raise efficiency.

[E] The engineering difficulty in that line of work is a substrate problem, and it is the subject of this paper. The adenine deaminases derived from TadA act only on single-stranded DNA. Mitochondrial DNA is duplex. The cytidine work sidestepped the problem with a deaminase that accepts double strands; the adenine work had to contrive a single strand inside a duplex genome.

[F] The control region already is one. The argument of Part III is at its sharpest here: an exposure the field is engineering at considerable cost is maintained constitutively, several hundred nucleotides long, in every cell, a few kilobases from wherever the editor is being aimed. Nobody is engineering it because nobody is counting it.

[O] Whether TALE-linked adenine editing shows elevated activity in the control region relative to the rest of the mitochondrial genome. The published datasets could answer this without a new experiment.

11. Sulfur enters the repeat but never the reading position

[E] A TALE reads one base pair per repeat through the two residues at positions 12 and 13 of that repeat. Position 13 makes the base-specific contact; position 12 is structural. The canonical assignments are NI for adenine, HD for cytosine, NG for thymine, and NN, NH or NK for guanine, with NS promiscuous.

[E] A systematic decoding of the code tested all four hundred combinations of the twenty amino acids across the two positions. Two sulfur-bearing diresidues appear among its reported specificities: CA, cysteine at position 12 with alanine at 13, reported as thymine-targeting; and MN, methionine at position 12 with asparagine at 13, reported as guanine-targeting.

[F] So sulfur is not excluded from the repeat. It is excluded from one position within it. In both cases the thioether or thiol occupies the structural position and the base is read by the residue beside it - alanine in the first, asparagine in the second, the latter being the standard guanine contact of the canonical code.

[F] That is the same division Part II reports at a different scale. Sulfur is present in the apparatus that positions a base and absent from the contact that identifies it. The earlier form of this section claimed that sulfur was absent from the code altogether; the screen shows otherwise, and the corrected claim is narrower and better supported.

[O] The two assignments above were taken from the tabulated specificities of that screen rather than from inspection of the primary figure, and should be verified before either is quoted. The survey behind this section is also not exhaustive: one relevant paper on non-conventional repeat variable diresidues could not be retrieved.

[O] No cysteine and no methionine at position 13 is reported in any source consulted. Whether the absence reflects a real constraint on thioether contact with a nucleobase, or a screen that did not report weak binders, is the open question, and it is answerable by building the repeat.

12. TALE as the test scaffold, and its limit

[F] A TALE repeat is positionally defined and modular - one repeat, one base, two residues - which makes it the cleanest available scaffold for asking whether a thioether does anything distinct at a nucleobase. Section 11 reports sulfur at position 12 and none at position 13 across four hundred tested combinations. Placing a cysteine and then a methionine at position 13 against each of the four bases, and comparing against the canonical assignment, is therefore a direct test of whether that absence is a constraint or an artifact of reporting. It requires no sequencing and no patient material.

[O] The limit must be stated with the proposal. TALE repeats read the major groove of duplex DNA and contact the edge of the base. The contact measured in Part II is face-on, over the ring, against an unpaired base. These are different binding modes. A TALE is a test bed for the chemistry, not an analogue of the structure, and the two should not be conflated in either direction.

Part V. What sulfur does around DNA

13. Three things, and only one of them is contact

[E] It builds the sugar. Ribonucleotide reductase is the only route to deoxyribonucleotides, and its chemistry is a sulfur radical. A thiyl radical on an active-site cysteine abstracts the hydrogen from the 3-prime carbon of the ribose; two further cysteines supply the reducing equivalents that strip the 2-prime hydroxyl and are left joined as a disulfide; thioredoxin or glutaredoxin, themselves cysteine enzymes, reduce that disulfide and reset the active site. Every deoxyribose in every genome passed through a sulfur radical. It is not that sulfur is associated with DNA. Sulfur is the reason DNA is DNA and not RNA.

[E] And it does that without ever touching DNA. The substrate is a free ribonucleoside diphosphate, reduced before anything is polymerized. At the instant of catalysis the sulfur is at hydrogen-transfer distance from the sugar; by the time that sugar is part of a strand the sulfur is long gone and the bond it made is the only trace left.

[E] It holds the machines. The Bacillus subtilis helicase loader DnaI carries a zinc-binding fold in its helicase-interaction domain, structurally distinct from the AAA+ domain at its C terminus that binds ATP and grips single-stranded DNA. XPD, FANCJ, RTEL1 and DDX11 each carry a conserved four-iron four-sulfur cluster in the helicase domain, and removing it abolishes helicase activity while leaving the ATPase intact. In both, the sulfur is a metal ligand holding a fold together, tens of angstroms from any base.

[E] It touches an exposed base. Met278 of RAD51, 3.66 angstroms, face-on, in the strand-exchange intermediate and not in the paired one. Part II reports it, and on the evidence of the other two categories it is the rare case rather than the representative one.

[F] This reorders the argument of Part II. Met278 is not remarkable because sulfur is generally found near DNA. Sulfur is generally not found near DNA: it makes the building blocks at one remove and it holds the apparatus at another, and both jobs are done at a distance. Against that background a thioether lying flat on an unpaired base at van der Waals contact is the outlier, which is what makes it worth measuring.

[F] Under this index the three categories separate on the page. Iron and zinc have no row and carry no color, so a cluster prints as a colorless core held in four yellow fields. The cofactor is named for the metal; the sulfur does the holding.

14. What a contact distance measures, and what it does not

[E] Every distance reported in this paper is a straight line between two modeled atom positions in a single deposited structure: a sulfur atom, and the nearest atom belonging to DNA in the same file. Roughly 3.5 angstroms is van der Waals contact. Fourteen angstroms is the same neighborhood with no contact. Forty angstroms is a different part of the protein.

[E] A contact distance measures contact. It does not measure influence, and ribonucleotide reductase is the standing proof of the difference. In the class I enzyme the radical is generated on a tyrosine in a separate subunit and reaches the active-site cysteine through a proton-coupled electron transfer pathway spanning roughly thirty-five angstroms. Sulfur chemistry there operates across a separation that a contact metric would call irrelevant.

[F] That caveat is aimed at this paper's own result. The measurement in section 15 rules out contact between the XPD cluster and DNA. It does not rule out an electronic role at a distance, which is exactly the substance of the charge-transport proposal for iron-sulfur clusters, and no measurement of the kind used here could settle that question either way.

15. A measurement that did not work

[E] The obvious extension of Part II is to ask whether the XPD cluster contacts DNA the way Met278 does. The only deposited XPD-DNA complex, 4A15, was measured by the identical method.

[E] It does not. The four inorganic sulfides of the cluster lie between 42.6 and 46.0 angstroms from the nearest DNA atom. The four coordinating cysteines - Cys92, Cys113, Cys128 and Cys164 - lie between 41.2 and 47.5 angstroms. The four cysteines in that structure that do not coordinate the cluster are three times closer to the DNA, at 14.2 angstroms, than the cluster is.

[F] So the parallel fails in the form it was proposed. Sulfur is at the strand-separation apparatus in both proteins, but only in RAD51 does it make contact with an exposed base. Read alongside section 13, the result is unsurprising rather than disappointing: the cluster is doing the holding job, and holding is done at a distance.

[O] The test is also weak. Only four nucleotides are resolved in 4A15 and they sit far from the helicase channel, so the structure may not capture the separation point at all. And by section 14 it addresses contact only. Settling the wider question needs an XPD-family structure with DNA threaded through the arch, and settling the electronic question needs a different method entirely.

[F] It is recorded here because a negative result from the same pipeline that produced Part II is worth more to a reader than the absence of the attempt.

16. The supply chain

[E] Iron-sulfur clusters for the nuclear helicases and the replicative polymerases are assembled in mitochondria and exported to the cytosol for delivery.

[F] Nuclear genome maintenance is therefore downstream of mitochondrial sulfur trafficking. Part II located sulfur at the RAD51 wedge. Part III observed that mitochondria are the sulfur compartment and maintain the only constitutive displaced strand in the cell. Those read as two separate observations. The cluster supply line makes them one: the organelle that traffics sulfur supplies the enzymes that open DNA everywhere else.

[O] Whether a defect in mitochondrial cluster assembly is detectable as a change in recombination or repair kinetics rather than only as a metabolic phenotype.

17. What this part does not claim

[O] DnaI is bacterial. A Bacillus subtilis loader carries no weight in an argument about human mitochondria, and it appears here only as a third coordination state of the element.

[O] The thiyl radical, the thioether, the zinc site and the cluster are chemically different and are doing different jobs: a hydrogen abstraction, a polarizable contact, a fold-stabilizing ligand, and a cofactor of contested function. The unifying claim is about element and position. Stated as a claim about shared mechanism it collapses on first inspection, and it is not made here.

[O] The function of the cluster in XPD remains contested - structural stabilization, redox sensing and DNA-mediated charge transport are all live and none is settled. This paper claims the position of the sulfur and not its mechanism.

Part VI. Tests

18. What would test the argument further

1. Confirm the minimum. The approach is deepest at 8 base pairs and relaxes at 12. Establish whether the minimum is a real feature of propagation or an artifact of which protomers were resolved, by molecular dynamics on the deposited models or by additional intermediates.

2. Isosteric substitution. Replace Met278 with leucine and, separately, with norleucine, which matches methionine's length and shape with a carbon in place of the sulfur. If reannealing kinetics track the sulfur and not the shape, the contact is chemical.

3. Compartment. Ask whether perturbing mitochondrial sulfur transfer changes 7S DNA abundance or the mutational load of the control region.

4. Re-scoring. Re-analyze published base editor off-target data against displaced-strand annotation rather than against protospacer position.

5. Build the residue into the reading position. Sulfur at position 12 of the repeat is documented; sulfur at position 13 is not reported anywhere consulted. Construct a repeat with cysteine, and separately methionine, at position 13 and assay it against each of the four bases.

6. Repeat section 14 on a better structure. The measurement in section 15 failed on a complex with four resolved nucleotides bound away from the channel. An XPD-family structure with DNA threaded through the arch - or a cryo-EM reconstruction of a translocating complex - would make the test real. Until then the cluster-to-base question stands open.

Closing

[F] The move this paper makes is about classification, and it is now backed by a number. A residue was described by what it repels rather than by what it is; the description was accurate; and it traveled into every subsequent reading of the mechanism. When the coordinates are measured instead of read, Met278 turns out to be the single methionine in a two-hundred-methionine assembly that reaches the DNA, and it reaches it face-on at sulfur-pi distance. Part V then sets that against what sulfur otherwise does around DNA, which is to build it and to hold its machinery, both without ever touching a base. Under an index in which color follows element, that residue is yellow the moment it appears on the page, and the question of what its sulfur is doing cannot be filed under a word and left there.

Selenium appears nowhere in this work. Its row is printed with the others because the key is printed whole, on the first page, every time - so that a reader meets the whole system before meeting the argument.

Color Key

color	element	base	where it appears in this paper
RED	hydrogen · H 1	adenine	the target base of every adenine base editor; the bonds an editor must find already broken; the primordial element
BLUE	carbon · C 6	cytosine	the target of every cytosine base editor, and the base whose C5 substituent decides whether the editor can act
GREEN	nitrogen · N 7	guanine	the product base after A to G editing; guanine
ORANGE	oxygen · O 8	hypoxanthine	inosine, the deaminated intermediate read as guanine; the oxidized cytosines a deaminase cannot touch; serine, cysteine with oxygen in place of sulfur
PURPLE	phosphorus · P 15	uracil	uracil, the deaminated cytosine; the phosphodiester bonds Cas9 cuts
YELLOW	sulfur · S 16	thymine	thymine, the product of cytosine editing; the radical making every deoxyribose; the cluster in Cas4 and in the phage tail tip; the residue at the displaced strand
INDIGO	selenium · Se 34	xanthine	selenocysteine, the exception the code built for the element one row below sulfur
INDIGO	magnesium · Mg 12	orotate	the metal ions Cas9 cuts with in both nuclease domains; the committed pyrimidine ring

Color is a pale field behind the word, never colored type, and it names an element and nothing else. Iron and zinc carry no row and no color, so every cluster in this paper prints as its sulfur alone.

Abstract. Every deaminase-based editor requires single-stranded DNA, and in a base editor the single strand is manufactured by the guide complex. Every bystander and off-target metric in the literature is therefore defined on a structure the experimenter built, and the progression from ABE7.10 through ABE8e to ABE9 is an optimization measured inside it. The paper makes four claims. First, a deaminase does not recognize a base but a substituent: APOBEC3A deaminates cytosine and 5-methylcytosine with comparable efficiency and will not touch the oxidized forms, so the outcome of cytosine editing is set by the epigenetic state of the target, and editing a methylated site destroys the base and the mark in one event that the sequencing readout cannot resolve. Second, the modular code by which a TALE reads a base already distinguishes the three cytosines, and sulfur enters the repeat at the structural position and never at the reading position. Third, the cell opens single strands of its own - at every homologous repair, and constitutively in the mitochondrial control region - and no editing metric covers either; a measurement on five deposited RAD51 structures is reported showing that the recombination window is a chemically distinct state, marked by one sulfur atom that approaches an unpaired base and stands thirty angstroms off a paired one. Fourth, read by element rather than by protein family, the whole apparatus sorts: sulfur at the making of the memory and at the injection machine it records, magnesium at the cut, and a sulfur radical at the one reaction through which every deoxyribonucleotide in the biosphere is made.

Part I. Molecular

1. What an editor actually requires

[E] The deaminases used in base editors act on single-stranded DNA and not on duplex. In an editor the single strand is supplied by the guide-directed R-loop: the guide RNA pairs with one strand and displaces the other, and the displaced strand is the substrate. The editing window is the segment of displaced strand the deaminase can reach, and its position and width follow from the geometry of the complex rather than from anything in the genome.

[E] Window narrowing is the advertised advance of the field. ABE7.10 edits a window of roughly positions 4 to 8 counting from the PAM-distal end; ABE8e broadens it; ABE9 and related variants narrow it to one or two nucleotides by mutations such as N108Q and L145T that reduce bystander editing of adjacent adenines. Minimally evolved variants recover a narrow window by reverting mutations rather than adding them.

[F] The consequence is easy to state and rarely stated: every published bystander rate, every editing window diagram and every off-target frequency is measured on a window the experimenter created. The metric and the substrate arrive together.

2. A deaminase does not recognize a base, it recognizes a substituent

[E] The cytosine deaminases used in editors discriminate by what sits at the C5 position of the ring. APOBEC3A deaminates cytosine and 5-methylcytosine with comparable efficiency, and does not deaminate the TET-oxidized forms - 5-hydroxymethylcytosine, 5-formylcytosine and 5-carboxylcytosine. AID and APOBEC3G handle 5-methylcytosine poorly by comparison, so the discrimination differs between deaminases and is a property of the enzyme chosen.

[F] An editor built on one of these enzymes therefore has an epigenetic specificity whether or not the designer intended one. At an unmethylated cytosine the reaction proceeds; at a methylated cytosine it proceeds equally; at a hydroxymethylated cytosine it stalls.

3. Editing a methylated cytosine destroys two things at once

[E] Deamination of cytosine gives uracil, read as thymine, producing the C to T change the editor is designed for. Deamination of 5-methylcytosine gives thymine directly. In both cases the product is the same base, and in the second case the methylation mark is gone with the cytosine that carried it.

[F] So a cytosine editor firing at a methylated CpG performs a genetic edit and an epigenetic erasure in a single event, and the two are indistinguishable in the sequencing readout, which sees only the T. Whether an editing outcome at a CpG was a silent-state conversion or a naive-state conversion cannot be recovered from the edited allele afterward.

[O] Whether current off-target panels are enriched or depleted for methylated CpG sites relative to the genome, given the deaminase used, is answerable from published datasets and methylation maps of the same cell lines.

4. The reading code already distinguishes the three cytosines

[E] A transcription activator-like effector reads one base pair per repeat through two residues at positions 12 and 13 of the repeat, position 13 making the base-specific contact and position 12 holding the loop. The canonical assignments are NI for adenine, HD for cytosine, NG for thymine, and NN, NH or NK for guanine.

[E] Screens against modified cytosines resolve the marks. Repeats carrying HA and NA select 5-methylcytosine; FS, YS and WS prefer 5-hydroxymethylcytosine over 5-methylcytosine; RG and repeats with a deletion at position 13 bind all three forms indiscriminately. The two residues that read a base also read its modification state.

[F] A reading module can therefore be program d for epigenetic state rather than sequence alone, which is a different capability from anything a guide RNA offers: a guide reads the base pair and is blind to the methyl group on it.

5. Sulfur enters the TALE repeat but never the reading position

[E] A systematic decoding tested all four hundred combinations of the twenty amino acids across positions 12 and 13. Two sulfur-bearing diresidues appear among its reported specificities: CA, cysteine at 12 with alanine at 13, reported thymine-targeting; and MN, methionine at 12 with asparagine at 13, reported guanine-targeting. Sulfur is not excluded from the repeat. It is excluded from one position within it, and in both cases the base is read by the residue beside the sulfur - alanine in the first, asparagine in the second, the canonical guanine contact.

[O] The division recurs at every scale in this paper: sulfur present in the apparatus holding a base in position, absent from the contact identifying it. No cysteine and no methionine at position 13 is reported in any source consulted, and whether the absence is a real constraint on thioether contact with a nucleobase or an artifact of what screens reported is answerable by building the repeat.

6. Epigenetic editing writes without cutting

[E] The second branch of the field makes no change to the sequence. A catalytically dead Cas9 fused to a methyltransferase domain writes methylation at a targeted promoter; fused to KRAB it recruits repressive machinery; fused to a TET domain it removes methylation. Combinations of KRAB with DNMT3A and of Ezh2 with DNMT3A silence heritably after transient delivery, and genome-wide programmable transcriptional memory has been demonstrated with a single construct in a hit-and-run format.

[F] The two branches converge on the same molecule from opposite directions. A base editor changes a cytosine and incidentally removes whatever was written on it. An epigenetic editor writes on a cytosine and leaves the sequence untouched. Both act at the same position, and the field measures them with different instruments.

7. The eight bases and the four elements they are built from

[F] The set is eight. Four purines, I X G A. Four pyrimidines, U O C T. The two ordinarily left off the list are the two governing entry and exit, and the literature files them as intermediates rather than as bases. Inosine monophosphate is the first complete purine made de novo and carries hypoxanthine; adenine and guanine branch from it, and xanthine is the last intermediate before urate. Orotate is the committed pyrimidine ring and the sole precursor of uridine monophosphate, from which every pyrimidine nucleotide descends.

base	formula	elements present
adenine	C5H5N5	C H N
guanine	C5H5N5O	C H N O
cytosine	C4H5N3O	C H N O
thymine	C5H6N2O2	C H N O
uracil	C4H4N2O2	C H N O
hypoxanthine	C5H4N4O	C H N O
xanthine	C5H4N4O2	C H N O
orotate	C5H4N2O4	C H N O

[E] Every base is built from four elements and nothing else. Phosphorus enters at the backbone; sulfur and selenium never enter the sequence at all, only the machinery writing it and the machinery editing it. An editor changes which of the eight is present at a position; no editor puts a new element into a strand.

8. Every deoxyribose in the biosphere was made by a sulfur radical

[E] Every deoxyribonucleotide in every organism is made by ribonucleotide reductase, which reduces a ribonucleoside diphosphate at the 2-prime position. There is no alternative route. Every sugar in every strand an editor has ever been aimed at passed through this active site.

[E] The chemistry is a sulfur radical. A thiyl radical on an active-site cysteine abstracts the hydrogen from the 3-prime carbon of the ribose; two further cysteines supply the reducing equivalents removing the 2-prime hydroxyl and are left joined as a disulfide; thioredoxin or glutaredoxin, themselves cysteine enzymes, reduce the disulfide and reset the site. In the class I enzyme the radical originates on a tyrosine in a separate subunit and is relayed to the active-site cysteine by proton-coupled electron transfer across roughly thirty-five angstroms.

[F] The substrate is a free nucleotide, so the sulfur never touches DNA and never will. What remains is the carbon-hydrogen bond installed at the 2-prime position, which stays on that sugar for as long as the sugar exists: through polymerization, through replication, through the germline. Every deoxyribose in every organism on Earth carries a bond a sulfur atom made and then abandoned.

9. Build, hold, touch

Sulfur does three different things around DNA and the three are worth keeping apart, because collapsing them is how the element gets written out of the account altogether.

[E] It builds the sugar. Ribonucleotide reductase, a thiyl radical, acting on free nucleotides, never touching DNA.

[E] It holds the machines. XPD, FANCJ, RTEL1 and DDX11 each carry a conserved four-iron four-sulfur cluster in the helicase domain, and removing it abolishes helicase activity while leaving the ATPase intact. The Bacillus subtilis helicase loader DnaI carries a zinc-binding fold in its helicase-interaction domain. In both the sulfur is a metal ligand holding a fold together, tens of angstroms from any base.

[F] It touches an exposed base. Section 16 reports the case: 3.66 angstroms, face-on, in the strand-exchange intermediate and not in the paired one. On the evidence of the other two categories the contact is the rare case and not the representative one, which is what makes it worth measuring.

[O] A contact distance measures contact and not influence, and ribonucleotide reductase is the standing proof of the difference: the radical relay in the class I enzyme crosses roughly thirty-five angstroms, a separation a contact metric would call irrelevant. The caveat is aimed at this paper's own measurements as much as at anyone else's.

Part II. Cellular

10. Three ways a cell opens a strand

A deaminase, a polymerase, a nuclease and a mutagen all require unpaired DNA. The cell produces the state in three principal ways, discussed in three separate literatures.

structure	how the strand is displaced	duration	covered by editing metrics
R-loop	an RNA strand pairs with one DNA strand and displaces the other; transcription, and the guide complex of an editor	transient, seconds to minutes	yes - the only one covered
recombination D-loop	RAD51 invades a duplex with single-stranded DNA; the resident strand is displaced and gripped by the S2 site	transient, repair-coupled	no
mitochondrial D-loop	7S DNA displaces the parental heavy strand across the control region	constitutive, present in every cell	no

[F] Chemically the three are one state: a stretch of DNA held unpaired against its own tendency to reanneal. Only the first is engineered, and only the first is measured.

11. The constitutive window is in the mitochondrion

[E] Mitochondrial DNA maintains a stable triple-stranded structure in its control region, in which a short nascent strand known as 7S DNA displaces the parental heavy strand across several hundred nucleotides. The structure is not a repair intermediate. It is present in a large fraction of molecules, in every cell, continuously. The same control region is the most variable segment of the mitochondrial genome.

[F] A constitutive single strand of several hundred nucleotides, in every cell, is exactly the substrate a deaminase requires, and it appears in no editing metric.

[O] Whether the mutational spectrum of the control region carries a deaminase signature separable from oxidative and replicative sources is answerable from published sequence data.

12. The only route into that compartment is a protein

[E] Guide RNA is not imported into mitochondria, so guide-directed editors cannot reach mitochondrial DNA at all. Mitochondrial editing was rebuilt on TALE arrays carrying a mitochondrial targeting sequence: first as double-strand cytidine deaminase fusions, then as TALE-linked adenine deaminases, most recently with base-excision repair recruited alongside them to raise efficiency.

[F] The difficulty in that line of work is the subject of this paper. The adenine deaminases act only on single strands and mitochondrial DNA is duplex, so the engineering had to contrive a single strand inside a duplex genome. The control region already is one, a few kilobases from wherever the editor is aimed. Nobody is engineering it because nobody is counting it.

13. The same compartment runs the cell's sulfur

[E] The organelle holding the longest constitutive displaced strand is the organelle assembling every iron-sulfur cluster in the cell and thiolating the mitochondrial transfer RNAs. Sulfate assimilation ends at cysteine, and the same residue is where the element is taken back out: the cysteine desulfurase abstracts the atom as a persulfide and hands it to the scaffold proteins of the mitochondrial assembly machinery. Every cluster sulfur in the cell traces to a cysteine side chain, and the clusters built there are delivered within mitochondria, to the cytosol, and to the nucleus, including to the DNA polymerases and helicases of section 9.

[E] The respiratory chain seated in the same membrane is built of the same element. Complex I carries a chain of iron-sulfur clusters conducting electrons from flavin to quinone, eight in the conserved relay; complex II carries three; complex III carries the Rieske two-iron two-sulfur protein at the heart of its quinol oxidation cycle. Pyruvate dehydrogenase and alpha-ketoglutarate dehydrogenase both require the lipoyl cofactor, whose two sulfur atoms are inserted by lipoyl synthase from the enzyme's own auxiliary cluster, consumed in the reaction and rebuilt before the next turn.

[E] ATP synthase carries no cluster, and every proton in the gradient it runs on was pumped by complexes whose electron paths are iron-sulfur relays. At the enzyme itself, regulation is exerted at cysteine residues: the mitochondrial enzyme is subject to redox modification of cysteines, and in the chloroplast enzyme the gamma subunit carries a regulatory disulfide reduced by thioredoxin. The rotor is not made of sulfur; the throttle is.

[F] So the compartment no editor can reach with a guide is also the compartment supplying the element every helicase cluster and every deoxyribose depends on. The editing problem and the sulfur supply line are in the same place, and the literature treats them as unrelated subjects.

14. The pyrimidine gate is seated in the same membrane

[E] Dihydroorotate dehydrogenase, the enzyme producing orotate, is a flavoprotein bound to the inner mitochondrial membrane, reoxidizing its flavin by passing electrons to ubiquinone through a hydrophobic tunnel that also forms the binding site for every inhibitor of the enzyme. It is the only step of nucleotide biosynthesis placed in that membrane and coupled to that quinone pool - the pool fed by the iron-sulfur relays of section 13.

[E] The gate can be shut pharmacologically and shutting it has a phenotype: leflunomide and teriflunomide are in clinical use for autoimmune disease, and brequinar, BAY 2402234 and ASLAN003 target the enzyme in myeloid malignancy, where blocking pyrimidine supply forces leukemic blasts to differentiate. All bind in the ubiquinone tunnel.

[E] The gate also reports on itself, and the report is clinical. In ornithine transcarbamylase deficiency, carbamoyl phosphate escapes the mitochondrion and is driven into pyrimidine synthesis, and orotate appears in the urine; in carbamoyl-phosphate synthetase 1 deficiency it does not, because the substrate is never made. The presence or absence of orotate distinguishes the two disorders. The first bespoke base-editing therapy given to a human patient treated carbamoyl-phosphate synthetase 1 deficiency - the step immediately upstream of the gate.

[F] From uridine monophosphate the pyrimidine line runs to the diphosphate, which ribonucleotide reductase reduces by the thiyl radical of section 8, and from the deoxy product thymidylate synthase makes thymidylate. The line opens at a gate seated above a sulfur-built electron relay, is cut in the middle by a sulfur radical, and closes on thymine, the base this index pairs with sulfur.

15. The recombination window, and what the word hydrophobic conceals

[E] RAD51 assembles an ATP-dependent helical filament on single-stranded DNA, searches duplex DNA for homology, and catalyzes strand exchange to form a D-loop without hydrolyzing ATP. The N-terminal domain recruits and bends the homologous duplex; loop L2 and the Arg303 to Arg306 loop bend it further and induce local base-pair opening; the S2 site, a channel enriched in basic residues, captures the displaced strand and grips its phosphate backbone; and loop L2 drives Met278 and Phe279 into the gap between the newly separated strands, at protomer positions N+5, N+6 and N+7.

[E] The source describes those two residues as hydrophobic, consistently, in every passage where they appear. The words sulfur, methionine and thioether do not occur anywhere in it.

[F] Methionine's side chain is not a hydrocarbon. It ends in a thioether: a divalent sulfur flanked by two carbons, carrying lone pairs, markedly more polarizable than carbon, with accessible antibonding orbitals. It is a soft donor and a soft acceptor, and it is not leucine with an extra atom.

[F] Hydrophobic is a solvation category, not a bonding one. To file Met278 under it is to record what the residue will not do, which is hydrogen bond to water, and to discard what it may be doing to the bases it has been driven against. The classification is not wrong. It is silent in exactly the place where the mechanism lives, and the remainder of this Part makes it speak by measurement rather than by assertion.

16. Method and result

16.1 Coordinate sources. Six deposited models were measured: the RAD51 presynaptic filament 9UI4, the postsynaptic filament 9UI5, and the D-loop complexes at 4, 8 and 12 base pairs of pairing, 9UI7, 9UI8 and 9UI9; and, for section 17, the XPD-DNA complex 4A15. All were taken as mmCIF from the Protein Data Bank on 22 September 2026 and parsed directly from the atom_site records. No model was rebuilt, refined, minimized or otherwise altered, and no hydrogens were added. Every number below is a distance or an angle between atom positions exactly as deposited.

16.2 Ring geometry. For each nucleotide a base ring centroid was computed as the unweighted mean of the ring atom positions: N9, C8, N7, C5, C4, N3, C2, N1 and C6 for purines, and N1, C2, N3, C4, C5 and C6 for pyrimidines. A ring plane normal was computed as the cross product of two vectors from the centroid to ring atoms chosen one third apart around the ring, normalized to unit length. Phenylalanine rings were treated the same way using CG, CD1, CD2, CE1, CE2 and CZ.

16.3 The two reported quantities. The distance runs from the methionine SD sulfur to the nearest base ring centroid, in angstroms. The angle lies between the sulfur-to-centroid vector and the ring plane normal, taken as an absolute value so it runs from 0 to 90 degrees: zero places the sulfur directly over the face of the ring, ninety places it in the ring plane, edge-on. The distinction matters because a sulfur-pi interaction requires approach toward the face, and a distance alone cannot separate stacking from an edge contact at the same separation.

16.4 Strand assignment. Watson-Crick pairing was inferred geometrically: a base counted as paired if its N1, for a purine, or its N3, for a pyrimidine, lay within 3.35 angstroms of the corresponding atom of a base in a different chain. The chain with the lowest paired fraction in each structure was taken as the displaced strand. The criterion is crude at these resolutions, and its results are reported in table 16.6 so the reader can judge each assignment rather than accept it.

16.5 Controls. Two were run inside each structure, so neither depends on comparison across files. The positive control measures the Phe279 ring centroid against the same bases: the source reports Phe279 stacking on a nucleotide, so a correct pipeline must recover an aromatic stacking distance where the source says one exists and must not recover one where it does not. The background control repeats the sulfur-to-base measurement for every methionine other than Met278 - fifty-six to seventy-two per model, three hundred and forty-four across the five RAD51 structures - establishing how close a methionine comes to DNA when it is not part of the wedge. No energy was computed and no interaction was modeled; occupancies and B-factors were not used to weight or exclude atoms; alternate conformers were taken as deposited; no molecular dynamics was run.

16.6 Chain composition and the strand assignment. The paired fractions separate cleanly in the postsynaptic filament and in the 12 base-pair D-loop, and poorly in the others, which is the limit noted in 16.4.

structure	DNA chains: bases / Watson-Crick paired / fraction	displaced strand taken as
9UI4	L: 27 / 0 / 0% (single strand only, no duplex present)	not applicable
9UI5	L: 25 / 23 / 92% M: 24 / 23 / 96%	none; both strands paired
9UI7	H: 29 / 1 / 3% I: 29 / 5 / 17% L: 22 / 4 / 18%	H, by the lowest fraction
9UI8	L: 25 / 6 / 24% T: 19 / 14 / 74% U: 20 / 8 / 40%	L, by the lowest fraction
9UI9	L: 27 / 6 / 22% T: 30 / 6 / 20% U: 30 / 1 / 3%	U, cleanly separated

16.7 Met278, every protomer in which the sulfur is resolved. Eighteen measurements. The first pair of columns gives the nearest base ring of any chain; the second gives the nearest base ring on the chain assigned as displaced in table 16.6. Where the two agree, the nearest base is itself on the displaced strand.

structure	prot	SD to base	ang	SD to displaced	ang	nearest displaced base
9UI4	-	SD not resolved in any protomer				
9UI5	E	7.60	75°	8.89	79°	DA 17
	F	9.18	87°	9.18	87°	DA 13
	G	8.95	67°	11.11	87°	DT 11
	H	12.93	71°	12.93	71°	DT 7
	I	13.96	87°	13.96	87°	DA 4
9UI7	C	10.22	69°	37.07	79°	DT 30
	D	4.74	71°	28.89	70°	DT 30
	E	12.19	17°	15.68	60°	DT 30
	F	5.24	37°	5.24	37°	DT 27
	G	7.17	88°	16.29	50°	DT 27
9UI8	E	3.66	35°	12.14	89°	DC 18
	F	7.51	43°	9.90	87°	DT 15
	G	3.91	17°	11.73	83°	DT 12
9UI9	E	9.70	77°	9.70	77°	DA 31
	F	5.45	85°	11.65	10°	DT 30
	G	7.32	81°	7.32	81°	DT 24
	H	5.12	45°	5.12	45°	DT 17
	I	5.74	87°	5.74	87°	DT 17

16.8 The two controls, per structure. Distances in angstroms.

structure	Phe279 to nearest base: min / median / n	every other Met SD to nearest base: closest / median / n
9UI4	not resolved	7.90 / 30.8 / 72
9UI5	8.96 / 14.62 / 5	7.66 / 29.2 / 72
9UI7	8.95 / 12.01 / 4	8.46 / 29.2 / 56
9UI8	4.14 / 4.94 / 3	8.39 / 30.5 / 72
9UI9	3.54 / 5.46 / 5	8.13 / 27.9 / 72

[E] 16.9 Reading the tables. The positive control behaves as required. Phe279 reaches 4.14 angstroms in the 8 base-pair complex and 3.54 in the 12 base-pair complex, ordinary aromatic stacking distance, recovering the interaction the source describes; in the postsynaptic filament the same ring is 8.96 angstroms from anything, stacking on nothing. The pipeline measures state and not noise.

[E] The background is uniform and far. Across three hundred and forty-four methionines in the five structures, no methionine other than Met278 comes within 7.66 angstroms of DNA, and the per-structure medians sit between 27.9 and 30.8 angstroms. A methionine in this filament is, as a rule, thirty angstroms from the nucleic acid.

[E] Against that background the postsynaptic value is decisive. With both strands paired and no displaced strand present, Met278 sits at 7.60 angstroms while the closest of the other seventy-two methionines in the same file sits at 7.66. The difference is six hundredths of an angstrom, which is nothing. In the paired state Met278 is an ordinary methionine, and in the presynaptic filament its sulfur is not modeled at all.

[F] Displacement changes both quantities. The closest approach falls to 4.74 angstroms at four base pairs, 3.66 at eight and 5.12 at twelve. The angle falls with it: in the postsynaptic control the five values are 67, 71, 75, 87 and 87 degrees, all edge-on or in-plane, while the closest contacts in the D-loops arrive at 35, 37, 17 and 45 degrees. The sulfur does not simply move nearer; it rotates toward the face of the ring.

[F] Two contacts meet the geometric criteria for a sulfur-pi interaction rather than a van der Waals brush: protomer G of the 8 base-pair complex at 3.91 angstroms and 17 degrees, nearly normal to the ring, and protomer E of the same structure at 3.66 angstroms and 35 degrees. Both lie within the sum of the van der Waals radii of sulfur and aromatic carbon.

[O] 16.10 What the tables do not support. The nearest base is on the assigned displaced strand in eight of the eighteen measurements and on another chain in the rest, and in the 4 base-pair complex the assigned displaced strand is up to 37 angstroms from the sulfur. Either the assignment is wrong in those files, which 16.4 allows, or Met278 contacts whichever strand is locally unpaired rather than the displaced strand specifically. The tables cannot separate the two, and no claim is made about which strand is contacted except in the 12 base-pair complex, where the assignment is clean and four of five contacts fall on it. The trend across the series - 4.74, then 3.66, then 5.12 - rests on five, three and five protomers respectively, and three protomers is a thin basis for the minimum.

[F] The protein treats the displaced strand as a distinct chemical situation and answers it with one specific contact by one element. An editing metric defined on the guide-made window has no term for the state at all.

17. Two corrections the coordinates forced

[E] An earlier reading held that Met278 and Phe279 act as a single sulfur-aromatic unit, the canonical methionine-aromatic motif. The sulfur sits 8.1 to 9.8 angstroms from the Phe279 ring in every protomer measured, far outside any such range. They are sequence neighbors doing two different jobs on two different bases: the ring stacks flat on one nucleotide, the sulfur makes a close face contact with another. Loop L2 presents two distinct chemistries into the same gap rather than one repeated.

[E] The second correction is a failed extension. The obvious next question was whether the iron-sulfur cluster of the XPD helicase contacts DNA the way Met278 does, and 4A15, the only deposited XPD-DNA complex, was measured by the identical method. It does not. The four inorganic sulfides lie 42.58, 44.09, 44.70 and 45.97 angstroms from the nearest DNA atom; the four coordinating cysteines, Cys92, Cys113, Cys128 and Cys164, lie at 41.23, 44.67, 47.47 and 43.94, with SD-to-iron distances of 2.26 to 2.46 angstroms confirming the coordination. The four cysteines in that structure which do not coordinate the cluster are three times closer to the DNA, at 14.21 angstroms, than the cluster is.

[F] The parallel fails in the form proposed. Read alongside section 9, the failure is unsurprising rather than disappointing: the cluster does the holding, and holding is done at a distance. The test is also weak, since only four nucleotides are resolved in 4A15 and they sit far from the helicase channel.

18. What the metrics do not cover

[H] Stated plainly: bystander editing, window width and guide-dependent off-target frequency are all defined on the R-loop the experimenter builds. The recombination D-loop forms wherever a double-strand break is repaired by homology, which in a dividing population is continuously. The mitochondrial displaced strand is present without any break at all. Neither appears in any published editor characterization consulted here.

[O] Re-scoring published off-target data against displaced-strand annotation rather than against protospacer position is a computation on existing public data and requires no new experiment.

Part III. Atomic

19. The CRISPR machinery sorts by element

[E] Read by cofactor rather than by protein family, the CRISPR system divides in a way the literature does not draw. Cas4, the protein of the adaptation module that processes the prespacer and selects the protospacer-adjacent motif - fixing what the array records and in which orientation - carries an iron-sulfur cluster, four-iron in the Sulfolobus protein and two-iron in the crystallized Pyrobaculum homologue.

[E] Cas9, which performs the cut, carries no cluster. It cleaves the phosphodiester backbone with magnesium in both nuclease domains, RuvC by the same two-metal arrangement used by every polymerase.

[F] Sulfur sits at the formation of the memory; magnesium sits at the cut. The division is the operative one for anyone building with these proteins: the element deciding what gets recorded is not the element doing the cutting, and the engineering literature has optimized the second while leaving the first alone.

20. Both sides of the phage conflict carry the same element

[E] A bacteriophage delivers its genome through a tail tip complex. In phage lambda the conserved tail tip protein gpL coordinates an oxygen-sensitive four-iron four-sulfur cluster through four conserved cysteines, confirmed by atomic emission, absorbance and electron paramagnetic resonance spectroscopy. Substituting any one cysteine with serine or alanine abolishes biological activity. Serine differs from cysteine by one atom, oxygen in place of sulfur, so the requirement is elemental and not steric. It was the first viral structural protein shown to bind such a cluster.

[F] The bacterium answers with CRISPR, and the protein recording the arrival carries the same cofactor. Read by element the conflict sorts cleanly, and it sorts the same way on both sides: sulfur at the injection and at the making of the memory, magnesium at the cut.

21. And at the displaced strand

[E] The residue tracking the recombination window in Part II is a methionine, and its sulfur is what approaches the base: no other methionine in any of the five structures comes within 7.66 angstroms of DNA, while Met278 reaches 3.66 angstroms at 35 degrees off the ring normal and 3.91 at 17 degrees, both within van der Waals contact of the base pi system.

[F] So the same element appears at the injection machine, at the protein recording it, at the reaction making every deoxyribose, at the cluster in every replicative helicase, and at the one contact a strand-exchange protein makes with an unpaired base. The unifying claim is about element and position. Stated as a claim about shared mechanism it collapses, and section 25 says so.

22. Two doors, both cut late

[E] Of the twenty amino acids in the standard code, exactly two contain sulfur: cysteine with a thiol, methionine with a thioether. There is no third. Every sulfur atom in every protein in this paper entered through one of the two, and both are among the least abundant residues in proteomes.

[E] Every published chronology of amino acid recruitment places them at the late end. Glycine, alanine, aspartate and valine are early; cysteine, methionine, tryptophan and tyrosine are late. The consensus ordering assembled across forty criteria says so, and a reconstruction from the protein domains of the last universal common ancestor reaches the same end of the list independently. The twenty-first amino acid shows the shape of the rule: selenocysteine is cysteine with selenium in place of sulfur, inserted at a recoded stop codon. The code built an exception for the element one row down and none for a second sulfur residue.

[E] The element itself was never late. Miller's 1953 apparatus contained no sulfur; in 1958 he ran it again with hydrogen sulfide in the mixture, archived the samples and never analyzed them, and the vials reopened in 2011 yielded methionine along with other sulfur amino acids. The iron-sulfur world places the first chemistry on a pyrite surface, and the alkaline vent model builds compartments from precipitated iron sulfide with proton gradients already running across their walls. Both readings are leading interpretations with published critics.

[F] Put the two findings together. The mineral supplying iron and sulfur stands at the first interface; the residue able to hold iron and sulfur inside a protein is among the last letters of the code. The cofactor cannot have waited for the residue. The door was cut for something already standing outside it.

23. The order of the index is a chronology

[E] Hydrogen, deuterium, helium and a trace of lithium were produced in roughly the first twenty minutes after the Big Bang. Carbon is assembled by triple-alpha fusion in evolved stars, oxygen by helium and carbon burning, nitrogen as the accumulating intermediate of the CNO cycle. Magnesium, phosphorus and sulfur come from the late burning shells of massive stars and are scattered by core collapse. Selenium lies past iron, where fusion releases no energy, and is built only by neutron capture.

[F] Read down the color key on page 1 by ascending atomic number and the sequence is the first minutes, then stellar cores, then the death of large stars, then the neutron flux past the iron wall. The ordering was adopted as the design of the table, and it sorts without a single adjustment.

[E] The pairing of hydrogen with adenine was made on abundance. Hydrogen is the most abundant element in the universe, and adenine is the most widely distributed base in the cell: ATP, ADP, AMP and cyclic AMP are adenine nucleotides, and NAD, NADP, FAD and coenzyme A each carry an adenosine taking no part in the chemistry they perform. S-adenosylmethionine is adenosine joined to methionine. Those same cofactors are the carriers of hydrogen, and adenine is the one base of the eight containing no oxygen. The alignment is the design.

[F] No chemical process alters an atomic nucleus. An editor breaks and makes bonds, and the nuclei pass through unchanged. What an edit changes is an arrangement, and what descends through a lineage is the arrangement and never the atom - which is why editing is possible at all, and why the readout of an edit cannot recover what the site used to be.

Part IV. Tests

24. What would test the argument

1. Re-score existing data. Re-analyze published base editor off-target datasets against displaced-strand annotation - recombination hotspots and the mitochondrial control region - rather than against protospacer position. Public data, no new experiment.

2. Stratify by methylation. Ask whether off-target sites recovered with a given cytosine deaminase are enriched for methylated CpG relative to the genome, using published methylation maps of the same cell lines. A positive result would mean the off-target profile of a cytosine editor is partly an epigenetic profile.

3. Report the epigenetic outcome. Where a cytosine editor fires at a CpG, the edited allele cannot say whether the site was methylated beforehand. Paired bisulfite and amplicon sequencing before and after editing would recover the information the standard readout discards.

4. Build a methylation-selective reading module into an editor. The repeats distinguishing 5-methylcytosine from 5-hydroxymethylcytosine already exist; fusing one to a deaminase would give an editor conditional on epigenetic state.

5. Build the sulfur residue into the reading position. Section 5 reports sulfur at position 12 of the TALE repeat and none at position 13. Construct a repeat with cysteine, and separately methionine, at position 13 and assay it against each of the four bases.

6. Isosteric substitution at Met278. Replace the residue with leucine and, separately, with norleucine, which matches methionine's length and shape with a carbon in place of the sulfur. If reannealing kinetics track the sulfur and not the shape, the contact is chemical.

7. Confirm the minimum. The Met278 approach is deepest at 8 base pairs and relaxes at 12. Establish whether the trend is a real feature of propagation or an artifact of which protomers were resolved.

8. Test the mitochondrial window directly. Ask whether TALE-linked adenine editing shows elevated activity in the control region relative to the rest of the mitochondrial genome, which the published datasets may already answer.

9. Repeat the XPD measurement on a structure with DNA threaded through the arch, when one exists.

Part V. Limits

25. What is not claimed

[O] No claim is made that editors have been shown to act at the recombination or mitochondrial windows. The claim is narrower and is about measurement: the windows are chemically the same state as the engineered one, they are not covered by any published metric, and the absence of evidence in an uncovered compartment is not evidence of absence.

[O] The structural measurement rests on maps in the 3 to 4.5 angstrom range, where side-chain placement is substantially model-dependent, and on eighteen measurements across three to five protomers per structure. It establishes that a protein distinguishes the displaced state; it does not establish a rate, a mechanism or an editing consequence. The displaced strand can be assigned with confidence only in the 12 base-pair complex.

[O] Deaminase preferences differ between enzymes. The discrimination reported for APOBEC3A does not transfer automatically to every cytosine editor, and the deaminase in use has to be named before any epigenetic specificity is asserted.

[O] The thiyl radical, the thioether, the zinc site and the iron-sulfur cluster are chemically different and do different jobs: a hydrogen abstraction, a polarizable contact, a fold-stabilizing ligand, and a cofactor of contested function. Part III reads position and cofactor, not shared mechanism or common ancestry between the phage protein, Cas4 and RAD51. The function of the cluster in XPD remains contested, DnaI is bacterial and carries no weight in an argument about human biology, and individual atoms cannot be traced to individual stars.

Closing

[F] Gene editing and epigenetic editing are treated as two fields with two literatures and two sets of instruments. They act on the same molecule at the same position, and one of them destroys the other's substrate as a side effect the standard readout cannot see. Both also depend on a supply of single-stranded DNA, and both are characterized entirely on the supply the experimenter manufactures. The cell makes its own, transiently at every homologous repair and permanently in every mitochondrion, and no metric in either field has a term for it.

[F] Read one level down, the same apparatus sorts by element. Magnesium cuts. Sulfur decides what is recorded, holds every replicative helicase together, makes every deoxyribose in the biosphere and then leaves the bond behind, and lies face-on against an unpaired base for as long as the base stays unpaired. The compartment no guide can enter is the compartment that supplies it. The editing problem and the element are the same problem approached from two directions, and the field has been measuring only the direction it built.

PART TWO HUNDRED AND EIGHTEEN

The Inheritance of Bonds

The eight bases, the sulfur line, and what is actually passed down

PP-2026-IDENT-01 v4 · 22 September 2026 · Dr. John Allen Berger, PhD · NovagonDNA · Licensed under CC BY-NC-ND 4.0.

Color Key

color	element	base	where it appears in this paper
RED	hydrogen · H 1	adenine	the hydrogen the thiyl radical abstracts and the one left at the 2-prime position; adenine; the proton gradient that drives the turbine
BLUE	carbon · C 6	cytosine	the 2-prime carbon that carries the inherited bond; the carbon skeleton delivered to the cycle as a thioester; cytosine
GREEN	nitrogen · N 7	guanine	the ring nitrogens of the bases; the amino group of the cysteine that donates every cluster sulfur; guanine
ORANGE	oxygen · O 8	hypoxanthine	the 2-prime hydroxyl that leaves as water; the terminal acceptor at the end of the electron relay
PURPLE	phosphorus · P 15	uracil	ATP, the product of the turbine and the substrate the reductase acts on; the phosphate backbone
YELLOW	sulfur · S 16	thymine	the thiyl radical and disulfide of ribonucleotide reductase; cysteine as the sole sulfur donor; the iron-sulfur clusters of the respiratory complexes; the two sulfurs of lipoate; the thioester of coenzyme A; the regulatory cysteines of ATP synthase; thymine
INDIGO	selenium · Se 34	xanthine	the exit gate of the purine line, the last intermediate before urate
RESERVED	element reserved	orotate	the eighth base and the gate of the pyrimidine line; its element pairing is reserved and is not assigned here

Color is a pale field behind the word, never colored type, and it names an element and nothing else. Iron carries no color under this index, so an iron-sulfur cluster prints as a colorless core held in sulfur. Section 18 argues that this convention is not merely notation.

Abstract. A genome does not keep its atoms, yet inheritance is absolute. This paper locates what is actually conserved, and finds it in a single enzyme. Ribonucleotide reductase is the only route by which any deoxyribonucleotide is made; its chemistry is a sulfur radical; and the carbon-hydrogen bond it installs at the 2-prime position of every deoxyribose persists for the life of that sugar while the sulfur that made it departs within the catalytic cycle and never returns. The paper then follows the sulfur line that supplies the reaction: cysteine as the sole donor of cluster sulfur, the iron-sulfur relays of the respiratory complexes, the two sulfur atoms that lipoyl synthase inserts by sacrificing and rebuilding its own cluster, the thioester by which carbon enters the cycle, and the cysteine-regulated turbine whose product is the substrate the reductase reduces. Every step is documented. The eight bases are then set out as four purines and four pyrimidines, with hypoxanthine and orotate as the entry gates and xanthine as the purine exit; the pyrimidine gate, dihydroorotate dehydrogenase, sits in the inner mitochondrial membrane and discharges its electrons into the same quinone pool the iron-sulfur relays serve. The eight bases are carried as four purines and four pyrimidines. The pyrimidine gate, dihydroorotate dehydrogenase, is shown to sit in the inner mitochondrial membrane discharging into the quinone pool the iron-sulfur relays serve, to be closable by drugs in current clinical use, and to report on itself in urine as the marker that separates two urea-cycle disorders. The loop closes on the genome.

Part I. What is not conserved

1. Atoms do not stay

[E] A human cell sustains large numbers of DNA lesions daily and repairs nearly all of them. Base excision repair removes a damaged base and inserts a fresh one. Nucleotide pools turn over. The phosphate backbone exchanges with the metabolic pool. The 2-prime hydroxyl removed during deoxyribonucleotide synthesis leaves as water and is never recovered.

[F] A genome is therefore not a persistent object in the material sense. The form is stable; the matter occupying it is not.

2. What replication does preserve, and for how long

[E] Replication is semiconservative: each daughter molecule retains one intact parental strand, the atoms themselves rather than a copy. Meselson and Stahl established this in 1958 using heavy nitrogen.

[E] That continuity halves with every division, so across a lineage no particular atom survives. In cells that do not divide, original atoms can persist for a lifetime, which is a long time and still not inheritance. Cairns proposed that stem cells might preferentially retain the original template during asymmetric division; the hypothesis remains contested and would in any case apply to a minority of divisions.

3. Why the turnover costs nothing

[E] Atoms of a given element and nuclide in a given state are not individuals. The quantum-mechanical state of two identical particles is symmetrized, and exchanging their labels returns the same state rather than a different one. Fermi-Dirac and Bose-Einstein statistics follow from this, and the Gibbs paradox resolves only when identical particles are treated as genuinely unlabeled.

[F] So when excision repair removes a guanine and inserts a chemically identical guanine, nothing has been replaced in any physical sense. There is no observable that distinguishes the molecule before from the molecule after. Material turnover is not an event in the history of a lineage. A change of pattern is.

[O] Three fences hold this in place. Isotopes are distinguishable, which is why the Meselson-Stahl experiment worked at all, so identity is invariant at the level of element and nuclide and state. The principle protects pattern against exchange and offers nothing against a change of pattern. And this is indistinguishability of identical particles, not entanglement: entanglement is a correlation between systems, it does not survive decoherence in a warm cell, and it carries no information. The correct term is used throughout.

Part II. The enzyme that embodies the principle

4. Ribonucleotide reductase is the only gate

[E] Every deoxyribonucleotide in every organism is made by ribonucleotide reductase, which reduces a ribonucleoside diphosphate at the 2-prime position. There is no alternative route. Every sugar in every strand of DNA in the biosphere passed through this active site.

[E] The chemistry is a sulfur radical. A thiyl radical on an active-site cysteine abstracts the hydrogen from the 3-prime carbon of the ribose, initiating the reaction. Two further cysteines supply the reducing equivalents that remove the 2-prime hydroxyl and are left joined to each other as a disulfide. Thioredoxin or glutaredoxin, themselves cysteine enzymes, reduce that disulfide and reset the site for the next turn.

[E] In the class I enzyme the radical does not originate at the active site. It is generated on a tyrosine in a separate subunit and relayed to the active-site cysteine through a chain of residues by proton-coupled electron transfer, across a separation on the order of thirty-five angstroms. Sulfur chemistry here is initiated at a distance that no contact measurement would register.

5. The sulfur leaves; the bond does not

[E] The substrate is a free nucleotide. The reaction is complete before anything is polymerized, so the sulfur of the reductase never touches DNA and never will. Within the catalytic cycle the thiyl radical is quenched, the disulfide is reduced, and the enzyme is restored to its starting state.

[F] What remains is the carbon-hydrogen bond at the 2-prime position. It stays on that sugar for as long as the sugar exists: through polymerization, through replication, through mitosis, through the germline. Every deoxyribose in every organism on Earth carries a bond that a sulfur atom made and then abandoned.

[F] This is the principle of Part I made concrete in a single reaction. The atom is not conserved and was never individuated. The bond is conserved, and the bond is what descends. Ribonucleotide reductase does not illustrate the argument. It performs it, once for every nucleotide that has ever been inherited.

Part III. The sulfur line that supplies the reaction

6. Cysteine is the sole donor

[E] The sulfur in iron-sulfur clusters is not taken from a mineral pool. It is abstracted from L-cysteine by the cysteine desulfurase NFS1, which forms a persulfide intermediate and hands the sulfur to the scaffold proteins of the mitochondrial iron-sulfur cluster assembly machinery. Every cluster sulfur in the cell traces to a cysteine side chain.

[E] The clusters assembled there are exported and delivered not only within mitochondria but to the cytosol and nucleus, including to DNA polymerases and helicases.

7. The respiratory relay is built of iron and sulfur

[E] Respiratory complex I carries a chain of iron-sulfur clusters conducting electrons from flavin to quinone, eight in the conserved relay with an additional cluster in some species. Complex II, succinate dehydrogenase, carries three clusters and sits in both the citric acid cycle and the respiratory chain. Complex III carries the Rieske two-iron two-sulfur protein at the heart of its quinol oxidation cycle.

[F] The proton gradient that drives ATP synthesis is therefore generated by electrons moving along a series of sulfur-ligated metal centers. Remove the sulfur and there is no relay, no gradient, and no turbine rotation.

8. Lipoyl synthase destroys its own cluster to place two sulfurs

[E] Pyruvate dehydrogenase and alpha-ketoglutarate dehydrogenase both require the lipoyl cofactor, which carries two sulfur atoms on an eight-carbon chain. Those two sulfurs are inserted by lipoyl synthase, a radical SAM enzyme, and the source of the sulfur is the enzyme's own auxiliary iron-sulfur cluster, which is consumed in the reaction and must be rebuilt before the next turn.

[F] An enzyme that dismantles part of itself to donate the element, and is then reassembled from the same supply line described in section 6, is the strongest single illustration available of sulfur as a currency rather than a fixture. The atom is transferred; the enzyme that gave it is restored; the bond in the product persists.

9. Carbon enters the cycle as a thioester

[E] Carbon is delivered into the citric acid cycle as acetyl-coenzyme A, and passes through it again as succinyl-coenzyme A. In both the linkage is a thioester, a carbon-sulfur bond whose reactivity is what makes the transfer thermodynamically useful.

[F] So the two entry points to oxidative metabolism are both sulfur-dependent: the decarboxylating complexes require the two sulfurs of lipoate, and the carbon they pass on is carried on a thiol.

10. The turbine, and where sulfur touches it

[E] ATP synthase converts the proton gradient into rotation and rotation into phosphoanhydride bonds. It carries no iron-sulfur cluster of its own. Its dependence on sulfur is of two other kinds.

[F] Upstream, every proton in the gradient it runs on was pumped by complexes whose electron paths are iron-sulfur relays, fed by cycles that require lipoate and coenzyme A. The fuel is made by sulfur chemistry from end to end.

[E] At the enzyme itself, regulation is exerted at cysteine residues: mitochondrial ATP synthase is subject to redox modification of cysteines, and in the chloroplast enzyme the gamma subunit carries a regulatory disulfide that thioredoxin reduces to permit activity, a switch whose structural basis has been resolved. The rotor is not made of sulfur, but the throttle is.

11. The loop closes on the genome

[F] Cysteine donates sulfur to the clusters. The clusters conduct the electrons. The electrons build the gradient. The gradient turns the turbine. The turbine makes ATP. ATP and the other nucleoside diphosphates are the substrates that ribonucleotide reductase reduces, using thiol chemistry, to make the deoxyribonucleotides. Those are polymerized into DNA, by polymerases that themselves carry iron-sulfur clusters built from the same cysteine sulfur.

[F] Each arrow in that sequence is separately documented and none of it is novel in isolation. What the sequence shows, taken whole, is that the path from a sulfur atom to a base pair is continuous and short, and that sulfur appears at every junction of it while being permanently retained at none.

Part IV. The eight bases

12. The eight bases

[F] Four purines, I X G A. Four pyrimidines, U O C T. The two ordinarily left off the list are the two that govern entry and exit, and they are left off because the literature files them as intermediates rather than as bases.

[E] The pathway literature supports the positions without dispute. Inosine monophosphate is the first complete purine made de novo and carries hypoxanthine; adenine and guanine branch from it. Xanthine is the last intermediate before urate. Orotate is the committed pyrimidine ring and the sole precursor of uridine monophosphate, from which every pyrimidine nucleotide in the cell descends.

[F] The framework does not contradict that literature. It differs from it in one respect only: it declines to demote the gates.

13. Where the gate is seated

[E] Dihydroorotate dehydrogenase, the enzyme that produces orotate, is a flavoprotein carrying FMN, targeted to the inner mitochondrial membrane and bound to its outer face. It reoxidizes its flavin by passing electrons to ubiquinone, reached through a hydrophobic tunnel that also forms the binding site for every inhibitor of the enzyme.

[E] It is the only step of nucleotide biosynthesis placed in that membrane and coupled to that quinone pool. The coupling is tight enough that breaking it required constructing an artificial cytosolic form of the enzyme, reported this year.

[F] Part III places the quinone pool downstream of iron-sulfur relays built from cysteine sulfur. The pyrimidine gate discharges into that same pool.

14. The gate can be closed, and closing it has a phenotype

[E] Leflunomide and teriflunomide inhibit this enzyme and are in clinical use for autoimmune disease. Brequinar, BAY 2402234 and ASLAN003 target it in myeloid malignancy, where blocking pyrimidine supply forces leukemic blasts to differentiate. All of them bind in the ubiquinone tunnel.

[F] A gate that can be shut pharmacologically, with a reproducible cellular consequence, is a gate in the operational sense and not only in the diagrammatic one. The inhibitor literature is the strongest external support available for orotate's position in the framework, and it was generated by people with no interest in the question.

[O] Whether the differentiation phenotype follows from pyrimidine limitation alone, or in part from the electron-transport coupling of section 13, is not settled in that literature.

15. The gate reports on itself in urine

[E] In ornithine transcarbamylase deficiency, carbamoyl phosphate accumulates in the mitochondrion, escapes to the cytosol and is driven into pyrimidine synthesis; orotate appears in the urine. In carbamoyl-phosphate synthetase 1 deficiency it does not, because the substrate is never made. The presence or absence of orotate distinguishes the two disorders clinically.

[F] The diagnostic marker for a urea-cycle lesion is the gate compound itself. Orotate is measurable precisely because it is the point at which carbon and nitrogen arriving from one cycle are committed to the pyrimidine line, and a blockage anywhere upstream or downstream changes how much of it appears.

[E] The first bespoke base-editing therapy given to a human patient treated carbamoyl-phosphate synthetase 1 deficiency: the enzyme immediately upstream of this gate. The editing thread and the pyrimidine gate meet at one step of one pathway.

16. The pyrimidine line ends in sulfur as well as opening under it

[E] From uridine monophosphate the line runs to the diphosphate, which ribonucleotide reductase reduces by the thiyl radical mechanism of Part II, and from the deoxy product thymidylate synthase makes thymidylate. Thymine is the terminus of the pyrimidine line.

[F] Thymine is also the base this index pairs with sulfur. The pyrimidine line therefore opens at a gate seated above a sulfur-built electron relay, is cut in the middle by a sulfur radical, and closes on the one base the index assigns to sulfur. The element brackets the line at both ends and appears again in the middle.

[O] Whether that is a real constraint or an artifact of which intermediates were historically granted the name of a base is put on the record here rather than settled.

Part V. The circle the bases close

17. From nucleotide to enzyme and back

[E] The eight bases become nucleotides. Nucleotides become RNA. RNA specifies amino acids through the code, amino acids are joined into peptides, peptides fold into proteins, and a subset of those proteins are enzymes.

[E] Among those enzymes are ribonucleotide reductase, which makes every deoxyribonucleotide; dihydroorotate dehydrogenase, which makes every pyrimidine ring; the cysteine desulfurase that supplies every cluster sulfur; and the respiratory complexes that carry those clusters. The products of the sequence are the machinery of the sequence.

[F] The circle is chemical rather than rhetorical, and the reason it can run on exchanged matter is section 3: no position in it is occupied by an individual. Each enzyme is rebuilt from amino acids that were elsewhere last year, using sulfur from cysteines that were elsewhere last month, to place bonds that will still be present in a descendant.

[F] Cysteine is the hinge. It donates the sulfur for the clusters, it carries the thiol that initiates the reductase, it forms the disulfide the reaction leaves behind, and it is itself specified by the code that the reductase makes possible.

Part VI. Notation and limits

18. The index is the claim

[E] The color index used across these papers assigns one color to one element, everywhere, permanently. RED is hydrogen in this paper and the next. Not one red per molecule: one red.

[F] A notation in which no instance of an element is ever distinguished from another instance is a notation built on the premise of section 3: that element identity is the invariant and everything else is arrangement. The convention was adopted for legibility and turns out to state the argument.

19. What is not claimed

[O] None of the individual links in Part III is new, and the paper says so. Each is drawn from published work and cited. The contribution offered is the assembly and the reading: that ribonucleotide reductase is the point at which the general principle of Part I becomes a specific, universal, physical event, and that the supply line feeding it is sulfur from end to end.

[O] No claim is made that matter carries memory, that inheritance involves quantum coherence or entanglement, or that an essence persists in a lineage. The argument runs the other way: nothing needs to persist materially, because nothing was individuated to begin with.

[O] Reserved: orotate is carried in the key without a color because its element pairing has not been assigned. This index is one element to one base, and the eighth pairing is the author to make and not this paper to invent.

Closing

[F] What passes from a parent to a child is a bonded arrangement maintained by an operation that has not stopped running. The sulfur that made the bond in every sugar you carry left before you existed, and it left by a mechanism that has been worked out in detail, in an enzyme that had to exist before there was any DNA to inherit. The atom is gone. The bond is the inheritance.

INDIGO	magnesium · Mg 12	orotate	the two metal ions of every polymerase and of Cas9; the ion that makes ATP a substrate

Color is a pale field behind the word, never colored type, and it names an element and nothing else. Iron and zinc carry no row and no color, so every cluster in this paper prints as its sulfur alone. The table is ordered by ascending atomic number, with magnesium set on the line below selenium.

Abstract. This paper consolidates five separate studies into one account of a single element. Hydrogen was made in the first minutes of the universe and has not been made since; carbon, nitrogen and oxygen in stellar cores; phosphorus and sulfur in the burning shells of massive stars; selenium past the iron limit where only neutron capture reaches. Sulfur enters biology through exactly two amino acids, both of them among the last letters recruited into the genetic code, although the element and its mineral clusters were present at the first interface - so the cofactor is older than the residue holding it. From cysteine the element runs through the iron-sulfur relays of respiration to the turbine, whose product is the substrate ribonucleotide reductase reduces by a sulfur radical to make every deoxyribonucleotide in the biosphere. Measurement of five deposited structures shows the same element in contact with an unpaired base in the strand-exchange intermediate of RAD51, and nowhere near DNA when the strands are paired. The same element holds the injection machine of a bacteriophage and the protein deciding what CRISPR records about it. Along the way the paper sets out the three ways a cell opens a strand, of which the editing literature measures only one, and reports where sulfur does and does not appear in the modular code by which a TALE reads a base. What descends through all of it is not the atom but the bond.

Part I. Provenance

1. The order of the index is a chronology

[E] Hydrogen, deuterium, helium and a trace of lithium were produced in roughly the first twenty minutes after the Big Bang, dated at approximately 13.8 billion years before the present. Nothing heavier formed, because the expanding universe cooled through the relevant temperature range first.

[E] Stars consume hydrogen and do not make it. The hydrogen in a body is therefore primordial, and deuterium is the clean case: produced only in that first episode, destroyed wherever it meets a stellar interior, with no later production channel, which is why its abundance serves as a direct probe of the baryon density of the cosmos.

[E] Carbon is assembled by triple-alpha fusion in evolved stars, oxygen by helium and carbon burning, nitrogen as the accumulating intermediate of the CNO cycle. Magnesium, phosphorus and sulfur come from the late burning shells of massive stars and are scattered by core collapse. Selenium lies past iron, where fusion releases no energy, and is built only by neutron capture.

[F] Read down the index by ascending atomic number and the sequence is the first minutes, then stellar cores, then the death of large stars, then the neutron flux past the iron wall. The ordering was adopted as the design of the table. The design is a chronology of cosmic nucleosynthesis, and it sorts without a single adjustment.

2. Hydrogen and adenine

[E] The pairing of hydrogen with adenine was made on abundance. Hydrogen is the most abundant element in the universe, and adenine is the most widely distributed base in the cell: ATP, ADP, AMP and cyclic AMP are adenine nucleotides, and NAD, NADP, FAD and coenzyme A each carry an adenosine taking no part in the chemistry they perform. S-adenosylmethionine is adenosine joined to methionine.

[E] Those same cofactors are the carriers of hydrogen. NAD and NADP move a hydride, FAD moves two hydrogens, and the energy in ATP is released against a proton gradient and stored by one. The hydrogen economy of the cell runs on adenine nucleotides and nothing else.

[E] Adenine is also the only one of the eight bases containing no oxygen, and its formula is five hydrogen cyanide molecules condensed. Its synthesis from hydrogen cyanide under prebiotic conditions is the oldest and most studied route to any nucleobase, and all five of the nucleobases used by life have since been identified in carbonaceous meteorites.

[F] The single color assignment in this index with a physical basis - hydrogen red, on the Balmer-alpha line at 656 nanometers, the line that makes emission nebulae red - therefore falls on the one primordial element and on the base appearing in more places than any other. The alignment is the design.

Part II. Two doors

3. Only two of the twenty, and both arrived late

[E] Of the twenty amino acids in the standard code, exactly two contain sulfur: cysteine with a thiol, methionine with a thioether. There is no third. Every sulfur atom in every protein entered through one of the two, and both are among the least abundant residues in proteomes.

[E] Every published chronology of amino acid recruitment places them at the late end. Glycine, alanine, aspartate and valine are early; cysteine, methionine, tryptophan and tyrosine are late. The consensus ordering assembled across forty criteria says so, and a reconstruction from the protein domains of the last universal common ancestor reaches the same end of the list independently.

[E] The twenty-first amino acid is the exception showing the shape of the rule. Selenocysteine is cysteine with selenium in place of sulfur, inserted at a recoded stop codon. The code built an exception for the element one row down and none for a second sulfur residue.

4. The element was never late

[E] Miller's 1953 apparatus contained no sulfur. In 1958 he ran it again with hydrogen sulfide in the mixture, archived the samples and never analyzed them. Reopened in 2011, the vials yielded methionine along with other sulfur amino acids. Methionine forms readily under the conditions; its arrival in the code is what was late.

[O] Two related proposals put the element at the beginning of metabolism. The iron-sulfur world places the first chemistry on a pyrite surface. The alkaline vent model builds compartments from precipitated iron sulfide with proton gradients already running across their walls. Both lead to the same reading of the modern cofactor: the clusters in ferredoxins and in the enzymes of this paper are fragments of those mineral surfaces, enclosed in protein and kept. The reading is the leading interpretation and has published critics.

[F] Put the two findings together. The mineral supplying iron and sulfur stands at the first interface; the residue able to hold iron and sulfur inside a protein is among the last letters of the code. The cofactor cannot have waited for the residue. The door was cut for something already standing outside it.

Part III. The supply line

5. Cysteine is the entrance and the dispensary

[E] Sulfate assimilation ends at cysteine: sulfate is activated with ATP, reduced through sulfite to sulfide, and the sulfide is fixed onto a carbon skeleton. The point where inorganic sulfur becomes part of a biological molecule is that reaction and no other.

[E] The same residue is where the element is taken back out. The cysteine desulfurase abstracts the atom as a persulfide and hands it to the scaffold proteins of the mitochondrial assembly machinery. Every cluster sulfur in the cell traces to a cysteine side chain, and the clusters built there are delivered within mitochondria, to the cytosol, and to the nucleus, including to DNA polymerases and helicases.

6. The respiratory relay is built of iron and sulfur

[E] Respiratory complex I carries a chain of iron-sulfur clusters conducting electrons from flavin to quinone, eight in the conserved relay. Complex II carries three and sits in both the citric acid cycle and the respiratory chain. Complex III carries the Rieske two-iron two-sulfur protein at the heart of its quinol oxidation cycle. The proton gradient driving ATP synthesis is generated by electrons moving along sulfur-ligated metal centers.

[E] Pyruvate dehydrogenase and alpha-ketoglutarate dehydrogenase both require the lipoyl cofactor, whose two sulfur atoms are inserted by lipoyl synthase from the enzyme's own auxiliary iron-sulfur cluster, consumed in the reaction and rebuilt before the next turn. An enzyme dismantling part of itself to donate the element, then reassembled from the supply line of section 5, is the clearest illustration available of sulfur as a currency rather than a fixture.

[E] Carbon enters the citric acid cycle as acetyl-coenzyme A and passes through it again as succinyl-coenzyme A. In both the linkage is a thioester. The two entry points to oxidative metabolism are sulfur-dependent: the decarboxylating complexes require the two sulfurs of lipoate, and the carbon they pass on is carried on a thiol.

7. The turbine, and where sulfur touches it

[E] ATP synthase carries no iron-sulfur cluster. Every proton in the gradient it runs on was pumped by complexes whose electron paths are iron-sulfur relays, fed by cycles requiring lipoate and coenzyme A. At the enzyme itself, regulation is exerted at cysteine residues: mitochondrial ATP synthase is subject to redox modification of cysteines, and in the chloroplast enzyme the gamma subunit carries a regulatory disulfide reduced by thioredoxin. The rotor is not made of sulfur; the throttle is.

Part IV. The eight bases and the gate

8. Four purines and four pyrimidines

[F] The set is eight. Four purines, I X G A. Four pyrimidines, U O C T. The two ordinarily left off the list are the two governing entry and exit, and the literature files them as intermediates rather than as bases.

[E] Inosine monophosphate is the first complete purine made de novo and carries hypoxanthine; adenine and guanine branch from it. Xanthine is the last intermediate before urate. The purine line begins at I and ends at X. Orotate is the committed pyrimidine ring and the sole precursor of uridine monophosphate, from which every pyrimidine nucleotide descends.

base	formula	elements present
adenine	C5H5N5	C H N
guanine	C5H5N5O	C H N O
cytosine	C4H5N3O	C H N O
thymine	C5H6N2O2	C H N O
uracil	C4H4N2O2	C H N O
hypoxanthine	C5H4N4O	C H N O
xanthine	C5H4N4O2	C H N O
orotate	C5H4N2O4	C H N O

[E] Every base is built from four elements and nothing else. Phosphorus enters at the backbone; sulfur and selenium never enter the sequence at all, only the machinery writing it.

9. The pyrimidine gate is seated in the mitochondrial membrane

[E] Dihydroorotate dehydrogenase, the enzyme producing orotate, is a flavoprotein bound to the inner mitochondrial membrane, reoxidizing its flavin by passing electrons to ubiquinone through a hydrophobic tunnel that also forms the binding site for every inhibitor of the enzyme. It is the only step of nucleotide biosynthesis placed in that membrane and coupled to that quinone pool.

[F] Part III places the quinone pool downstream of iron-sulfur relays built from cysteine sulfur. The pyrimidine gate discharges into the same pool.

[E] The gate can be shut pharmacologically and shutting it has a phenotype: leflunomide and teriflunomide are in clinical use for autoimmune disease, and brequinar, BAY 2402234 and ASLAN003 target the enzyme in myeloid malignancy, where blocking pyrimidine supply forces leukemic blasts to differentiate. All bind in the ubiquinone tunnel.

[E] The gate also reports on itself. In ornithine transcarbamylase deficiency, carbamoyl phosphate escapes the mitochondrion and is driven into pyrimidine synthesis, and orotate appears in the urine; in carbamoyl-phosphate synthetase 1 deficiency it does not, because the substrate is never made. The presence or absence of orotate distinguishes the two disorders clinically. The first bespoke base-editing therapy given to a human patient treated carbamoyl-phosphate synthetase 1 deficiency - the step immediately upstream of the gate.

10. The pyrimidine line is bracketed by sulfur

[F] From uridine monophosphate the line runs to the diphosphate, which ribonucleotide reductase reduces by the thiyl radical mechanism of Part V, and from the deoxy product thymidylate synthase makes thymidylate. Thymine is the terminus of the pyrimidine line and the base this index pairs with sulfur. The line opens at a gate seated above a sulfur-built electron relay, is cut in the middle by a sulfur radical, and closes on the sulfur base.

Part V. The enzyme at the center

11. Ribonucleotide reductase is the only gate to DNA

[E] Every deoxyribonucleotide in every organism is made by ribonucleotide reductase, which reduces a ribonucleoside diphosphate at the 2-prime position. There is no alternative route. Every sugar in every strand of DNA in the biosphere passed through this active site.

[E] The chemistry is a sulfur radical. A thiyl radical on an active-site cysteine abstracts the hydrogen from the 3-prime carbon of the ribose; two further cysteines supply the reducing equivalents removing the 2-prime hydroxyl and are left joined as a disulfide; thioredoxin or glutaredoxin, themselves cysteine enzymes, reduce the disulfide and reset the site. In the class I enzyme the radical originates on a tyrosine in a separate subunit and is relayed to the active-site cysteine by proton-coupled electron transfer across roughly thirty-five angstroms.

[F] The substrate is a free nucleotide, so the sulfur never touches DNA and never will. What remains is the carbon-hydrogen bond installed at the 2-prime position, which stays on that sugar for as long as the sugar exists: through polymerization, through replication, through the germline. Every deoxyribose in every organism on Earth carries a bond a sulfur atom made and then abandoned.

Part VI. The measurement

12. What the structures show, and what the word hydrophobic conceals

[E] RAD51 assembles an ATP-dependent helical filament on single-stranded DNA, searches duplex DNA for homology, and catalyzes strand exchange to form a D-loop without hydrolyzing ATP. The N-terminal domain recruits and bends the homologous duplex; loop L2 and the Arg303 to Arg306 loop bend it further and induce local base-pair opening; the S2 site, a channel enriched in basic residues, captures the displaced strand and grips its phosphate backbone; and loop L2 drives Met278 and Phe279 into the gap between the newly separated strands, at protomer positions N+5, N+6 and N+7.

[E] The source describes those two residues as hydrophobic, consistently, in every passage where they appear. The words sulfur, methionine and thioether do not occur anywhere in it.

[F] Methionine's side chain is not a hydrocarbon. It ends in a thioether: a divalent sulfur flanked by two carbons, carrying lone pairs, markedly more polarizable than carbon, with accessible antibonding orbitals. It is a soft donor and a soft acceptor, and it is not leucine with an extra atom.

[F] Hydrophobic is a solvation category, not a bonding one. To file Met278 under it is to record what the residue will not do, which is hydrogen bond to water, and to discard what it may be doing to the bases it has been driven against. The classification is not wrong. It is silent in exactly the place where the mechanism lives, and the rest of this Part is an attempt to make it speak by measurement rather than by assertion.

13. Method

13.1 Coordinate sources. Six deposited models were measured: the RAD51 presynaptic filament 9UI4, the postsynaptic filament 9UI5, and the D-loop complexes at 4, 8 and 12 base pairs of pairing, 9UI7, 9UI8 and 9UI9; and, for section 15, the XPD-DNA complex 4A15. All were taken as mmCIF from the Protein Data Bank on 22 September 2026 and parsed directly from the atom_site records. No model was rebuilt, refined, minimized or otherwise altered, and no hydrogens were added. Every number below is a distance or an angle between atom positions exactly as deposited.

13.2 Ring geometry. For each nucleotide a base ring centroid was computed as the unweighted mean of the ring atom positions: N9, C8, N7, C5, C4, N3, C2, N1 and C6 for purines, and N1, C2, N3, C4, C5 and C6 for pyrimidines. A ring plane normal was computed as the cross product of two vectors from the centroid to ring atoms chosen one third apart around the ring, normalized to unit length. Phenylalanine rings were treated the same way using CG, CD1, CD2, CE1, CE2 and CZ.

13.3 The two reported quantities. The distance runs from the methionine SD sulfur to the nearest base ring centroid, in angstroms. The angle lies between the sulfur-to-centroid vector and the ring plane normal, taken as an absolute value so it runs from 0 to 90 degrees: zero places the sulfur directly over the face of the ring, ninety places it in the ring plane, edge-on. The distinction matters because a sulfur-pi interaction requires approach toward the face, and a distance alone cannot separate stacking from an edge contact at the same separation.

13.4 Strand assignment. Watson-Crick pairing was inferred geometrically: a base counted as paired if its N1, for a purine, or its N3, for a pyrimidine, lay within 3.35 angstroms of the corresponding atom of a base in a different chain. The chain with the lowest paired fraction in each structure was taken as the displaced strand. The criterion is crude at these resolutions, and its results are reported in table 14.1 so the reader can judge each assignment rather than accept it.

13.5 Controls. Two were run inside each structure, so neither depends on comparison across files. The positive control measures the Phe279 ring centroid against the same bases: the source reports Phe279 stacking on a nucleotide, so a correct pipeline must recover an aromatic stacking distance where the source says one exists and must not recover one where it does not. The background control repeats the sulfur-to-base measurement for every methionine other than Met278 - fifty-six to seventy-two per model, three hundred and forty-four across the five RAD51 structures - establishing how close a methionine comes to DNA when it is not part of the wedge.

13.6 What was not done. No energy was computed and no interaction was modeled. Occupancies and B-factors were not used to weight or exclude atoms. Alternate conformers were taken as deposited. No molecular dynamics was run. The measurement is geometric and its claims extend no further than geometry.

14. Result

14.1 Chain composition and the strand assignment. The paired fractions separate cleanly in the postsynaptic filament and in the 12 base-pair D-loop, and poorly in the others, which is the limit noted in 13.4.

structure	DNA chains: bases / Watson-Crick paired / fraction	displaced strand taken as
9UI4	L: 27 / 0 / 0% (single strand only, no duplex present)	not applicable
9UI5	L: 25 / 23 / 92% M: 24 / 23 / 96%	none; both strands paired
9UI7	H: 29 / 1 / 3% I: 29 / 5 / 17% L: 22 / 4 / 18%	H, by the lowest fraction
9UI8	L: 25 / 6 / 24% T: 19 / 14 / 74% U: 20 / 8 / 40%	L, by the lowest fraction
9UI9	L: 27 / 6 / 22% T: 30 / 6 / 20% U: 30 / 1 / 3%	U, cleanly separated

14.2 Met278, every protomer in which the sulfur is resolved. Eighteen measurements. The first pair of columns gives the nearest base ring of any chain; the second gives the nearest base ring on the chain assigned as displaced in table 14.1. Where the two agree, the nearest base is itself on the displaced strand.

structure	prot	SD to base	ang	SD to displaced	ang	nearest displaced base
9UI4	-	SD not resolved in any protomer				
9UI5	E	7.60	75°	8.89	79°	DA 17
	F	9.18	87°	9.18	87°	DA 13
	G	8.95	67°	11.11	87°	DT 11
	H	12.93	71°	12.93	71°	DT 7
	I	13.96	87°	13.96	87°	DA 4
9UI7	C	10.22	69°	37.07	79°	DT 30
	D	4.74	71°	28.89	70°	DT 30
	E	12.19	17°	15.68	60°	DT 30
	F	5.24	37°	5.24	37°	DT 27
	G	7.17	88°	16.29	50°	DT 27
9UI8	E	3.66	35°	12.14	89°	DC 18
	F	7.51	43°	9.90	87°	DT 15
	G	3.91	17°	11.73	83°	DT 12
9UI9	E	9.70	77°	9.70	77°	DA 31
	F	5.45	85°	11.65	10°	DT 30
	G	7.32	81°	7.32	81°	DT 24
	H	5.12	45°	5.12	45°	DT 17
	I	5.74	87°	5.74	87°	DT 17

14.3 The two controls, per structure. Distances in angstroms.

structure	Phe279 to nearest base: min / median / n	every other Met SD to nearest base: closest / median / n
9UI4	not resolved	7.90 / 30.8 / 72
9UI5	8.96 / 14.62 / 5	7.66 / 29.2 / 72
9UI7	8.95 / 12.01 / 4	8.46 / 29.2 / 56
9UI8	4.14 / 4.94 / 3	8.39 / 30.5 / 72
9UI9	3.54 / 5.46 / 5	8.13 / 27.9 / 72

[E] 14.4 Reading the tables. The positive control behaves as required. Phe279 reaches 4.14 angstroms in the 8 base-pair complex and 3.54 in the 12 base-pair complex, ordinary aromatic stacking distance, recovering the interaction the source describes; in the postsynaptic filament the same ring is 8.96 angstroms from anything, stacking on nothing. The pipeline measures state and not noise.

[E] The background is uniform and far. Across three hundred and forty-four methionines in the five structures, no methionine other than Met278 comes within 7.66 angstroms of DNA, and the per-structure medians sit between 27.9 and 30.8 angstroms. A methionine in this filament is, as a rule, thirty angstroms from the nucleic acid.

[E] Against that background the postsynaptic value is decisive. With both strands paired and no displaced strand present, Met278 sits at 7.60 angstroms while the closest of the other seventy-two methionines in the same file sits at 7.66. The difference is six hundredths of an angstrom, which is nothing. In the paired state Met278 is an ordinary methionine, and in the presynaptic filament its sulfur is not modeled at all.

[F] Displacement changes both quantities. The closest approach falls to 4.74 angstroms at four base pairs, 3.66 at eight and 5.12 at twelve. The angle falls with it: in the postsynaptic control the five values are 67, 71, 75, 87 and 87 degrees, all edge-on or in-plane, while the closest contacts in the D-loops arrive at 35, 37, 17 and 45 degrees. The sulfur does not simply move nearer; it rotates toward the face of the ring.

[F] Two contacts meet the geometric criteria for a sulfur-pi interaction rather than a van der Waals brush: protomer G of the 8 base-pair complex at 3.91 angstroms and 17 degrees, nearly normal to the ring, and protomer E of the same structure at 3.66 angstroms and 35 degrees. Both lie within the sum of the van der Waals radii of sulfur and aromatic carbon.

[O] 14.5 What the tables do not support. The nearest base is on the assigned displaced strand in eight of the eighteen measurements and on another chain in the rest, and in the 4 base-pair complex the assigned displaced strand is up to 37 angstroms from the sulfur. Either the assignment is wrong in those files, which 13.4 allows, or Met278 contacts whichever strand is locally unpaired rather than the displaced strand specifically. The tables cannot separate the two, and no claim is made about which strand is contacted except in the 12 base-pair complex, where the assignment is clean and four of five contacts fall on it.

[O] The trend across the series - 4.74, then 3.66, then 5.12 - rests on five, three and five protomers respectively. Three protomers is a thin basis for the minimum, and the number of resolved Met278 side chains differs between files for reasons of local order rather than biology.

15. Two corrections the coordinates forced

[E] An earlier reading held that Met278 and Phe279 act as a single sulfur-aromatic unit, the canonical methionine-aromatic motif. The sulfur sits 8.1 to 9.8 angstroms from the Phe279 ring in every protomer measured, far outside any such range. They are sequence neighbors doing two different jobs on two different bases: the ring stacks flat on one nucleotide, the sulfur makes a close face contact with another. Loop L2 presents two distinct chemistries into the same gap rather than one repeated.

[E] The second correction is a failed extension. The obvious next question was whether the iron-sulfur cluster of the XPD helicase contacts DNA the way Met278 does, and 4A15, the only deposited XPD-DNA complex, was measured by the identical method. It does not. The four inorganic sulfides lie 42.58, 44.09, 44.70 and 45.97 angstroms from the nearest DNA atom; the four coordinating cysteines, Cys92, Cys113, Cys128 and Cys164, lie at 41.23, 44.67, 47.47 and 43.94, with SD-to-iron distances of 2.26 to 2.46 angstroms confirming the coordination. The four cysteines in that structure which do not coordinate the cluster are three times closer to the DNA, at 14.21 angstroms, than the cluster is.

[F] The parallel fails in the form proposed. Read alongside section 16, the failure is unsurprising rather than disappointing: the cluster does the holding, and holding is done at a distance. The test is also weak, since only four nucleotides are resolved in 4A15 and they sit far from the helicase channel.

Part VII. Three things sulfur does around DNA

16. Build, hold, touch

[E] It builds the sugar. Ribonucleotide reductase, a thiyl radical, on free nucleotides, never touching DNA.

[E] It holds the machines. The Bacillus subtilis helicase loader DnaI carries a zinc-binding fold in its helicase-interaction domain. XPD, FANCJ, RTEL1 and DDX11 each carry a conserved four-iron four-sulfur cluster in the helicase domain, and removing it abolishes helicase activity while leaving the ATPase intact. In both, the sulfur is a metal ligand holding a fold together, tens of angstroms from any base.

[F] It touches an exposed base. Met278, 3.66 angstroms, face-on, in the strand-exchange intermediate and not in the paired one. On the evidence of the other two categories the contact is the rare case and not the representative one, which is what makes it worth measuring.

17. What a contact distance measures, and what it does not

[E] Every distance in Part VI is a straight line between two modeled atom positions. Roughly 3.5 angstroms is van der Waals contact; fourteen is the same neighborhood with no contact; forty is a different part of the protein.

[E] A contact distance measures contact and not influence, and ribonucleotide reductase is the standing proof of the difference: in the class I enzyme the radical is generated on a tyrosine in a separate subunit and relayed to the active-site cysteine across roughly thirty-five angstroms by proton-coupled electron transfer. Sulfur chemistry there operates across a separation a contact metric would call irrelevant.

[F] The caveat is aimed at this paper's own result. Section 15 rules out contact between the XPD cluster and DNA. It does not rule out an electronic role at a distance, which is the substance of the charge-transport proposal for iron-sulfur clusters, and no measurement of the kind used here could settle the question either way.

Part VIII. The displaced strand as a chemical state

18. Three ways a cell opens a strand

A deaminase, a polymerase, a nuclease and a mutagen all require the same thing: unpaired DNA. The cell produces the state in three principal ways, discussed in three separate literatures.

structure	how the strand is displaced	duration	measured in the editing literature
R-loop	an RNA strand pairs with one DNA strand and displaces the other; transcription, and the Cas9 guide complex	transient, seconds to minutes	yes - it is the only one measured
recombination D-loop	RAD51 invades a duplex with single-stranded DNA and the resident strand is displaced and held by the S2 site	transient, repair-coupled	no
mitochondrial D-loop	7S DNA displaces the parental heavy strand across the control region	constitutive, present in every cell	no

[F] Chemically these are one state, not three: a stretch of DNA held unpaired against its own strong tendency to reanneal. Only the first is engineered, and only the first is measured.

19. The mitochondrial control region

[E] Mitochondrial DNA maintains a stable triple-stranded structure in its control region, in which a short nascent strand known as 7S DNA displaces the parental heavy strand across several hundred nucleotides. The structure is not a repair intermediate but a standing feature, present in a large fraction of molecules, in every cell, continuously. The same control region is the most variable segment of the mitochondrial genome.

[E] Part III places the cell's sulfur trafficking in the same compartment. The organelle maintaining the longest constitutive displaced strand is the organelle assembling every iron-sulfur cluster and thiolating the mitochondrial transfer RNAs.

[H] Part VI establishes that in one displaced-strand machine the residue contacting the exposed bases is a sulfur, and the only sulfur of its kind in the assembly. Whether the same holds for the machinery maintaining the constitutive displaced strand in mitochondria is the question this section puts on the record.

Part IX. Consequences for base editing

20. Where the deaminase window actually is

[E] The adenine deaminases used in base editors act only on single-stranded DNA. In an editor the single strand is supplied by the guide-directed R-loop, and the editing window is defined by its geometry. Every bystander and off-target metric in the literature is therefore defined on the engineered window, and window narrowing - the advertised advance from ABE7.10 through ABE8e to ABE9 - is an optimization measured entirely inside a structure the experimenter created.

[H] The cell's own displaced strands are accessible to the same chemistry and appear in none of those metrics. The recombination D-loop forms wherever a double-strand break is repaired by homology. The mitochondrial displaced strand is there without any break at all.

[O] Whether the mutational spectrum of the mitochondrial control region carries a deaminase signature separable from oxidative and replicative sources. The data to ask are public.

21. TALE is the only route to the mitochondrial displaced strand

[E] Guide RNA is not imported into mitochondria, so guide-directed editors cannot reach mitochondrial DNA at all. Mitochondrial base editing was rebuilt on transcription activator-like effector arrays, which carry a mitochondrial targeting sequence and do enter: first as double-strand cytidine deaminase fusions, then as TALE-linked adenine deaminases, most recently with base-excision repair recruited to raise efficiency.

[F] The engineering difficulty in that line of work is the subject of this paper. TadA-derived deaminases act only on single-stranded DNA and mitochondrial DNA is duplex; the adenine work had to contrive a single strand inside a duplex genome. The control region already is one - several hundred nucleotides, constitutive, in every cell, a few kilobases from wherever the editor is aimed. Nobody is engineering it because nobody is counting it.

22. Sulfur enters the TALE repeat but never the reading position

[E] A TALE reads one base pair per repeat through the two residues at positions 12 and 13. Position 13 makes the base-specific contact; position 12 is structural. The canonical assignments are NI for adenine, HD for cytosine, NG for thymine, and NN, NH or NK for guanine.

[E] A systematic decoding tested all four hundred combinations of the twenty amino acids across the two positions. Two sulfur-bearing diresidues appear among its reported specificities: CA, cysteine at 12 with alanine at 13, reported thymine-targeting; and MN, methionine at 12 with asparagine at 13, reported guanine-targeting. Sulfur is not excluded from the repeat. It is excluded from one position within it, and in both cases the base is read by the residue beside the sulfur - alanine in the first, asparagine in the second, the canonical guanine contact.

[O] The division is the one Part VII reports at a different scale: sulfur present in the apparatus positioning a base, absent from the contact identifying it. No cysteine and no methionine at position 13 is reported in any source consulted, and whether the absence is a constraint on thioether contact with a nucleobase or an artifact of reporting is answerable by building the repeat.

Part X. Both sides of the phage conflict

23. Both sides of the phage conflict

[E] A bacteriophage delivers its genome through a tail tip complex. In phage lambda the conserved tail tip protein gpL coordinates an oxygen-sensitive four-iron four-sulfur cluster through four conserved cysteines, confirmed by atomic emission, absorbance and electron paramagnetic resonance spectroscopy. Substituting any one cysteine with serine or alanine abolishes biological activity. Serine differs from cysteine by one atom, oxygen in place of sulfur, so the requirement is elemental and not steric. It was the first viral structural protein shown to bind such a cluster.

[E] The bacterium answers with CRISPR, and Cas4 - the protein processing the prespacer and selecting the protospacer-adjacent motif, fixing both what the array records and in which orientation - also carries an iron-sulfur cluster, four-iron in the Sulfolobus protein and two-iron in the crystallized Pyrobaculum homologue.

[F] Cas9, which performs the cut, carries no cluster. It cuts the phosphodiester backbone with magnesium in both nuclease domains, RuvC by the same two-metal arrangement used by every polymerase. Read by element the conflict sorts cleanly: sulfur at the injection and at the making of the memory, magnesium at the cut.

Part XI. What descends

24. The atoms do not stay

[E] A cell sustains large numbers of DNA lesions daily and repairs nearly all of them; base excision repair removes a damaged base and inserts a fresh one; nucleotide pools turn over; the backbone exchanges with the metabolic pool. Replication is semiconservative, so each daughter molecule keeps one intact parental strand, but the fraction of molecules carrying an original strand halves with every division and across a lineage no particular atom survives.

[E] The turnover costs nothing. Atoms of a given element and nuclide in a given state are not individuals: the quantum-mechanical state of two identical particles is symmetrized, and exchanging their labels returns the same state. Fermi-Dirac and Bose-Einstein statistics follow from the fact, and the Gibbs paradox resolves only when identical particles are treated as unlabeled. Replacing a guanine with a chemically identical guanine is not a replacement in any physical sense.

[O] Three fences hold the argument in place. Isotopes are distinguishable, which is why tracing experiments work at all, so identity is invariant at the level of element and nuclide and state. The principle protects pattern against material exchange and offers nothing against a change of pattern. And the principle is indistinguishability of identical particles, not entanglement.

25. Chemistry does not touch a nucleus

[E] No chemical process alters an atomic nucleus. Bonds form and break, molecules are built and destroyed, and the nucleus passes through unchanged. The hydrogen nuclei in a body have been through an indefinite number of molecules and through no event capable of altering them since the first minutes. They are not descendants of primordial hydrogen. They are primordial hydrogen.

[F] And the pairing is held by hydrogen: two bonds across A to T, three across G to C, formed between nuclei 13.8 billion years old and untouched by chemistry since. The bond is remade continually and the rule for making it has been passed down without interruption. The arrangement descends; the nuclei were already here.

[F] What is inherited is not the atom. It is the bond the atom made - and the clearest single instance is the carbon-hydrogen bond ribonucleotide reductase installs at the 2-prime position of every deoxyribose, through a sulfur that departs within the catalytic cycle and never returns.

Part XII. Tests

26. What would test the argument

1. Confirm the minimum. The Met278 approach is deepest at 8 base pairs and relaxes at 12. Establish whether the trend is a real feature of propagation or an artifact of which protomers were resolved.

2. Isosteric substitution. Replace Met278 with leucine and, separately, with norleucine, which matches methionine's length and shape with a carbon in place of the sulfur. If reannealing kinetics track the sulfur and not the shape, the contact is chemical.

3. Build the residue into the reading position. Section 22 reports sulfur at position 12 of the TALE repeat and none at position 13. Construct a repeat with cysteine, and separately methionine, at position 13 and assay it against each of the four bases.

4. Re-score. Re-analyze published base editor off-target data against displaced-strand annotation rather than protospacer position, and ask whether the mitochondrial control region carries a deaminase signature separable from oxidative and replicative sources.

5. Test the relic reading. A mineral fragment enclosed in protein should leave traces in cluster geometry or in the binding motifs. Comparing cluster coordination across the oldest protein folds against mineral sulfide geometry is a calculation available from deposited structures.

6. Repeat the XPD measurement on a structure with DNA threaded through the arch, when one exists.

Part XIII. Limits

27. What is not claimed

[O] The maps behind Part VI are in the 3 to 4.5 angstrom range, where side-chain placement is substantially model-dependent, and the series rests on eighteen measurements across three to five protomers per structure. The displaced strand can be assigned with confidence only in the 12 base-pair complex.

[O] The thiyl radical, the thioether, the zinc site and the cluster are chemically different and do different jobs: a hydrogen abstraction, a polarizable contact, a fold-stabilizing ligand, and a cofactor of contested function. The unifying claim is about element and position, not mechanism. Stated as a claim about shared mechanism it collapses.

[O] The function of the cluster in XPD remains contested, and the relic reading of cofactors is the leading interpretation rather than a demonstrated lineage. DnaI is bacterial and carries no weight in an argument about human biology. Individual atoms cannot be traced to individual stars; attribution of an element to a class of source is statistical.

[O] No claim is made that matter carries memory, that inheritance involves quantum coherence, or that an essence persists in a lineage. The argument runs the other way: nothing needs to persist materially, because nothing was individuated to begin with.

Closing

[F] One element, at every point where DNA is made or opened or handed on. It builds the sugar and leaves. It holds the clusters conducting the electrons that fill the gradient that turns the turbine whose product the reductase reduces. It is the ligand in the injection machine of a phage and in the protein recording the phage's arrival. It lies face-on against an unpaired base for as long as the base is unpaired, and nowhere near one otherwise. It entered biology through two doors cut late in the code for chemistry already standing outside them. And what it leaves behind in every sugar in every genome is not itself but a bond, which is the only thing any of this was ever passing down.

PART TWO HUNDRED AND TWENTY

The Element on Both Sides

Iron-sulfur clusters in the phage injection machine and in the CRISPR memory machine

PP-2026-PHAGE-01 v1 · 22 September 2026 · Dr. John Allen Berger, PhD · NovagonDNA · Licensed under CC BY-NC-ND 4.0.

Color Key

color	element	base	where it appears in this paper

INDIGO	magnesium · Mg 12	orotate	the metal ions Cas9 cuts with, in both of its nuclease domains

Color is a pale field behind the word, never colored type, and it names an element and nothing else. Iron carries no color under this index, so each cluster in this paper prints as its sulfur alone - which is the point the paper makes.

Abstract. A bacteriophage delivers its genome through a tail tip complex whose conserved protein coordinates an oxygen-sensitive four-iron four-sulfur cluster through four cysteine residues; replacing any one of them abolishes biological activity. The bacterium defends itself with CRISPR, and the protein that decides what the array records - Cas4, which processes the prespacer and selects the protospacer-adjacent motif - also carries an iron-sulfur cluster. Cas9, which performs the cut, carries none, and cuts with magnesium in both of its nuclease domains. Read by element, the conflict sorts cleanly: sulfur at the injection and at the formation of the memory, magnesium at the cut.

Part I. The injection machine

1. The tail tip complex

[E] The assembly of a long non-contractile phage tail begins with the tail tip complex, a multi-protein structure that mediates adsorption to the host cell and injection of the genome. In phage lambda the complex is built from multiple copies of eight different proteins, one of which is gpL.

2. gpL coordinates a cluster, and the cluster is required

[E] Purified gpL and its homologues carry a distinct reddish color, and characterization of the homologue from phage N15 established the source: the C-terminal domain coordinates an oxygen-sensitive four-iron four-sulfur cluster, confirmed by atomic emission, absorbance and electron paramagnetic resonance spectroscopy.

[E] Four highly conserved cysteine residues hold it. Substituting any one of them with serine or alanine in lambda gpL abolishes biological activity, so the intact cluster is required for function rather than incidental to folding. The same four cysteines are present in the C-terminal regions of very diverse gpL homologues, which makes the arrangement a general feature of non-contractile tailed phages infecting Gram-negative bacteria.

[E] This was the first viral structural protein shown to bind an iron-sulfur cluster.

[F] Serine differs from cysteine by one atom: oxygen in place of sulfur. Alanine removes the position entirely. Either substitution kills the phage, so the requirement is for the sulfur specifically and not for a side chain of that size at that place.

[O] The cluster is oxygen-sensitive, which is an unusual property for a structural component of a particle that must survive outside a host. Whether the sensitivity constrains where these phages can persist, or whether it does work beyond structure, is not settled in the source.

Part II. The memory machine

3. Cas4 carries a cluster too

[E] CRISPR is the bacterial adaptive immune system against phages. Its adaptation module captures a fragment of the invading genome and writes it into the array as a spacer, and Cas4 is the protein that prepares that fragment.

[E] Cas4 is a nuclease with an iron-sulfur cluster. The Sulfolobus protein was characterized as a 5-prime to 3-prime exonuclease carrying a four-iron four-sulfur cluster; the Pyrobaculum homologue was crystallized with a two-iron two-sulfur cluster. The cofactor is a defining feature of the family rather than a property of one organism.

4. What Cas4 decides

[E] Cas4 processes the prespacer and selects the protospacer-adjacent motif, which fixes both what is written into the array and in which orientation. High-fidelity programming of the array depends on it: without Cas4 the sequences integrated are imprecise and often oriented wrongly, and the resulting immunity does not work.

[F] So the protein holding the iron-sulfur cluster on the bacterial side is not a structural component and not the weapon. It is the one that decides what the cell will remember about the phage.

Part III. The cut

5. Cas9 carries no cluster

[E] Cas9 performs interference: it finds the sequence the array recorded and cuts it. It carries no iron-sulfur cluster. Its two nuclease domains, RuvC and HNH, are metal-dependent nucleases that cut the phosphodiester backbone using magnesium ions, the RuvC domain by the same two-metal-ion arrangement used by every nucleic-acid polymerase and by the RNase H fold it belongs to.

[F] The division is clean and it is not one the CRISPR literature draws, because that literature is organized by protein family rather than by element. Sulfur is present where the genome is delivered and where the record of it is made. Magnesium is present where the bond is broken.

Part IV. Reading it by element

6. The elements sort the functions

[F] Phage tail tip, sulfur: four cysteines, one cluster, and no injection without it. CRISPR adaptation, sulfur: a cluster in the protein that chooses the spacer and its orientation. CRISPR interference, magnesium: two metal ions in a nuclease domain that carries no sulfur at all.

[F] Iron appears in both clusters and carries no color under this index, so on the page each cluster shows as its cysteines. The reading is not a claim that iron does nothing. It is a claim that the sulfur is what the two sides have in common, and the index makes the commonality visible without argument.

[F] The companion papers report sulfur at the point where a duplex is opened and sulfur in the enzyme that makes every deoxyribonucleotide. Here it is at the point where a genome is delivered into a cell and at the point where the cell writes down what arrived. The same element, at four different moments in the handling of DNA, in four unrelated protein folds.

7. What is open

[O] Whether the two clusters are related in any evolutionary sense, or whether the shared cofactor reflects nothing more than the usefulness of a four-cysteine site, is not addressed anywhere consulted.

[O] Whether the oxygen sensitivity of the phage cluster is exploited by the host as a defense, or by the phage as a timer, is likewise open.

[O] Cas4 is absent from many CRISPR systems, including the type II systems that supply Cas9 for genome editing. Whether those systems achieve the same fidelity of spacer selection by a route that requires no sulfur would test whether the cofactor is functionally necessary to the decision or simply the solution one lineage found.

PART TWO HUNDRED AND TWENTY-ONE

Two Doors

Methionine and cysteine arrived last and were given the oldest cofactor to hold

Color Key

color	element	base	where it appears in this paper
RED	hydrogen · H 1	adenine	hydrogen sulfide, the form sulfur arrives in; adenine, joined to methionine to make the methyl donor
BLUE	carbon · C 6	cytosine	the carbons flanking the thioether; cytosine
GREEN	nitrogen · N 7	guanine	the amino group both doors carry; guanine
ORANGE	oxygen · O 8	hypoxanthine	serine, which is cysteine with oxygen in place of sulfur, and which does not work
PURPLE	phosphorus · P 15	uracil	ATP, consumed to activate sulfate before assimilation can begin
YELLOW	sulfur · S 16	thymine	methionine and cysteine, the only two doors; the thiol, the thioether, the disulfide and every cluster ligand; thymine
INDIGO	selenium · Se 34	xanthine	selenocysteine, the twenty-first, which is cysteine with selenium in place of sulfur
INDIGO	magnesium · Mg 12	orotate	not present in this paper; the row is printed because the key is printed whole

Color is a pale field behind the word, never colored type, and it names an element and nothing else.

Abstract. Sulfur enters protein through two amino acids and no others. Both of them, methionine and cysteine, are placed among the last recruited into the genetic code by every published chronology. Sulfur itself was present at the start: the iron-sulfur mineral surfaces proposed for the first metabolism, and the sulfur amino acids recovered from flasks Miller sparked with hydrogen sulfide in 1958 and never analyzed. The cofactor is therefore older than the residue holding it. This paper sets out the two doors, the evidence that they are late, the evidence that the element is not, and what each door came to do once it opened.

Part I. Two doors

1. Only two of the twenty

[E] Of the twenty amino acids specified by the standard genetic code, exactly two contain sulfur: cysteine, carrying a thiol, and methionine, carrying a thioether. There is no third. Every sulfur atom in every protein in every organism entered through one of the two.

[E] A twenty-first exists and is the exception proving the shape of the rule. Selenocysteine is cysteine with selenium in place of sulfur, inserted at a recoded stop codon. The cell built an exception for the element one row down, and none for any additional sulfur residue.

[E] Both are among the least abundant residues in proteomes. The two doors are narrow as well as few.

2. Both arrived late

[E] Chronologies of amino acid recruitment into the code agree on the ends of the sequence. Glycine, alanine, aspartate and valine are early. Cysteine, methionine, tryptophan and tyrosine are late. The consensus ordering assembled across forty separate criteria places them there, and a recent reconstruction from the protein domains of the last universal common ancestor reaches the same end of the list by an independent route.

[F] So the two residues carrying the element are among the last letters the code acquired.

Part II. The element was already there

3. Miller's other flasks

[E] The 1953 spark-discharge experiment contained no sulfur and produced no sulfur amino acids. In 1958 Miller ran the apparatus again with hydrogen sulfide in the mixture, archived the samples and never analyzed them. Reopened and analyzed in 2011, the vials yielded methionine along with other sulfur-bearing amino acids and a wide range of amines.

[F] Methionine forms under the conditions in a sealed flask with hydrogen sulfide and a spark. The residue is chemically easy; its arrival in the code is what was late.

4. The mineral interface

[E] Two related proposals put sulfur at the beginning. The iron-sulfur world places the first metabolism on the surface of pyrite, where iron and sulfur supply the reducing power and the surface supplies the organization. The alkaline hydrothermal vent model builds compartments out of precipitated iron sulfide with proton gradients already running across their walls.

[O] Both lead to the same reading of the modern cofactor: the iron-sulfur clusters in ferredoxins and in the enzymes of the companion papers are held to be fragments of those mineral surfaces, enclosed in protein and retained. The reading is the leading interpretation and has published critics; it is not a demonstrated lineage.

5. The cluster is older than the cysteine

[F] Put the two findings together. The mineral supplying iron and sulfur is at the first interface. The amino acid able to hold iron and sulfur inside a protein is among the last letters of the code. The cofactor cannot have waited for the residue.

[F] The sequence the evidence supports runs the other way: the element and its clusters were available and doing work first, and cysteine was recruited into the code as the means of carrying a fragment of that chemistry into the protein world. The door was cut for something already standing outside it.

Part III. What each door does

6. Cysteine is where inorganic becomes organic

[E] Sulfate assimilation ends at cysteine. Sulfate is activated with ATP, reduced through sulfite to sulfide, and the sulfide is fixed onto a carbon skeleton to give cysteine. The point where inorganic sulfur becomes part of a biological molecule is that reaction and no other.

[E] It is also where the sulfur is taken back out. The cysteine desulfurase abstracts the atom from cysteine as a persulfide and hands it to the scaffold proteins that assemble every iron-sulfur cluster in the cell. The same residue is the entrance and the dispensary.

[E] And it is the ligand. Four conserved cysteines hold the cluster in the phage tail tip protein, four in the XPD helicase family, four in Cas4. Replacing one of them with serine - the same residue with oxygen in place of sulfur - abolishes function in the phage. The requirement is elemental, not steric.

7. Methionine is the first residue of every protein

[E] Translation initiates at AUG, and the residue placed first is methionine; in bacteria and in mitochondria it is formylated. One of the last amino acids recruited into the code became the obligatory first letter of every protein sequence written with it.

[E] Joined to adenosine it becomes S-adenosylmethionine, the methyl donor for essentially every methylation in the cell, and the radical source for the enzyme family that inserts sulfur into the lipoyl cofactor.

[E] And as a bare side chain it does the work reported in the companion paper: the thioether of Met278 driven between the separated strands of a D-loop, the only methionine in a two-hundred-methionine assembly to reach the DNA at all.

[F] Two doors, two jobs. Cysteine binds metals and carries the element. Methionine starts the sequence, donates the methyl, and wedges the strand. Neither job is available to any other residue.

Part IV. What is open

8. Open questions

[O] Whether the lateness of cysteine and methionine in the code reflects difficulty of biosynthesis, difficulty of charging a transfer RNA with them, or the reactivity of a free thiol in an early cell, is not settled by the chronologies, which establish the order without establishing the cause.

[O] Whether the relic reading of the clusters can be tested rather than argued. A mineral fragment enclosed in protein should leave traces in cluster geometry or in the sequence of the binding motifs, and comparing cluster coordination across the oldest protein folds against mineral sulfide geometry is a calculation available from deposited structures.

[O] Why the code built an exception for selenium and none for a second sulfur residue.

Color is a pale field behind the word, never colored type, and it names an element and nothing else. Molybdenum and bromine carry no row and no color, so the cofactor of Part III prints as its sulfur alone and hypobromous acid as its oxygen. Gene symbols are set in italic and take no field.

Abstract. PADMAL is caused by a variant that destroys a miR-29 docking site in the 3′UTR of *COL4A1*, so the gene overproduces a structurally normal collagen and the vessel wall thickens until the lumen closes. The disease is therefore a dosage disorder, and this paper follows one mechanistic question through it from end to end, keeping the failed steps in. Four claims are made. First, the lesion `c.*32G>T` is a transversion, so no adenine base editor can correct it whatever its window; prime editing is the matching chemistry, and the check that would have caught this is a one-line comparison of tool chemistry against edit

chemistry. Second, delivery to brain microvascular mural cells, not editor choice, is the gate, and an intrathecal phosphorothioate oligonucleotide has human CNS validation that no editing platform can currently match. Third, a proposed link from an Alu insertion in *XDH* through xanthine to the guanine nucleotide pool is refuted by the 1988 experiment that prompted it, because human cells cannot convert xanthine to XMP; the real connection between the purine and collagen arms runs through sulfur, at a shared cofactor and at a covalent bond. Fourth, because miR-29 brakes a whole matrix program including the crosslinker LOX, the inherited cis-acting lesion and the trans-acting redox modifier make opposite predictions about sulfilimine density per unit collagen — a falsifiable claim about human tissue that appears not to have been tested.

Paragraph tags. **[E]** established in the cited literature. **[F]** a finding or inference drawn here from that evidence. **[O]** an open question, answerable but not yet answered. No new experimental data is reported in this paper.

Part I. The lesion

1. Why this paper keeps its errors in

[F] Most of what gets published is the conclusion. The reasoning that produced it — the wrong turns, the terminology collisions, the moment the chosen tool turns out to be chemically incapable of the job — is edited out before submission. That editing is understandable, and it is why the literature is a poor teacher of judgment.

[F] This paper is a worked case and it keeps the errors in. Two proposed connections fail in what follows. Both are documented rather than deleted, because the failure modes are more transferable than the surviving claim.

[F] It is written for researchers competent in their own area but newer to genome editing, regulatory RNA or variant interpretation — the readers for whom "use CRISPR to fix it" still sounds like a plan rather than the beginning of a list of constraints. Nothing here assumes prior familiarity with base editors, prime editors or HGVS nomenclature.

2. The vocabulary the argument needs

[E] **Alu elements.** About a tenth of the human genome is Alu: short repeats near 300 base pairs descended from the 7SL RNA gene, copied through an RNA intermediate and pasted elsewhere. Over a million copies exist. Most are inert, but young subfamilies such as AluYa5 still move, so some insertions are polymorphic — present in some people, absent in others.

[E] **The 3′UTR.** The untranslated region after the stop codon codes for nothing and is not inert. It carries the instructions for how much protein is made and how long the transcript survives. A mutation here changes quantity, not sequence.

[E] **MicroRNAs as brakes.** A microRNA of about 22 nucleotides pairs with a short site in a target 3′UTR and suppresses that transcript. Destroy the docking site and the brake is gone: the gene makes a structurally perfect protein, and too much of it.

[E] **Cis and trans.** A cis-acting change alters the DNA of the gene being regulated and affects that gene only. A trans-acting change alters the regulator and affects everything that regulator controls. The distinction does real work in Part III.

[E] **Base editing.** A CRISPR protein that does not cut both strands, carrying an enzyme that converts one base to another. Adenine base editors perform adenine–thymine to guanine–cytosine; cytosine base editors perform cytosine–guanine to thymine–adenine. Both are transitions, purine to purine and pyrimidine to pyrimidine. Neither performs a transversion.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

[E] Prime editing. A nicking CRISPR protein fused to a reverse transcriptase and directed by an extended guide that carries a template of the sequence wanted. Because the replacement is written directly, all twelve substitutions are available, along with small insertions and deletions.

[E] Notation. In HGVS, `c.` numbers the coding sequence and an asterisk before the number places the position in the 3′UTR. So `c.32G>T` and `c.*32G>T` are different variants in different parts of the gene, and they cause different diseases.

3. A disease of too much normal protein

[E] PADMAL — pontine autosomal dominant microangiopathy with leukoencephalopathy — is a monogenic cerebral small vessel disease. Carriers develop repeated small infarcts concentrated in the pons, progressive white matter change, cognitive decline and microbleeds, typically from mid-adulthood. One affected parent transmits it to half their children.

[E] Verdura and colleagues established the mechanism in 2016 through six independent steps: linkage plus exome sequencing in a large French family pointing to a heterozygous variant in a predicted miR-29 site in the *COL4A1* 3′UTR; five further unrelated probands out of 202 screened carrying variants in the same site, including the proband of the original PADMAL family; cosegregation with a cumulative LOD of 6.03; a case-control burden difference at $p = 1.77 \times 10^{-12}$; luciferase reporters and RT-qPCR on patient primary fibroblasts both indicating upregulation; and multiple pontine infarcts in every symptomatic carrier.

[F] What makes that chain convincing is its shape. Statistical genetics establishes that the locus matters; two independent functional assays establish how. A luciferase result without linkage is a cell-culture curiosity, and linkage without function names a region rather than a mechanism.

[E] *COL4A1* encodes the α1 chain of type IV collagen, the structural collagen of basement membranes — the sheets underlying endothelium and supporting small vessel walls. In PADMAL the protein sequence is normal. The regulatory brake fails, the transcript escapes suppression, and the cell overproduces good collagen. Excess matrix thickens the membrane, the wall stiffens, the lumen narrows and perfusion falls, producing ischaemic rather than haemorrhagic disease.

The reframing that governs everything after this

For a broken-protein disease the aim is to supply or repair function. Here function is intact and quantity is wrong, so the aim is to restore a set-point. That single distinction decides which molecular tool can act, which delivery route is adequate, and what counts as success.

---

4. The asterisk that changes the diagnosis

[E] The canonical PADMAL variant is `c.*32G>T`. A *COL4A1* variant `c.32G>T` also exists. One character separates them and they are different diseases with opposite bleeding phenotypes.

	c.*32G>T	c.32G>T
Location	3′UTR, position 32 after the stop codon	Coding sequence, exon 2
Protein consequence	none — sequence unchanged	p.Gly11Val
Mechanism	destroys the miR-29 docking site; brake lost	glycine substitution disrupts triple-helix packing
Collagen made	normal protein, excessive quantity	abnormal protein, misassembled
Vessel failure mode	thickened, stiff, narrowed	structurally fragile
Dominant stroke type	**ischaemic** — pontine lacunar infarcts	**haemorrhagic** — intracerebral bleeds
Syndrome	PADMAL	COL4A1-related disorder / Gould syndrome
Onset	adulthood	any age, including prenatal porencephaly

[F] The clinical stakes are not subtle. One variant gives an ischaemic small-vessel disease; the other gives fragile vessels prone to bleeding. Antithrombotic decisions run in opposite directions. A report transcribed without the asterisk, or a literature search that silently conflates the two, can invert management.

[F] HGVS nomenclature is not clerical pedantry. It is the compression format in which variant position travels, and the compression is lossy if every character is not read. Confirm the reference transcript, since coordinates shift between transcripts. Treat the asterisk, hyphen, plus and underscore as semantic. When a paper and a clinical report disagree about a variant, suspect nomenclature before suspecting biology.

[F] This is the first of three near-identical names in this paper concealing unrelated entities. The others are xanthine against XMP, and HER1 against HAR1.

Part II. The tools

5. Why the obvious editor cannot work

[E] Every adenine base editor performs adenine–thymine to guanine–cytosine and nothing else. Reverting `c.*32G>T` requires restoring thymine to guanine on the sense strand, equivalently adenine to cytosine on the antisense strand. Both are transversions. Cytosine base editors convert cytosine–guanine to thymine–adenine, also wrong, and the CGBE and GBE transversion editors act on cytosine, not thymine.

[F] Narrowed-window ABE variants do not change this. A narrower window reduces bystander editing, which is worth having in an A/U-rich 3′UTR where neighboring adenines are dense, but it is a precision improvement to a chemistry that still cannot make the required change.

The discipline this teaches

Check the chemistry of the edit against the chemistry of the tool before anything else — before efficiency, before delivery, before off-target rates. Those matter only once the tool can in principle produce the product. A great deal of effort is spent optimizing approaches that were chemically impossible from the first slide.

[E] A prime editor is a Cas9 nickase (H840A) fused to an engineered reverse transcriptase and directed by a pegRNA that both targets the locus and carries a primer binding site and a reverse transcription template encoding the wanted sequence. The nicked 3′ end anneals to the primer binding site, the template is copied, and the edited flap resolves into

the genome. Because the replacement is specified directly, a thymine-to-guanine transversion is no harder than a transition.

Component	What it is	Why it matters here
PEmax	optimized effector architecture; codon optimization, NLS layout, SpCas9 R221K/N394K	the current baseline; PE2 is obsolete as a starting point
epegRNA	pegRNA with a 3′ structured motif (tevopreQ$_1$, mpknot) blocking exonuclease degradation	several-fold higher efficiency; no reason to design without it
PE4 / PE5	co-expressed dominant-negative MLH1 suppressing mismatch repair	critical here: single-base mismatches are what MMR excises best
PE3	a second nick on the non-edited strand	raises efficiency and raises indel risk
PE3b	nicking guide matching only the already-edited sequence	most of the gain, far fewer indels, and designable at this site
PE6	evolved compact reverse transcriptases	matters when AAV cargo limits bite
PE7	La-protein fusion stabilising the pegRNA 3′ end	efficiency refinement
twinPE	paired pegRNAs writing matched flaps, optionally with Bxb1	the route for excising a segment, not for a single base

[F] A reasonable starting stack for this lesion is PE5max with an epegRNA and a PE3b nicking guide.

[F] **Strand.** *COL4A1* lies at 13q34 and is transcribed from the minus strand, so cDNA-coordinate notation and genomic sequence are inverted relative to one another. Spacer, PAM, primer binding site and template must all be laid out in genomic coordinates. This is the commonest single point of failure in pegRNA design.

[F] **No silent co-edit.** In an exon a silent change can destroy the PAM and prevent re-editing. A 3′UTR offers no such trick, so a poor local PAM forces either a compromise or a PAM-relaxed nickase such as SpRY, at some cost in specificity.

[F] **Allele selectivity is close to free.** The mutant base can sit inside the spacer, discriminating mutant from wild-type. In a heterozygous dominant dosage disease that matters: the goal is to normalize output, not halve it.

[F] **The readouts already exist.** Verdura's work left behind patient fibroblasts, a 3′UTR luciferase reporter and RT-qPCR for transcript level. Validation runs from amplicon sequencing for editing and indels, to luciferase rescue showing the site functional again, to RT-qPCR showing transcript returning toward wild-type. Most editing targets offer only the first of those.

[E] **The Alu problem is a different problem.** No base editor removes a 300 bp AluYa5 insertion; that needs paired nucleases or a twinPE-class platform. And with over a million Alu copies, guides against Alu consensus have no specificity. The only handle is unique flanking sequence spanning the insertion junction.

6. Delivery is the gate

[F] Editor selection is solvable. Delivery decides whether any of it reaches a patient, and it is largely independent of which editor was chosen. The editing literature reports efficiencies in cultured cells, where delivery is free, and readers new to the field inherit that distortion.

[E] The diseased cells are brain microvascular mural cells — pericytes and smooth muscle — and endothelium, behind the blood-brain barrier. Lipid nanoparticles, the delivery success of the last decade, are overwhelmingly hepatic in

tropism and do not meaningfully reach brain pericytes. The AAV capsids with the strongest CNS-crossing data, PHP.eB above all, produced those results in particular mouse strains through a receptor interaction that does not translate to primates. And prime editors are larger than base editors, which are larger than Cas9 alone, so packaging requires dual-AAV split-intein reconstitution or engineered virus-like particles, each with its own efficiency penalty.

[F] Here the disease class returns with force. PADMAL is a dosage disorder, and lowering output does not require a permanent genomic change. Antisense oligonucleotides and siRNA lower output, and they have a delivery route with human validation that no editing platform currently matches: intrathecal administration of phosphorothioate-backbone oligonucleotides, of which nusinersen and tofersen are the proof. CSF-delivered oligonucleotides also distribute along perivascular spaces, which is the compartment of interest.

	Prime editing	Allele-selective ASO or miR-29 mimic
Effect	permanent correction	titratable suppression
Reversible if wrong	no	yes — stop dosing
CNS delivery in humans	not demonstrated	demonstrated, intrathecal
Dosing	single	repeated, indefinitely
Risk if overshoot	haploinsufficiency, permanent	adjust dose

[O] Whether CSF-delivered oligonucleotides reach mural cells specifically, at therapeutic concentration, is the open question. CNS penetration is settled; this compartment is not, and it is answerable from distribution studies in large animals.

[F] One caveat applies to every option. Basement membrane thickening and accumulated lacunar infarcts are structural. Normalizing dosage may halt progression. Nothing in the mechanism supports reversal of established pontine infarcts.

Part III. The chemistry

7. A false lead, kept in

[F] The material that seeded this analysis carried a second thread: AluYa5 insertions in *XDH*, alongside a 1988 experiment in which an Alu element disrupted xanthine metabolism. A synthesis suggested itself.

> *XMP is the immediate precursor of GMP. If an Alu lesion impairs xanthine handling, does it not compromise GTP supply, and therefore every GTP-dependent signaling protein?*

[F] The reasoning is structurally sound and the conclusion is wrong, and the failure mode is common enough to be worth dissecting.

[E] Two molecules share a name fragment. Xanthine is a free purine base; XDH oxidises hypoxanthine to xanthine to urate, the terminal catabolic step by which purine leaves the nucleotide economy. XMP is xanthosine 5′-monophosphate, a nucleotide, produced by IMPDH oxidising IMP at carbon 2 and converted to GMP by GMP synthetase. XDH appears nowhere in GMP synthesis, and XMP is never made by phosphoribosylating free xanthine, because humans possess no xanthine phosphoribosyltransferase.

[E] The 1988 experiment is its own disproof. Lin, Goldthwait and Samols used the bacterial *Ecogpt* gene, encoding xanthine-guanine phosphoribosyltransferase, as a mutation trap in human A549 cells. *Ecogpt* does precisely what

no human enzyme does: xanthine plus PRPP to XMP. The selective medium paired xanthine with mycophenolic acid, an IMPDH inhibitor closing the endogenous route.

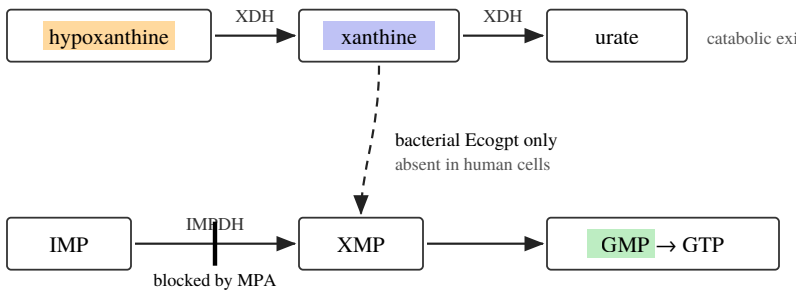

Figure 1. The dashed arrow exists only in cells carrying the bacterial gene. The selection works because human xanthine handling is disconnected from guanine nucleotide supply. Had the proposed link been real the assay would have had no discriminating power.

[E] The clinical control already exists. Classical xanthinuria type I is complete XDH loss of function. Were the guanine nucleotide pool throttled by it, these patients would present with multisystem signaling failure. They do not. They present with near-absent urate, elevated xanthine, and the consequences of its poor solubility: urolithiasis, occasionally crystal myopathy, often found incidentally. Genuine GTP-supply lesions look nothing like this — GTP cyclohydrolase I deficiency gives dopa-responsive dystonia, *IMPDH1* mutations give retinitis pigmentosa. If anything XDH loss shunts hypoxanthine back toward HGPRT salvage into IMP, marginally favouring the pool.

[E] GTP-binding proteins are not substrate-limited. Small GTPases and heterotrimeric G proteins are governed by the GTP/GDP ratio and by GEF and GAP kinetics, not by bulk availability. Cellular GTP runs at several hundred micromolar against low-micromolar affinities. Only pharmacological depletion perturbs it, which is how mycophenolate and mizoribine work.

[F] Guanine tetraloop enzymes is not a category. GNRA tetraloops are RNA structural motifs in rRNA and ribozymes; G-quadruplexes are stacked guanine tetrads in G-rich nucleic acid. Neither is an enzyme class, and both follow from sequence rather than from free guanine or GTP concentration.

[F] Why this stays in the paper. The instinct was sound. Purine chemistry does connect to GTP signaling by a different route, shown in section 8. A hypothesis can be wrong in mechanism and right that a connection exists; the discipline is to test the specific claim rather than accept or discard the whole intuition.

8. Sulfur enters three times

[E] One: inside the enzyme. XDH is a molybdo-flavoenzyme whose catalytic molybdenum center carries a terminal sulfido ligand. Strip that single sulfur and the enzyme is dead. It is installed post-translationally by molybdenum cofactor sulfurase. Following the convention of the key, molybdenum carries no row, so the cofactor prints as its sulfur alone.

Type	Gene	Lesion	Enzymes lost
I	*XDH*	apoenzyme absent or truncated	XDH only
II	*MOCOS*	sulfurase fails; apoenzyme intact but unsulfurated	XDH and aldehyde oxidase
III	*MOCS1*, *MOCS2*, *GPHN*	the cofactor itself is not made	XDH, aldehyde oxidase and sulfite oxidase

The xanthinuria series read as a sulfur-dosage ladder. Type III is molybdenum cofactor deficiency.

The conceptual payload

Purine catabolism and sulfur amino acid catabolism — cysteine to sulfite to sulfate — share a cofactor. Not a substrate and not a pathway: a cofactor. When it fails, sulfite accumulates and produces devastating neonatal encephalopathy. This is a defensible unifying claim of exactly the kind the nucleotide-pool hypothesis was not.

[E] **Two: the defining bond of collagen IV.** Collagen IV networks are crosslinked at the NC1 hexamer by sulfilimine bonds, a covalent sulfur–nitrogen linkage between a methionine sulfur and a hydroxylysine nitrogen, identified by Vanacore and colleagues in 2009. The bond is formed by peroxidasin using hydrogen peroxide and bromide to generate hypobromous acid as oxidant. Bromide carries no row, so that oxidant prints as its oxygen; on present evidence bromide is an essential trace element specifically for this reaction.

Where the two arms actually meet

The structural integrity of the exact protein network that PADMAL overproduces depends on a sulfur crosslink whose formation is driven by peroxide. The redox arm and the collagen arm do not merely correlate through signalingThey meet at a chemical bond.

[E] Peroxidasin mutations cause anterior segment dysgenesis and congenital cataract, overlapping the ocular features of COL4A1-related disease.

[E] **Three: thiophosphate, in three registers.** Azathioprine, 6-mercaptopurine and 6-thioguanine are purine analogues bearing sulfur at carbon 6. 6-MP is oxidised by xanthine oxidase to 6-thiourate, which is why allopurinol with azathioprine is a classic dangerous interaction and why TPMT and NUDT15 pharmacogenetics carry clinical weight.

[E] Azathioprine's immunosuppressive action runs substantially through 6-thio-GTP, which incorporates into the guanine nucleotide pool and blocks Rac1 activation. A real route therefore connects a sulfur-modified purine to a small GTPase — not by depleting the pool but by placing a chemically altered nucleotide into it that the GTPase binds and cannot signal from. The intuition of section 7 was sound; it ran through sulfur substitution and XDH as catabolic gatekeeper, not through XMP supply.

[E] GTPγS and GDPβS are non-hydrolysable thiophosphate analogues that lock GTPases in defined states, with ATPγS serving the same role in kinase substrate labelingTools rather than biology, but they explain why thiophosphate and GTP signalingo-occur so often in the literature.

[E] Replacing a non-bridging phosphate oxygen with sulfur confers nuclease resistance and promotes protein binding and uptake. Any miR-29 mimic or allele-selective antisense oligonucleotide against the mutant 3′UTR will carry that backbone, which is the chemistry underwriting the delivery argument of section 6. And if the editing route is taken instead, the pegRNA and nicking guide carry it too: 2′-O-methyl-3′-phosphorothioate end modifications are

standard for efficient editing in primary cells. Thiophosphate is present in both branches regardless of which is chosen.

[E] These linkages are chiral, R_p and S_p, stereopure oligonucleotide chemistry is an active field, and R_p/S_p substitution with Mn^{2+} rescue — the thio effect — remains the classical method for identifying catalytic metal coordination in ribozymes.

9. The hypothesis: two routes, opposite crosslink predictions

[E] miR-29 does not regulate *COL4A1*. It regulates a program The family, encoded at 7q32.3 and 1q32.2, brakes a large matrix regulon — collagens I, III, IV and V, elastin, fibrillin, and critically LOX, the other collagen crosslinker.

[F] **Route A, cis.** The `c.*32G>T` variant destroys one site in one transcript. *COL4A1* output rises and the rest of the regulon is untouched: LOX unchanged, peroxidasin unchanged, elastin unchanged. Crosslinking capacity stays at baseline while its substrate floods in.

[F] **Route B, trans.** Oxidative stress, including xanthine-oxidase-derived superoxide and peroxide, drives TGF-β, an established repressor of miR-29. Lowering miR-29 globally raises collagen output and LOX together, while the same peroxide feeds peroxidasin directly.

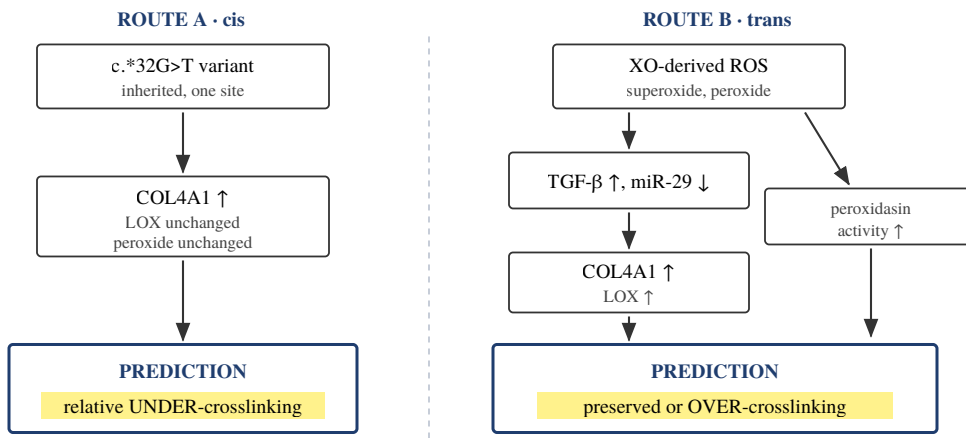

Figure 2. Both routes raise collagen IV. They differ in whether crosslinking capacity rises with it, which is what makes the sulfilimine measurement discriminating. The highlighted field marks the sulfur bond being counted.

	Route A — cis, inherited	Route B — trans, redox
COL4A1 protomer	increased	increased
LOX	unchanged	increased
Peroxidasin substrate	unchanged	increased
Capacity against substrate	outstripped	matched or exceeded
Sulfilimine density per unit collagen	**decreased**	**preserved or increased**

[F] If this holds, a PADMAL vessel and a hypertensive arteriolosclerotic vessel should differ measurably in crosslink density even where conventional histology makes them look alike. That is a falsifiable claim about human tissue,

and it distinguishes mechanism from appearance: thickened basement membrane is a description shared by many small-vessel pathologies, while crosslink stoichiometry is a fingerprint.

[F] It also carries therapeutic weight. If PADMAL matrix is under-crosslinked the vessel is not merely thicker but differently constituted, and lowering collagen output might improve stoichiometry as well as bulk. If it is over-crosslinked, peroxidasin and the redox arm become targets in their own right.

[O] I am not aware of anyone having measured sulfilimine density in PADMAL tissue, though that absence is itself uncertain. Peroxidasin capacity in cerebral microvasculature is not welcharacterized, so fixed capacity is an assumption rather than a measurement. The TGF-β to miR-29 link is established in fibrosis models generally and extrapolated to brain mural cells here. And miR-21 runs the other way: TGF-β induces it, and it is pro-fibrotic, so treating TGF-β as a single vector is a simplification this hypothesis has not resolved.

[E] If the redox arm is load-bearing, XILO-FIST must be engaged: allopurinol after ischaemic stroke, with white matter hyperintensity progression as an imaging endpoint, did not show benefit. Dosing, timing and whether oxypurinol reaches the compartment are live objections, but a treatment of the redox axis that omits the trial is advocacy rather than analysis.

Part IV. Reading the literature

10. The wider regulatory layer, graded by evidence

[F] The *COL4A1* regulatory literature has a large low-quality tail: single-paper cell-line claims, luciferase-only validation, no in vivo follow-up. Listing names without tiering them is how phantom mechanisms enter a review.

microRNA	Role	Relevance here
miR-143/145	co-transcribed pair, SRF and myocardin driven; governs the contractile against synthetic smooth muscle state	the cell type that thickens in this disease
miR-126	endothelial-restricted, hosted in an *EGFL7* intron; targets SPRED1 and PIK3R2	vascular integrity and angiogenic signaling
miR-21	TGF-β induced and pro-fibrotic; targets PTEN and SMAD7	the counterweight to miR-29 on the same axis
miR-132	dysregulated in CADASIL smooth muscle work	a monogenic small-vessel comparator

[O] For *XDH* I am aware of no well-established microRNA regulator and decline to name one.

[E] Canonical snoRNAs — C/D box directing 2′-O-methylation through fibrillarin, H/ACA box directing pseudouridylation through dyskerin — modify rRNA and snRNA. No snoRNA to collagen or basement-membrane axis is established. Two adjacencies are real: sno-derived RNAs, processed into miRNA-sized fragments that can load into RISC, where the phenomenon is real but validated vascular targets are thin; and snoRNA host genes, the SNHG family and *GAS5*, widely reported as miR-29 sponges.

The stoichiometry objection

The competing-endogenous-RNA field carries an unresolved problem: derepressing a microRNA requires target-site abundance far above what most claimed sponges provide at physiological expression. Most SNHG papers do not address it. A sponge invoked without an expression-level argument will be dismissed by anyone who knows the field.

[E] *COL4A1* and *COL4A2* share a bidirectional promoter, head to head at 13q34. Dosage cannot be reasoned about in isolation: the α1 to α2 ratio governs protomer assembly, so an intervention changing one without the other risks a stoichiometry problem a naive knockdown would miss.

[O] The paradigm for RNA-binding-protein control of collagen is LARP6, which binds a 5′ stem-loop in collagen I transcripts and coordinates their translation. Whether an analogous layer operates on collagen IV is, as far as I can establish, open.

[O] The most actionable question this material generates: what other deeply conserved microRNA sites exist in the *COL4A1* 3′UTR? Verdura's cohort screened 202 probands and most remained unexplained. Other conserved sites would be candidate loci for those cases — same mechanism, different brake. The analysis is a conserved-site pull cross-referenced against constraint metrics and published variant sets, with an evidence tier on each candidate.

11. How not to fool yourself

[F] The specific biology above will date. These habits will not, and each comes from an error made in the course of this analysis rather than from a textbook list.

Looks like one thing	Is actually two
`c.32G>T` / `c.*32G>T`	a coding glycine substitution, and a 3′UTR regulatory variant, with opposite bleeding phenotypes
xanthine / XMP	a free purine base at the end of catabolism, and a nucleotide in the middle of GMP synthesis
HER1 / HAR1	EGFR, a receptor tyrosine kinase, and Human Accelerated Region 1, a non-coding locus at 20q13.33

The failure mode, named

A shared name fragment generates a plausible mechanistic bridge between unconnected systems, and the bridge feels like insight because it arrived as a connection rather than as a fact. Insight and confusion produce the same subjective sensation.

[F] The defense is mechanical. Before building on a link between two entities, confirm each entity independently: full name, gene symbol, chromosomal location, pathway position. If they are genuinely connected the check costs a minute; if not, it saves a chapter. This matters disproportionately for literature-assembled work. Bench researchers are protected by experiments that refuse to work. Synthesis from published sources has no such error-correction, so the only check is a deliberate one.

[F] Every subfield has one objection insiders raise automatically and outsiders miss. Human accelerated regions carry GC-biased gene conversion: many, HAR1 among them, show substitutions skewed toward AT to GC in recombination-adjacent sequence, and gBGC is a neutral fixation bias rather than selection, so accelerated is not a synonym for adaptive. Competing-endogenous-RNA claims carry the stoichiometry objection above. AAV CNS delivery carries mouse-strain specificity. Before importing a finding from a field not your own, find that field's standard objection; the fastest route is the most-cited critical commentary on the most-cited paper.

Tier	Description	How to treat it
1	primary paper, replicated, with orthogonal functional validation	state as established
2	primary paper, single cohort or single assay type	attribute to the authors by name
3	review or consensus statement	use for framing, cite the primary for facts
4	single cell-line paper, luciferase only, no replication	name the limitation in the same sentence
5	aggregator summary, AI-generated overview, secondary web source	not citable; use only to locate primaries

[F] The material that seeded this analysis was largely tier 5: useful for orientation, unusable as evidence. That is a normal way to begin. It becomes a problem only when tier 5 content passes unmarked into a manuscript. The same applies to confidence within a paper — this one carries established findings, extrapolations and one untested hypothesis, and marking them differently in the body costs a few words. A reviewer who finds an unmarked speculation distrusts the whole document; one who finds a labeled speculation engages with it.

12. Testable predictions

[O] P1. Sulfilimine crosslink density is reduced per unit collagen IV in PADMAL vessels. Requires post-mortem or biopsy cerebral vessel tissue from genotyped carriers, with hypertensive arteriolosclerosis, CADASIL and age-matched control as comparators. A null result — preserved density despite elevated collagen — falsifies the fixed-capacity assumption and is equally informative.

[O] P2. Other deeply conserved microRNA sites exist in the *COL4A1* 3′UTR and rare variants in them are enriched in unexplained familial disease. Stage one is bioinformatics against public databases and needs no new samples; stage two needs cohort sequencing.

[O] P3. Patient fibroblasts show altered peroxidasin-dependent crosslinking under defined peroxide load. Requires the primary lines already established in the Verdura work, and tests Route A against Route B where the redox term can be set rather than inferred.

[O] P4. Allele-selective suppression of the mutant transcript normalize output without disturbing the α1 to α2 ratio. Requires patient fibroblasts and an oligonucleotide panel. The α2 measurement is the part usually omitted, and the bidirectional promoter makes it necessary.

[F] Two results would reorder the therapeutic options. Demonstration that CSF-delivered oligonucleotides reach mural cells at useful concentration would make the suppression route dominant for this disease and probably for other dosage-type small-vessel diseases, reducing prime editing to a fallback. Evidence that PADMAL matrix is substantially under-crosslinked would reframe the disease from too much collagen to too much poorly integrated collagen, making crosslinking capacity — peroxidasin, bromide availability, local peroxide tone — a therapeutic axis orthogonal to dosage.

13. References

[F] Citations are short form and should be verified against primary sources before submission. Details drawn from memory rather than from an opened source are marked *[verify]*. If you read one paper, read Verdura 2016; if you read one more and editing is new to you, read the Anzalone prime editing literature.

A closing note on method

This paper began with nine fragments of search-engine output on loosely related topics. What made the sequence productive was not any single fact but a repeated cycle: propose a connection, identify the specific claim it depends on, check that claim against a primary source or a known experiment, and either keep the connection or record why it failed. Two proposed connections failed and are documented here rather than deleted. One survived, sharpened into a testable prediction, and is the only genuinely new thing in these pages. That ratio is normal. Publishing only the survivor is what makes the process look unlike itself to anyone learning it.

Deleting a Hydrogen Bond - Does the Rare Tautomer Get Easier?

Inosine·cytosine against guanine·cytosine as a controlled probe of double proton transfer

PP-2026-ICDPT-01 v2 · 23 September 2026 · Dr. John Allen Berger, PhD · NovagonDNA · Licensed under CC BY-NC-ND 4.0.

Color Key

color	element	base	where it appears in this paper
RED	hydrogen · H 1	adenine	the two protons that transfer; the atom whose isotope substitution is the proposed experiment
BLUE	carbon · C 6	cytosine	the pyrimidine partner, held constant across both systems compared here
GREEN	nitrogen · N 7	guanine	the reference purine; and the ring nitrogen atoms N1 and N3 that carry the first transferring proton
ORANGE	oxygen · O 8	hypoxanthine	the test purine, guanine minus its 2-amino group; and O6, which accepts the second transferring proton and becomes an enol
PURPLE	phosphorus · P 15	uracil	no role in this calculation; the bases are modeled without the sugar-phosphate backbone
YELLOW	sulfur · S 16	thymine	no role here; retained for continuity with the series
INDIGO	selenium · Se 34	xanthine	named only in the discussion of purine catabolism; not modeled

Color is a pale field behind the word, never colored type, and it names an element and nothing else. Method, software and basis-set names take no field. Inosine is the nucleoside of hypoxanthine and takes its color.

Abstract. The Watson-Crick guanine·cytosine pair is held by three hydrogen bonds; the inosine·cytosine pair is the same geometry with exactly one of them deleted, because hypoxanthine is guanine without its 2-amino group. That makes the substitution a controlled perturbation of the Löwdin double proton transfer coordinate: one bond removed, everything else held constant. This paper reports a first-pass calculation of the tautomerisation energy for both pairs. Two independent methods agree that **removing the third bond lowers the double proton transfer energy by about 2 kcal/mol**, making the rare tautomer more accessible in inosine·cytosine than in guanine·cytosine. Decomposition shows the result is not what it appears: the intrinsic base effect runs the other way by about 3 kcal/mol, and is overcome by a pairing effect of about 5 kcal/mol in which the rigid three-bond network resists the proton shifts far more strongly than the two-bond network does. The calculation is thermodynamic, not kinetic; no transition state was located, and the effect is the same size as the method error. It is reported as a directional prediction with a specific experimental test attached: the two templates should differ in their kinetic isotope effect if the tautomer channel is real.

Paragraph tags. **[E]** established in the literature. **[F]** computed or argued here. **[O]** open question. All energies are gas-phase electronic energies without zero-point or thermal correction.

Part I. The question

1. Why this substitution is the right probe

[E] Löwdin proposed in 1963 that proton transfer within the hydrogen bonds of a base pair could produce rare enol and imino tautomers that mispair at replication, giving a quantum-mechanical route to spontaneous mutation. The proposal was placed on a modern footing by treating the pair as an open quantum system coupled to a solvent bath, which found the tautomer population non-negligible and the interconversion fast relative to strand separation.

[E] Every such treatment models guanine·cytosine, which has three hydrogen bonds: N1-H···N3, O6···H-N4, and N2-H···O2. The first two carry the transferring protons. The third does not participate directly.

[F] Hypoxanthine is guanine lacking the exocyclic 2-amino group, and nothing else. Pairing it with cytosine therefore deletes the N2-H···O2 bond and leaves the two proton-carrying bonds in place. This is a rare thing in molecular biology: a single specified interaction removed with the rest of the system held constant. If the non-participating third bond influences the transfer, this substitution isolates that influence.

1a. Related work

[E] Double proton transfer in nucleobase pairs has been surveyed extensively. Brovarets′ and Hovorun and co-workers have mapped tautomerisation pathways across many pairs, including a QM/QTAIM treatment of the hypoxanthine·adenine pair [5], and a broader quantum-chemical survey of guanine·cytosine mechanisms [7]. The strategy of perturbing one partner to modulate the transfer has also been applied from the pyrimidine side, in a study of cytosine analogues designed to induce transfer with guanine [6]. Duplex stabilities for inosine-containing sequences have been computed in gas and solution phase [8].

[O] A calculation comparing inosine·cytosine against guanine·cytosine specifically on this coordinate was not found in the searches performed for this paper. Given the coverage of the surveys cited above, that absence should be read as the limit of the search rather than as established novelty. A systematic check of the Brovarets′/Hovorun corpus is required before any priority claim is made, and none is made here.

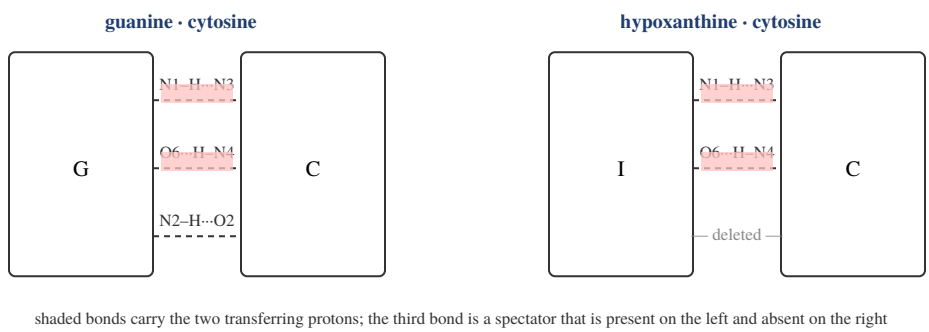

Figure 1. The controlled deletion. Both pairs carry the same two proton-transfer bonds; only the spectator N2-H···O2 differs.

Part II. Method

2. Procedure

[F] Bases were modeled as 9-methylpurines and 1-methylpyrimidine, the standard practice for isolating base-pair energet-

pair. In the rare tautomer the N1 proton of the purine has moved to N3 of cytosine, and the N4 proton of cytosine has moved to O6 of the purine, giving an enol purine and an imino pyrimidine.

1. Monomers generated from SMILES, embedded in 3D with ETKDGv3, pre-optimized with MMFF94.
2. Each monomer optimized with GFN2-xTB.
3. The reference guanine·cytosine pair constructed deterministically: the three hydrogen-bond partner atoms on the purine define an edge line; the in-plane outward normal gives target positions for the three cytosine partners at 2.95, 2.91 and 2.86 Å; cytosine is placed by Kabsch superposition onto those targets.
4. The three remaining complexes built by Kabsch grafting onto the optimized reference frame, so all four share a common starting geometry and no pair is advantaged by a better guess.
5. For the enol tautomers the hydroxyl hydrogen was rotated about the C6-O6 bond to point at N4. For the imino pyrimidine both in-plane rotamers were built and optimized the lower-energy valid structure was retained.
6. All complexes optimized in Cartesian coordinates with L-BFGS-B on analytic GFN2-xTB gradients.
7. Single-point B3LYP/6-31G* energies computed on the optimized geometries with density fitting.
8. Structures accepted only if every hydrogen-bond heavy-atom distance fell between 1.5 and 3.6 Å, which rejects dissociated and clashed geometries automatically.

[F] Software: RDKit 2026.03.6, tblite (GFN2-xTB), SciPy L-BFGS-B, PySCF 2.14.0. The final pipeline runs in under an hour on two cores; reaching a working pipeline took considerably longer, and two earlier assembly approaches failed outright before the deterministic construction in step 3 was adopted.

3. Validation before interpretation

[F] Four quantities have known values and were checked before the comparison of interest was examined.

Quantity	This work	Literature range
G·C interaction energy	−29.1	−25 to −30 kcal/mol, gas phase
G·C tautomerisation, B3LYP	+11.3	11.7 kcal/mol (0.507 eV), ref [3]
Third hydrogen bond contribution	6.4	5 to 8 kcal/mol
Hydrogen-bond heavy-atom distances	2.62–2.83 Å	2.86–2.95 Å experimental

The short distances are the known overbinding signature of GFN2-xTB for hydrogen bonds and were expected. The other three land inside their accepted ranges.

[E] The comparison in row two is worth stating precisely. Reference [3] reports the guanine·cytosine reaction asymmetry as 0.507 eV, or 11.7 kcal/mol, computed at B3LYP+XDM/6-311++G** with implicit solvation. The present work gives 11.26 kcal/mol at a considerably cheaper level, a difference of under half a kcal/mol. The same reference gives forward and reverse barriers of 13.2 and 11.9 kcal/mol, only slightly above the endpoint asymmetry. For this system the endpoint energy is therefore a reasonable proxy for the barrier — but that relationship is a property of guanine·cytosine and cannot be assumed to carry over to inosine·cytosine, which is precisely the pair whose network stiffness differs.

Part III. Results

4. The comparison

	G·C	I·C	difference (I – G)
Interaction energy, xTB	−29.07	−22.71	+6.36
Tautomerisation, GFN2-xTB	+9.98	+7.90	**−2.07**
Tautomerisation, B3LYP/6-31G*	+11.26	+9.31	**−1.95**

kcal/mol. B3LYP single points on the GFN2-xTB geometries. Positive tautomerisation energy means the rare tautomer pair lies above the canonical pair.

Result

Deleting the third hydrogen bond lowers the double proton transfer energy by about 2 kcal/mol. The rare tautomer is more accessible in inosine·cytosine than in guanine·cytosine. A semi-empirical method and a hybrid density functional agree on the difference to within 0.12 kcal/mol, which is closer agreement than either method merits and should be treated as partly fortuitous.

5. Decomposition: two effects in opposition

[F] Subtracting the isolated-monomer tautomerisation energies from the complex values separates what the base does on its own from what the hydrogen-bond network does. The subtraction is algebraically exact rather than approximate: the pairing term equals the interaction energy of the tautomer pair minus the interaction energy of the canonical pair, since the monomer reference energies cancel identically. It is a difference of two well-defined binding energies, not a partition requiring assumptions.

Term	G·C	I·C	difference
purine monomer, keto → enol	−0.23	+2.84	+3.07
cytosine monomer, amino → imino	+2.36	+2.36	0.00
monomer sum	+2.13	+5.21	+3.07
complex, total	+9.98	+7.90	−2.07
pairing contribution	**+7.85**	**+2.69**	**−5.16**

kcal/mol, GFN2-xTB. The pairing contribution is the complex value minus the monomer sum.

[F] The result is a competition, and the naive expectation loses. **Intrinsic base effect:** hypoxanthine's enol is 3.07 kcal/mol less stable, relative to its keto form, than guanine's is. On its own this would make inosine·cytosine harder to tautomerise, not easier. **Pairing effect:** the three-bond network penalises the proton shifts by 7.85 kcal/mol, the two-bond network by only 2.69. The spectator bond acts as a clamp, holding the canonical geometry while the other two protons attempt to move. The clamp is worth 5.16 kcal/mol and it overcomes the intrinsic term by roughly 2.

What the mechanism turns out to be

Not electronics. The 2-amino group's influence on the transfer runs mainly through *mechanical rigidity* of the pair, not through its electron-donating effect on the ring. That was not the expected answer and it is the part of this result most worth checking with a better method.

6. One known method error, and which way it pushes

[E] GFN2-xTB places the enol tautomer of 9-methyl guanine slightly below the keto form. Higher-level calculations and experiment put the keto form lower, by a few tenths of a kcal/mol.

[F] Correcting that error raises the guanine tautomerisation energy and therefore makes the difference *more* negative, not less. The known failure of the cheaper method works against the reported result rather than producing it. The sign is more robust than the magnitude.

Part IV. Limits and the experiment

7. What this calculation does not establish

- **It is thermodynamic, not kinetic.** No transition state was located. Tunneling rate depends on barrier height and barrier width; this work reports only the energy difference between endpoints. A nudged elastic band or transition-state search is the necessary next step and was beyond the available compute.
- **Gas phase.** No solvent. The open-quantum-system treatments that motivate this work found the solvent bath material to the conclusion.
- **No zero-point or thermal correction**, which matters disproportionately for hydrogen motion and is required before any isotope prediction is quantitative.
- **Single-point energies on semi-empirical geometries.** The geometries should be re-optimized at the density functional level.
- **Methylated free bases**, not nucleosides in a duplex. Stacking and backbone constraint are absent.
- **The effect is the size of the error bar.** Roughly 2 kcal/mol, against a method uncertainty of similar magnitude. This is a direction, not a measurement.
- **No vibrational frequencies were computed.** The four structures are therefore not confirmed to be true minima rather than saddle points. Standard practice requires this check and it was not performed.
- **The conformational search is thin.** Two rotamer variants per tautomer complex, of which only one was valid for inosine·cytosine. A lower-lying tautomer geometry missed on either side would shift the result, and the bias is not one-directional: a missed inosine tautomer would enlarge the effect, a missed guanine tautomer would shrink it.
- **No dispersion correction and no counterpoise correction.** B3LYP with a 6-31G* basis underbinds hydrogen-bonded complexes and carries basis-set superposition error. For the tautomerisation energies this largely cancels, because both sides of the difference have identical composition and identical basis; it does not cancel in the quoted interaction energies, which should be treated as indicative only.

8. The experiment this implies

[F] If the tautomer channel contributes to mispairing, templates containing inosine should mispair through that channel more readily than guanine templates. Inosine's promiscuous pairing is well documented and is universally attributed to wobble geometry. This work proposes a second, additive mechanism.

[F] The two are distinguishable. A tautomer-driven channel proceeds by hydrogen transfer and should show a substantial kinetic isotope effect when exchangeable protons are replaced by deuterium; a wobble-geometry channel should not. Comparing misincorporation rates on defined synthetic templates carrying inosine against guanine, in H_2O against D_2O, tests both the tautomer hypothesis and its predicted dependence on hydrogen-bond count in one design. Anomalous temperature dependence, in the form of curvature in an Arrhenius plot, is the second signature

[O] Because inosine and guanine are difficult to distinguish in most sequencing readouts — polymerases copy inosine as guanine — such an experiment must use defined templates with known base positions rather than calling the base from the data.

9. Reproduction

[F] The four optimized geometries and all energies are retained. The pipeline is three short scripts: monomer construction and optimization, deterministic pair assembly and complex optimization, and density functional single points. Total runtime under one hour on two cores. The SMILES strings that define the eight monomers are the only chemistry input:

```
9-methylguanine        CN1C=NC2=C1N=C(N)NC2=O
  rare tautomer        CN1C=NC2=C1N=C(N)N=C2O
9-methylhypoxanthine   CN1C=NC2=C1N=CNC2=O
  rare tautomer        CN1C=NC2=C1N=CN=C2O
1-methylcytosine       CN1C=CC(N)=NC1=O
  rare tautomer        CN1C=CC(=N)NC1=O
```

INDIGO	magnesium · Mg 12	orotate	no role in this paper

This is a mathematical and circuit result, so most rows are inactive. Silicon, the principal material discussed, carries no row and therefore no color — the convention operating as intended rather than an omission. Color is a pale field behind the word, never colored type, and it names an element and nothing else.

Abstract. A Mach-Zehnder interferometer mesh is a programmable unitary. Unit quaternions are SU(2). This paper establishes numerically that the correspondence is exact rather than analogical, and reports three results a designer needs before building on it. First, the quaternion-to-SU(2) map is a group homomorphism verified to 2.5×10^{-16} over two thousand random pairs, so matrix multiplication in a photonic mesh *is* quaternion multiplication, and a three-stage cascade reproduces the triple quaternion product to machine tolerance. Second, and contrary to a claim the author made before testing it, **a Mach-Zehnder interferometer with two phase shifters cannot realise an arbitrary unit quaternion** — the median residual over random targets is 0.44 rad and the worst case 1.38 rad. SU(2) is a three-parameter group and two controls cannot cover it. A third phase shifter reduces the residual to numerical zero. Third, propagated phase error obeys a clean law: the root-mean-square rotation error equals $\sqrt{3}$ times the per-shifter phase error, confirmed to four significant figures, giving an effective-bit expression $\log_2(\pi / \sqrt{3}\sigma)$. The mesh reaches ten to eleven effective bits at milliradian phase control and exceeds the four-to-eight-bit range of analog resistive crossbars for any phase error below roughly 0.02 rad. The double cover is also realised physically: the simulated mesh returns to the identity only after 720 degrees, reading exactly −1 at 360.

Paragraph tags. **[E]** established in the literature. **[F]** computed or argued here. **[O]** open question. All results are from numerical simulation of an idealised circuit; no device was fabricated or measured.

Part I. The algebra

1. What is claimed, and what is not

[F] **Claimed:** that a programmable photonic mesh implements unit quaternion arithmetic exactly, that three phase shifters per interferometer are necessary and sufficient, that phase error propagates by a √3 law, and that the resulting precision exceeds analog resistive crossbars over a practically relevant range.

[F] **Not claimed:** that this is quantum computing. The mesh manipulates classical coherent light. There is no entanglement and no superposition of computational states, and the interference is described completely by Maxwell's equations. Nor is any priority claimed — programmable photonic meshes, the Reck and Clements decompositions, and the SU(2) structure of two-mode interferometers are all established. What is offered is the specific identification, its exactness, the component count, and the tolerance law.

2. The map, and its exactness

[E] For a unit quaternion $q = a + bi + cj + dk$ with $a^2 + b^2 + c^2 + d^2 = 1$, the corresponding element of SU(2) is

$$U(q) = \begin{bmatrix} a - i\cdot d & -c - i\cdot b \\ c - i\cdot b & a + i\cdot d \end{bmatrix}$$

[E] Equivalently $U = a\cdot I - i(b\,\sigma_1 + c\,\sigma_2 + d\,\sigma_3)$ in the Pauli basis, which is the same statement as the isomorphism between the unit quaternions and SU(2) and between the quaternion units and the Pauli matrices under $i \mapsto -i\sigma_1$, $j \mapsto -i\sigma_2$, $k \mapsto -i\sigma_3$.

[F] **Result 1.** Over 2000 random unit quaternion pairs, the maximum absolute deviation of U(pq) from U(p)U(q) was $\mathbf{2.483 \times 10^{-16}}$ — machine epsilon. The map is a homomorphism, not an approximation. The practical consequence is that a photonic mesh does not *model* quaternion multiplication; cascading unitaries and multiplying quaternions are the same operation in two notations.

Part II. The circuit

3. Two phase shifters are not enough

[F] The interferometer was modeled from components: two ideal 50:50 couplers $B = (1/\sqrt{2})[[1, i],[i, 1]]$ and phase shifters $P(x) = \mathrm{diag}(e^{ix}, 1)$. Two configurations were tested against random unit quaternion targets, fitting phase settings by multi-start Nelder-Mead on the SU(2) geodesic distance with global phase removed.

Configuration	median residual	worst case	verdict
$B\cdot P(\theta)\cdot B\cdot P(\varphi)$ — two shifters	0.4417 rad (25.3°)	1.384 rad (79.3°)	cannot reach arbitrary q
$P(\psi)\cdot B\cdot P(\theta)\cdot B\cdot P(\varphi)$ — three shifters	**0.000**	**0.000**	exact

30 random targets per configuration, 40 optimizer restarts each.

Result 2 — and a correction

SU(2) is a three-parameter group; the unit quaternions form the three-sphere S^3. Two tunable phases span a two-dimensional subset and cannot cover it. **Three phase shifters per interferometer are necessary and sufficient** to realise an arbitrary unit quaternion up to global phase.

This corrects a two-parameter claim made in working discussion before the calculation was run. The dimension count should have settled it without simulation. It is recorded here because the component count per quaternion rises by half, which changes area, static power and calibration burden — and because the episode is the argument for simulating before writing.

4. Composition through a cascade

[F] **Result 3.** Three random unit quaternions were each fitted to a three-shifter interferometer and the three stages cascaded. Compared against the triple quaternion product over 40 trials, the median discrepancy was **4.7×10^{-8} rad**, which is optimizer convergence tolerance rather than a physical limit. A mesh composes rotations; it does not merely represent them.

5. The double cover is physically realised

[E] SU(2) double-covers SO(3). A rotation of angle θ about axis n̂ acts on a spinor as $U = \cos(\theta/2)I - i \sin(\theta/2)\, \hat{n}\cdot\vec{\sigma}$, and the half-angle means a full revolution returns −I rather than +I. The state is periodic in 4π, not 2π.

[F] **Result 4.** Sweeping a mesh-implemented rotation from 0 to 720 degrees about [1,1,1], the quantity ½·Tr U reads **+1.000000 at 0°, −1.000000 at 360°, and +1.000000 at 720°**. The sign is carried as a physical optical phase and is measurable by interference against a reference.

[F] This is the operational difference from a rotation-matrix implementation. A 3×3 matrix in SO(3) cannot distinguish q from −q; the information is discarded before computation begins. The mesh retains it, which matters wherever accumulated rotation over many revolutions carries information — attitude propagation being the obvious case.

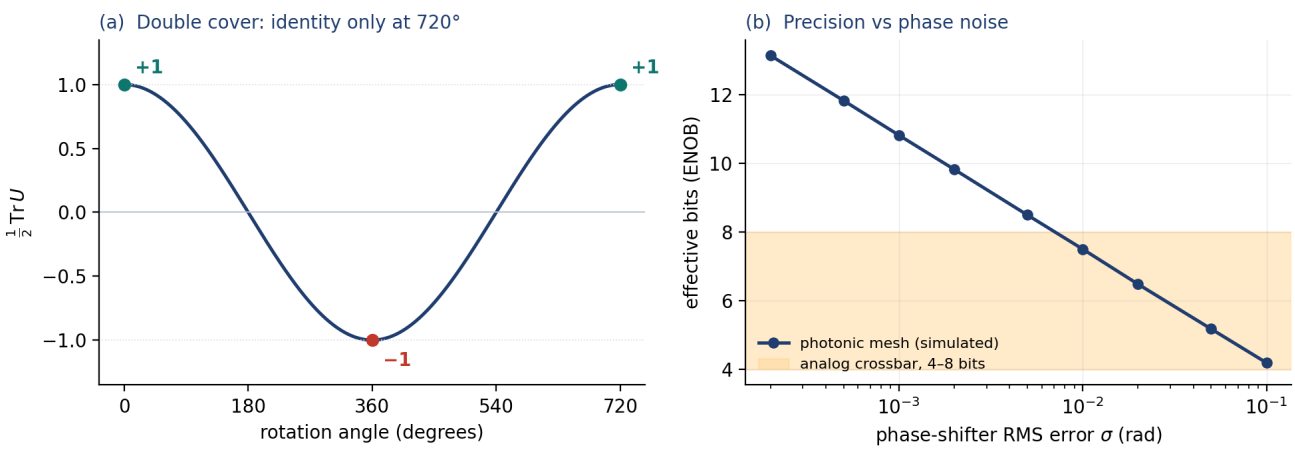

Figure 1. (a) The double cover realised in a simulated mesh: the identity is recovered only at 720 degrees, with an exact sign inversion at 360. (b) Effective bits against per-shifter phase error, with the four-to-eight-bit band of analog resistive crossbars shaded for comparison.

Part III. Tolerance

6. Phase error propagates by a √3 law

[F] Independent Gaussian error of standard deviation σ was added to each of the three phase settings, and the geodesic rotation error measured against the intended quaternion over 60 targets × 60 trials per noise level. **Result 5:** the ratio of root-mean-square rotation error to σ was constant at 1.7292, 1.7213, 1.7332 and 1.7294 across the four lowest noise levels, against √3 = 1.73205. Three independent phase errors adding in quadrature.

$$\text{RMS rotation error} = \sqrt{3} \cdot \sigma$$

$$\text{ENOB} = \log_2\left(\pi \,/\, (\sqrt{3} \cdot \sigma) \right)$$

σ (rad)	RMS rotation error	ENOB	against the crossbar
0.0002	19.8 mdeg	13.2	far exceeds
0.001	99.3 mdeg	10.8	exceeds
0.005	0.50°	8.5	at the top of the crossbar range
0.01	0.99°	7.5	within the crossbar range
0.02	2.02°	6.5	crossover
0.10	9.89°	4.2	below the crossbar

ENOB defined against a full-scale of π radians, the maximum geodesic separation of two rotations. Other full-scale conventions shift every figure by a constant and should be stated when comparing.

7. What this requires of calibration

[F] The photonic path beats an analog resistive crossbar for any phase error below roughly 0.02 rad, and reaches ten to eleven effective bits at milliradian control. The qualifier is decisive: **open-loop fabrication variation in silicon photonics is far worse than milliradian, frequently of order radians.** The figures above are therefore reachable only with closed-loop calibration.

[E] Self-configuring mesh architectures set phases progressively against measured output power, and because a unitary mesh conserves total power, power monitoring supplies its own error signal. That body of work is not an optional refinement to this proposal; it is the precondition for it.

[O] Whether calibration can hold milliradian precision against thermal drift and crosstalk in a large mesh during operation — as opposed to at set-up — is not addressed here and is the question that decides whether the ENOB figures survive into a device.

Part IV. Method, limits, reproduction

8. Limits of this calculation

- **Ideal couplers.** Perfect 50:50 splitting assumed; real directional couplers carry imbalance and wavelength dependence.
- **Lossless.** A unitary mesh conserves power by construction. Real waveguides, bends and shifters do not. Insertion loss is not modeled and does not appear in the error budget.
- **Independent Gaussian phase error.** Real fabrication error has systematic and spatially correlated components that this treatment excludes, and correlated error may behave better or worse than the √3 law.

- **No thermal crosstalk.** Thermo-optic shifters heat their neighbors. Untreated.
- **Static.** No bandwidth, no dynamics, no settling time.
- **Small circuits only.** One interferometer and a three-stage cascade. Behavior of a large N × N mesh, where routing depth and accumulated loss dominate, is not simulated.
- **No device.** Nothing was fabricated or measured.

9. Reproduction

[F] One Python file, NumPy and SciPy only, runs in about fifteen minutes on two cores. Seeded at 20260923. The components are five functions: quaternion product, the SU(2) map above, the interferometer built from B and P, a global-phase-invariant SU(2) distance, and a multi-start Nelder-Mead fit.

```
BS   = [[1, i],[i, 1]] / sqrt(2)
P(x) = [[exp(i x), 0],[0, 1]]
mzi3(theta, phi, psi) = P(psi) @ BS @ P(theta) @ BS @ P(phi)
U(q) = [[a - i d, -c - i b],[c - i b, a + i d]]
dist(U,V) = 2 arccos( |Tr(A* B)| / 2 ),  A,B normalized  to det = 1
```

10. What follows

[O] Three things would move this from a simulation to a proposal. A circuit-level model with measured component libraries, replacing ideal couplers and adding loss. A large-mesh study establishing how the √3 law degrades with depth. And a small fabricated test structure — three phase shifters and two couplers — measured against the predicted tolerance law, which is within reach of a multi-project shuttle run.

Status. Simulation only. One prior working claim is corrected in Section 3. The results are reproducible from the description above in under an hour. **Distribution held pending IP determination.**

Color is a pale field behind the word, never colored type, and it names an element and nothing else. Inosine is the nucleoside of hypoxanthine and takes its color. Drug, enzyme and method names take no field.

Abstract. A companion calculation [1] finds that deleting the third hydrogen bond of a Watson-Crick pair — the difference between guanine·cytosine and inosine·cytosine — lowers the double proton transfer energy by about 2 kcal/mol, making the mutagenic rare tautomer more accessible. This paper does not repeat that result. It answers the question a practitioner actually has: *what would this change about what I am doing?* Three things follow. First, the direction is settled for thermodynamics and unsettled for kinetics, and the difference matters, because population and rate are not the same risk. Second, because population depends exponentially on energy, an uncertainty the size of the effect becomes a thirty-fold uncertainty in consequence — so the calculation is either unimportant or substantially important and current precision cannot tell you which. Third, exposure is highly unequal across fields: adenine base editing transits inosine in DNA at every edit and is maximally exposed; ADAR-based RNA editing generates far more inosine but through a pathway where the mutagenic consequence largely does not apply; epigenetic editing is barely exposed at all; and nucleoside analogue development already has a marketed drug whose mechanism and whose principal liability are both tautomer ambiguity. The paper closes with the three results that would move this from watch-list to action, and one cheaper calculation that would matter more.

Paragraph tags. **[E]** established in the literature. **[F]** inference drawn here. **[O]** open question. **How to read this:** Part I is the finding, Part II the landscape it sits in, Part III is organized by what you do — go to your own section. Part IV is what would change the answer.

Part I. What the finding actually says

1. The result, and the trap in reading it

[E] Löwdin's proposal is that a proton can shift within the hydrogen bonds of a base pair, producing rare enol and imino tautomers that mispair when a polymerase copies them. The companion calculation compares two pairs that differ by exactly one hydrogen bond and finds the tautomer roughly 2 kcal/mol more accessible in the two-bond pair [1].

[F] The trap is that an energy difference between endpoints is not a rate. Two distinct quantities are in play and they carry different risks:

Quantity	What it governs	Status after the companion paper
Endpoint energy ΔE	how much tautomer exists at equilibrium	**settled in direction.** More tautomer in the two-bond pair
Barrier height and width	how fast the tautomer forms and reverts, including by tunneling	**not computed.** No transition state was located

[F] Theory expects the two to track each other. The Bell-Evans-Polanyi relation and Hammond's postulate both say that within a related series a less endothermic reaction generally has a lower and earlier barrier. That would make the transfer faster as well as more favourable.

[F] The companion structures argue against assuming it. Tunneling probability depends exponentially on barrier width, which is set by the donor-acceptor heavy-atom separation. The optimized geometries give inosine·cytosine a *shorter* N1···N3 distance than guanine·cytosine (2.716 against 2.833 Å) but a *longer* O6···N4 distance (2.746 against 2.679 Å). One proton has less distance to cross, the other more. The geometry does not reinforce the thermodynamics, and the kinetic claim should not be made until the barrier is computed.

The one-line answer

More rare tautomer present in inosine·cytosine: yes, almost certainly. Faster proton tunneling: probably, but unproven, and the structural evidence is mixed.

2. Why the exponent matters more than the number

[F] Tautomer population scales as exp(−ΔΔG/RT). A modest energy change is a large population change, which is what makes a 2 kcal/mol result worth anyone's attention — and equally what makes a 2 kcal/mol *error* disqualifying.

ΔΔG (kcal/mol)	fold change at 298 K	implied I·C occupancy	reading
0.5	2.3×	4×10^{-4}	negligible
1.0	5.4×	9×10^{-4}	marginal
1.5	12.6×	2×10^{-3}	worth measuring
1.95 (computed)	**27×**	$\mathbf{5 \times 10^{-3}}$	**worth designing around**
2.5	68×	1×10^{-2}	material
3.0	158×	3×10^{-2}	dominant

Occupancies scaled from the guanine·cytosine value of 1.73×10^{-4} reported in [2]. Assumes $\Delta\Delta G \approx \Delta\Delta E$, which neglects zero-point and entropic terms and is the weakest step in this table.

What this table is for

Do not read the bold row as the answer. Read the *spread*. The companion calculation carries roughly ±2 kcal/mol of method uncertainty, which on this table spans from "negligible" to "dominant." The correct conclusion is not a risk estimate but a statement about what is currently unknown: **the effect is either irrelevant or important, and the present precision cannot distinguish those two.** That is a reason to compute better, not a reason to act.

Part II. The context you are working in

3. Where inosine actually appears

Source	Where	Scale	Copied by a polymerase?
Adenine base editing	DNA	one per edit, plus off-targets	**yes** — this is the mutagenic route
ADAR, therapeutic and endogenous	RNA	thousands per transcriptome	no — translated, not replicated
Adenine deamination, spontaneous	DNA	low, constitutive	yes, but repaired by AlkB/endonuclease V
Wobble position of tRNA	RNA	constitutive	no

[F] The fourth column is the one that matters. A rare tautomer becomes a mutation only when something copies the template while the proton is displaced. That single criterion separates the exposed applications from the unexposed ones, and it does not track total inosine burden. The field generating the most inosine is the least exposed to this particular hazard.

4. What this mechanism is competing against

[E] Honest ranking matters more than advocacy. For adenine base editing, the established off-target mechanisms are, in approximate order of measured contribution:

1. Cas9-dependent editing at sequence-similar off-target sites.
2. Cas9-independent deamination of transiently single-stranded DNA at replication forks and behind polymerase.
3. Bystander editing of neighboring adenines inside the activity window.
4. TadA-mediated off-target editing of cellular RNA.

[F] A tautomer-driven fidelity term would be a fifth contributor and, on present numbers, smaller than all four. It has one distinguishing property that keeps it worth tracking: it is **systematic rather than sequence-dependent**. It scales with total inosine-residence time rather than with guide specificity, so it is unaffected by the engineering that suppresses mechanisms one through three. Better guides do not reduce it.

Part III. Consequences, by what you do

If you run adenine base editing

Exposure: highest of any application. Every ABE edit passes through hypoxanthine in double-stranded DNA. After one replication cycle the site is an inosine·cytosine pair — exactly the species computed — until repair or a second round resolves it to guanine·cytosine.

What to do now: nothing to your protocol. The effect is below the four mechanisms above and is not actionable at current precision. What is worth doing is *recording* the variable that would let you detect it later: the duration of inosine residence, which is set by expression window, delivery dose and the cell's repair capacity. Transient delivery shortens it; long-expression constructs and repair-deficient backgrounds lengthen it.

The signature to look for, if you already have data: a mutation excess at edited sites that is *independent of guide sequence* and scales with editor exposure time rather than with off-target homology. Sequence-independence is what distinguishes this from mechanisms one through three.

If you run ADAR-recruiting RNA editing

Exposure: large in inosine quantity, small in consequence. Off-target ADAR editing generates inosine across the transcriptome at a scale base editing never approaches. But edited messenger RNA is translated, not replicated, so the tautomer-to-mutation route largely does not operate.

The question that does apply is decoding fidelity. If an inosine·cytosine codon-anticodon contact spends more time in a tautomer, does the ribosome misread it more often? That is a genuinely open problem and far less studied than replication fidelity. It would show as amino-acid misincorporation, not as sequence change, and would therefore be invisible to every sequencing-based off-target assay in current use.

What to do now: nothing, but note that your off-target panel is structurally incapable of seeing this class of error. If proteomic mass spectrometry is available, misincorporation is the readout.

If you do epigenetic editing

Exposure: minimal, directly. dCas9 fused to DNMT3A, TET or KRAB creates no inosine and changes no sequence.

But the general principle transfers, and it lands somewhere more important. The finding is not about inosine — it is that *hydrogen-bond count modulates tautomer accessibility*. The epigenetic base that matters is 5-methylcytosine, which deaminates to thymine far faster than cytosine deaminates to uracil, and which is why CpG sites are mutation hotspots. That route is hydrolytic. Whether the *tautomer* channel also differs between cytosine·guanine and 5-methylcytosine·guanine has, as far as I can establish, not been asked.

What to do now: nothing operationally. But see Section 8 — that calculation is cheaper than the one already done and sits in a far better-characterized chemical area.

If you develop nucleoside analogues

Exposure: this is already your mechanism, whether or not you designed it that way.

Molnupiravir is the existence proof. Its active form, N4-hydroxycytidine, interconverts between amino and imino tautomers and consequently pairs with both adenine and guanine. That ambiguity is not a side effect — it *is* the antiviral mechanism, driving error catastrophe in viral replication. It is also the origin of the host-mutagenesis concern that accompanied its review. One phenomenon, therapeutic effect and principal liability, in the same molecule. *[verify the regulatory detail before citing it.]*

What to do now, concretely. Tautomer accessibility is computable at low cost, before synthesis, from the hydrogen-bonding architecture of the candidate. Use it in two directions: *maximize* it where lethal mutagenesis is the intent, and *screen against* it where mutagenicity is an unwanted liability. The pipeline in [1] runs in under an hour on two cores per candidate pair, which puts it inside the budget of a routine filter rather than a special study.

Adjacent compounds worth running through it: ribavirin, favipiravir, 5-fluorouracil, gemcitabine, and the thiopurines. 6-thioguanine incorporates into DNA and is mutagenic, and sulfur substitution at C6 alters precisely the hydrogen-bonding face this method models.

5. Summary table

If you are doing	Exposure	Act now?	What would change that
Adenine base editing	**high**	No. Track inosine-residence time as a covariate	a computed barrier, plus a sequence-independent mutation excess in existing data
Cytosine base editing	indirect	No	the analogous calculation on the uracil intermediate
ADAR RNA editing	high volume, low consequence	No. Note that sequencing assays cannot see the relevant error	evidence of tautomer-driven ribosomal misreading
Epigenetic editing	minimal	No	the 5-methylcytosine calculation, Section 8
Nucleoside analogue design	**mechanistic**	**Yes** — usable as a pre-synthesis filter	already actionable; validate against molnupiravir as positive control

Part IV. What would change the answer

6. Three results that would move this from watch-list to action

1. **A transition state at density functional level, with zero-point correction and solvent.** This converts a population statement into a rate statement and resolves the ambiguity in Section 1. Until it exists, no kinetic claim should be made.
2. **A kinetic isotope effect measurement.** Misincorporation rates on defined synthetic templates carrying inosine against guanine, run in H_2O against D_2O. A tautomer channel proceeds by hydrogen motion and should show a substantial isotope effect; wobble geometry should not. This separates the proposed mechanism from the established explanation of inosine promiscuity.
3. **Re-analysis of existing base-editing off-target data for sequence-independence.** Requires no new experiment. The signature is a mutation excess that scales with editor exposure and not with guide homology.

7. A caution on the experiment

[E] Polymerases copy inosine as guanine, so inosine and guanine are not distinguishable in ordinary sequencing readouts. Any test must use defined synthetic templates with known base positions rather than calling the base from data. The same structural minimalism that makes inosine an elegant probe makes it a difficult analyte.

8. The cheaper calculation that matters more

[F] Before extending the inosine work, run the same comparison on cytosine·guanine against 5-methylcytosine·guanine. It is the same pipeline with one new SMILES string and one additional methyl group. It costs an afternoon.

[F] It is worth more than the barrier search for three reasons. CpG methylation is the most clinically consequential base modification there is, and its mutational hotspot behavior is measured in enormous detail, so a computed prediction has real data to be checked against. The methyl group is electron-donating and alters the cytosine ring without removing a hydrogen bond, which cleanly separates the electronic effect from the mechanical one that dominated the inosine result. And every epigenetic editing program operates on exactly this base pair.

The honest bottom line

A plausible, systematic, currently unquantified contributor to editing fidelity. Most relevant to DNA base editing, least relevant to epigenetic editing, and already demonstrably consequential in nucleoside analogue pharmacology. Not yet a reason to change any protocol. Worth one afternoon of compute to find out whether it should be.

---

Status. Interpretive companion paper. Contains no new calculation. Its claims are conditional by construction: each depends on a companion result carrying an error bar the size of its own effect, and each section states what would have to be true for the conclusion to change. Readers should treat Part III as a map of exposure, not as a risk assessment.

PART TWO HUNDRED AND TWENTY-SIX

Vertical Quaternion Accelerator - Preliminary Design

Four stacked crossbar planes, one per quaternion component

PP-2026-VCHIP-01 v1 · 23 September 2026 · Dr. John Allen Berger, PhD · NovagonDNA · Licensed under CC BY-NC-ND 4.0.

Color Key

color	element	base	where it appears in this paper
RED	hydrogen · H 1	adenine	passivates dangling bonds at the silicon interface; the reliability element, and the degradation mechanism under bias stress
BLUE	carbon · C 6	cytosine	nanotube field-effect transistors in the thin-film logic layer, processable below the thermal budget of the stack
GREEN	nitrogen · N 7	guanine	nitrided gate dielectrics in the base die; gallium nitride if the power stage is integrated
ORANGE	oxygen · O 8	hypoxanthine	gate oxides, and the hafnium-oxide filaments of the baseline crossbar element
PURPLE	phosphorus · P 15	uracil	the donor that dopes the base die n-type; and, by analogy, the charge-recovery loop of Part III
YELLOW	sulfur · S 16	thymine	chalcogenide phase-change cells as the alternate crossbar element; molybdenum sulfide as the alternate thin-film channel
INDIGO	selenium · Se 34	xanthine	appears only as a constituent of the chalcogenide alloys above; no independent role in this design
INDIGO	magnesium · Mg 12	orotate	the magnesium-oxide tunnel barrier of the magnetic junction, the fourth candidate crossbar element

Color is a pale field behind the word, never colored type, and it names an element and nothing else. Silicon, hafnium, molybdenum, tantalum, iridium and the rare earths carry no row and no color, so each compound prints as its keyed constituent alone. Device and process names take no field.

Abstract. This is a preliminary architecture for a monolithically stacked analog accelerator that computes quaternion products. The design assigns each of the four quaternion components to its own crossbar plane in the vertical stack, so that the sixteen partial products of a quaternion multiply are summed through inter-layer vias rather than routed laterally across a die. Everything else in the design is established practice: analog matrix-vector multiplication on a resistive crossbar, monolithic three-dimensional integration using layers that process below four hundred degrees, and resonant clock distribution on a balanced tree. The plane assignment is the one claim the design exists to test. Two consequences follow that were not obvious at the outset. First, because the sign pattern of quaternion multiplication is fixed by the algebra rather than by the data, signs cost routing and not devices — each plane connects its columns to a positive or negative summing rail chosen at design time, halving the device count a general signed crossbar would need. Second, the timing spine and the energy-recovery loop are the same physical structure, since a resonant clock tree recovers charge rather than dissipating it. The dominating risk is thermal: a gradient across the stack shifts conductances differently on each plane, and the four values being summed are precisely the four that sit at different temperatures. Section 8 treats this as the problem that decides whether the architecture works.

Paragraph tags. **[E]** established in the literature or in shipping practice. **[F]** a finding or design decision argued here. **[O]** an open question. No fabrication has been attempted; nothing here is measured.

Part I. The mapping

1. Design brief

[F] The architecture has to satisfy five requirements carried over from the working session. It must stack vertically rather than spread laterally. It must compute quaternion products in analog rather than by iterative digital loops. It must use the element scheme as a real materials specification rather than a mnemonic. It must take its timebase from a physical invariant rather than a manufactured crystal. And it must be buildable in stages, so that the novel part can be tested before the whole stack is committed.

[F] One requirement was dropped. An earlier version took the timing reference from an optical transition in hydrogen. That fails on units: the Lyman-alpha transition is 2,466 THz in the vacuum ultraviolet, roughly five orders of magnitude above anything a switching circuit can follow, and it would require vacuum optics and fluoride windows to deliver. The reference is now microwave, which removes the optics entirely.

2. Quaternion multiplication as four planes

[E] For q = a + bi + cj + dk and p = e + fi + gj + hk, left multiplication by q acts on the coefficient vector of p as a real four-by-four matrix:

```
[ a  −b  −c  −d ]   [ e ]
[ b   a  −d   c ]   [ f ]
[ c   d   a  −b ]   [ g ]
[ d  −c   b   a ]   [ h ]
```

[F] Each row produces one output component. The design assigns one row to one plane. The input coefficients (e, f, g, h) are driven onto all four planes simultaneously through vertical rails, and each plane holds the same four magnitudes |a|, |b|, |c|, |d| arranged in a different permutation with a different sign pattern. Programming a weight quaternion therefore means writing four conductance values, replicated across four planes under a permutation fixed at design time.

Consequence: signs cost routing, not devices

A general signed analog crossbar needs two devices per weight, a positive and a negative conductance, with the output taken as their difference. Here the sign pattern is a property of quaternion algebra, not of the data, so it is known when the mask is drawn. Each device is wired at design time to either the positive or the negative summing rail of its plane. One device per weight, and the sign is free.

[F] The case for stacking is about interconnect. In a planar implementation the four output components are assembled by routing partial sums across the die, and that routing dominates both latency and energy. Stacked, the four partial results sit at the same lateral coordinate on four adjacent planes; the summation path is the height of the stack. Monolithic integration matters here rather than die bonding, because inter-layer vias are lithographically defined at roughly a hundrednanometerpitch, three orders of magnitude finer than the through-silicon vias used to bond finished dies.

[O] Whether that advantage survives the peripheral circuitry is not established. The converters at the edge of each plane may dominate area and energy regardless of how short the summation path is. This is the first thing simulation should settle.

Part II. The stack

3. Layer assignment

Layer	What it is	Materials	Function
L6	thin-film logic	carbon nanotube FETs, or molybdenum sulfide	local accumulation, activation, plane-to-plane routing
L5	crossbar plane *k*	hafnium oxide filamentary cells	fourth row of the multiplication matrix
L4	crossbar plane *j*	hafnium oxide	third row
L3	crossbar plane *i*	hafnium oxide	second row
L2	crossbar plane, real	hafnium oxide	first row
L1	clock and power	thick copper, integrated inductors	resonant balanced tree; charge recovery
L0	silicon base die	bulk CMOS, phosphorus-doped	host core, converters, calibration, thermal sensing, I/O

Built bottom to top. L0 takes the full thermal budget; every layer above it must process below roughly 400 °C, which is what selects the materials in the third column.

[F] The hot layer sits at the bottom, nearest the heat sink, which is the correct arrangement and also the only one available: conventional silicon cannot be fabricated on top of finished layers without destroying them. The crossbar planes above draw little static power, so the thermal path runs downward through the substrate rather than upward through the stack.

4. Four candidate crossbar elements

Element	Keyed to	Strength	Weakness
filamentary oxide	oxygen	mature, low-temperature deposition, small cell	cycle-to-cycle variability; conductance drift
chalcogenide phase change	sulfur	large dynamic range, good retention	resistance drift with time; write energy
ferroelectric	oxygen, iridium electrodes	low write energy, fast	electrode stack complexity; fatigue
magnesium oxide tunnel junction	magnesium	effectively unlimited endurance	small resistance ratio; analog levels limited

[F] The baseline is filamentary oxide, chosen for process maturity rather than performance. The other three are carried as alternates because they fail in different directions, and the thermal analysis in Section 8 may select against the baseline.

Part III. Timing, energy, heat

5. The clock tree and the recovery loop are one structure

[E] A balanced H-tree distributes a clock so that every endpoint is equidistant from the source, which is how skew is eliminated. Driven resonantly — as a standing wave on a tree with distributed inductance rather than as a square wave against capacitance — the energy oscillates between inductive and capacitive storage instead of being dissipated each cycle. This is charge recovery, and it is the one context in which adiabatic technique has reached production silicon.

[F] The two functions are therefore the same wire. The tree that defines simultaneity across the die is also the loop that returns charge to the supply. Placing it on L1, immediately above the base die and immediately below the crossbar planes, puts it where both the converters and the plane drivers can reach it with minimum vertical distance.

[F] Reference: a rubidium chip-scale atomic clock at 6.835 GHz, divided by a phase-locked loop to the core rate. **This is optional and should be justified by the application rather than assumed.** For general compute a temperature-compensated crystal is adequate and far cheaper. The atomic reference earns its place only if the workload needs holdover accuracy without a network reference — navigation, long coherent integration, or distributed nodes that must agree on time without communicating.

6. Execution of one multiply

1. Host on L0 writes the weight quaternion: four conductance magnitudes, replicated across the four planes under the fixed permutation.
2. Input coefficients are converted to analog voltages on L0 and driven up the vertical rails to all four planes at once.
3. Each plane settles. Current on its positive and negative summing rails is the signed dot product of one matrix row with the input vector.
4. Rail currents are differenced per plane, producing four analog partial results stacked at one lateral coordinate.
5. L6 accumulates vertically and hands four values back down to the converters on L0.
6. Digital residual correction on L0, if the precision budget of Section 9 requires it.

[F] Settling dominates. A crossbar plane resolves in tens to hundreds of nanoseconds, so the analog path runs three orders of magnitude slower than the digital clock while performing the entire matrix operation in one step. The design is throughput-oriented, not latency-oriented, and should not be pitched otherwise.

7. Precision

[E] Analog crossbars deliver roughly four to eight bits of effective resolution once device variability, read noise and converter error are accounted for. That is the honest ceiling, and it has not moved much despite a decade of work.

[F] Quaternion rotation for graphics, robotics and attitude control tolerates this; scientific computation does not. The design therefore targets rotation-heavy workloads and carries a digital residual path for anything tighter: compute the bulk product in analog, estimate the error against a digital reference on a sampled subset, and correct. This is a mixed-precision scheme, and its overhead has to be counted against the analog saving rather than assumed away.

8. Thermal, which decides the design

[F] Two distinct thermal problems are usually merged and should not be.

[E] **Fabrication budget.** Every layer above the base die must be processed below roughly 400 °C or the interconnect beneath it degrades. This is why the stack uses carbon nanotubes or molybdenum sulfide for thin-film logic and low-temperature oxide deposition for the crossbars. It is a hard constraint on materials, not a performance target.

[F] Operating gradient, and why it is worse here. In a digital stack a thermal gradient costs timing margin. In this architecture it costs *correctness*. Crossbar conductance is temperature-dependent, the four planes sit at four different heights and therefore four different temperatures, and the four values being summed to form one quaternion are precisely the four that disagree. The error is systematic rather than random, so it does not average out across many operations.

Mitigations, in order of preference

Reference columns per plane. Dedicate columns on each plane to known conductances, read them every cycle, and normalise that plane's output against them. This tracks temperature locally and is standard practice in analog in-memory compute. It costs area and converter bandwidth, not new physics.

Interleaving. Do not stack the four planes contiguously. Distribute them so that the vertical temperature difference between any two is reduced, at the cost of longer vias and some of the interconnect advantage the design exists to capture.

Per-plane sensing and digital trim. Thermal sensors on each plane feeding a correction table on L0. Cheapest to add, slowest to respond, and it only corrects what it can model.

[O] How large is the gradient in practice? Unknown, and it is the single most important number in this document. A first-order thermal simulation of the stack under realistic activity, with the conductance temperature coefficient of the chosen cell folded in, would either retire this risk or end the project. It should be done before anything is fabricated.

Part IV. Risk and build order

9. Risk register

#	Risk	Severity	What retires it
1	Thermal gradient corrupts the inter-plane sum	fatal	thermal simulation with measured conductance coefficients; reference-column correction demonstrated
2	Converters at the plane edges dominate area and power, erasing the analog advantage	fatal	area and energy budget at the intended array size, counted honestly against a digital baseline
3	Monolithic 3D process maturity; yield across seven layers	high	staged build, Section 10; two-layer yield before four
4	Analog precision below what the workload needs	high	characterise effective bits on a single planar array first
5	Device drift and variability over write cycles	medium	endurance testing per candidate element; may select the tunnel junction
6	Resonant clock tuning across process corners	medium	standard practice; tunable capacitance banks
7	Atomic reference adds cost without application need	low	decide from the workload; default to crystal

[F] Risks 1 and 2 are both capable of ending the design, and neither requires fabrication to investigate. They should be settled on paper and in simulation first. Risk 2 in particular is the known failure mode of analog in-memory computing generally: the periphery eats the gain.

10. Build order

[F] Build the smallest thing that tests the novel claim, not the smallest thing that works.

Stage	What is built	What it answers
0	circuit and thermal simulation only	risks 1 and 2, before any silicon is committed
1	single planar crossbar, one quaternion multiply, conventional process	does the row-to-plane mapping compute correctly; does sign-by-routing work; what is the effective precision
2	**two stacked planes**	**the novel claim.** Two planes is the minimum that has a vertical summation path and a thermal gradient between planes
3	four planes, full quaternion	does the advantage scale, or does the gradient grow faster
4	integration with base die, clock tree, host	system-level energy and throughput against a digital baseline

[F] Stage 2 is the decision point. Everything before it is preparation and everything after it is scaling. A two-plane test structure is small enough to be run in a university or consortium facility with monolithic capability, which matters because stage 3 onward is not.

11. Open questions

- What is the vertical temperature gradient across the stack under realistic activity, and what is the conductance temperature coefficient of the chosen cell? These two numbers together decide the architecture.
- At what array size do the edge converters stop dominating? If the answer is larger than the stack can host, the design does not work at any temperature.
- Does the fixed sign pattern really halve device count, or does routing congestion on each plane consume what it saves?
- Is there a workload that genuinely needs both quaternion throughput and an atomic timebase? If not, the reference should be dropped as the optical transition was.
- Would the same plane-per-component mapping pay off for complex numbers (two planes) or octonions (eight)? Two planes is a cheaper test of the same principle.

Status. No fabrication attempted, no simulation run, no measurement taken. Every quantity in this document is either a literature value or a placeholder, and the placeholders are marked as such by context. The document exists to be attacked at Section 8 first.

From BCL-2 to Selenium

The Sulfur Superstring: Supply Chain of Species Homo sapiens

A Real-World Primer in Genetic Research

Part I — Orientation

Method, then Map — in that order

1. Why this primer

[F] Seven prompts took me from a textbook protein family, BCL-2, to a trace element, selenium, and every link held. This is a record of how that happened, written so another researcher can repeat the method rather than just admire the result.

[F] The method has two motions. **Width** means stepping sideways into a neighboring domain to see what the known material touches. **Depth** means stopping on one vein and digging straight down. The AI is very good at width: it can lay out a whole domain in one answer. The human's job is to sense which nugget in that spread is worth digging, and to say so in a single short question.

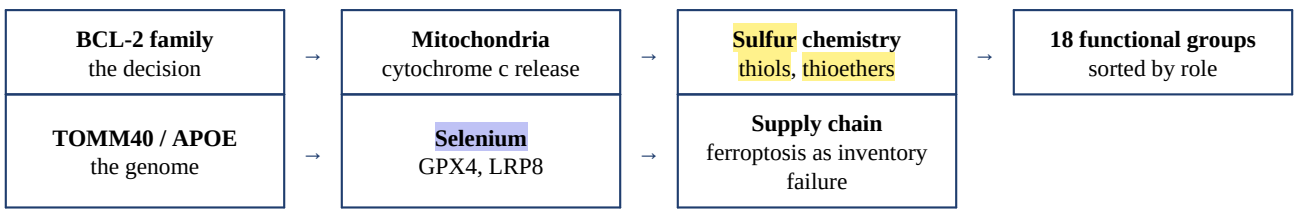
[F] A third motion is easy to miss: **calibration**. Twice in this session the AI told me my framing went too far, and both times the correction became the next step. A research partner that only agrees with you is not a partner.

[E] I am a theoretician. I have no bench data of my own in this chain. Everything here came from published literature, public databases, and the conversation itself. That is the point: this kind of work is open to anyone who can ask good questions.

2. The chain at a glance

[E] Each answer opened the next question. The prompts are quoted close to how I actually typed them, typos included, because a short, rough question is enough when it points in the right direction.

Step	My prompt	Move	What came back	The question it opened
1	Five web clippings on BCL-2, the intrinsic pathway, TOM40	Starting material	The mitochondrion is where the death decision is carried out	What chemistry does that step run on?
2	“does sulfur control cell death”	Width: leap to chemistry	Sulfur runs through cytochrome c, caspases, BAX, glutathione and ferroptosis	Is sulfur the mechanism itself?
3	“the master mechanism”	Calibration	No: the BAX/BAK pore and necroptosis do not run on sulfur. A shared thread, not a master switch	Which sulfur chemistry, exactly?
4	“which of 18 sulfur functional groups participates”	Width: systematic inventory	5 central, 2 minor, 3 drug-only, 8 absent, plus 4 groups missing from the table	Where does the machinery sit in the genome?
5	“what role does Tam40 and its gene neighbors play”	Depth: into the genome	TOMM40 sits next to APOE, the strongest Alzheimer's risk locus	What stands beside sulfur at the critical sites?
6	“selenium ... very narrow band”	Depth: the human intuition	Selenium guards GPX4 against permanent damage; its supply is rationed and delivered through LRP8, an APOE-family receptor	How does the cell keep the books?
7	“supply chain inventory management accounting”	Width: reframe through another field	Intake, stock, reserve, recycling, write-off: ferroptosis is an inventory failure	The finished chain



Read left to right, top row then bottom: each box is one prompt's answer, and each arrow is the question I asked next.

Part II — The Chain

Cellular, Atomic, Molecular, Genetic, Atomic, Systemic — in that order

Step 1. The starting material

[E] I began with five clippings dragged from my browser: a summary of BCL-2, a description of the mitochondrial intrinsic pathway, a table of the anti-apoptotic proteins, a search answer about TOM40, and the abstract of Youle and Strasser's 2008 review in *Nature Reviews Molecular Cell Biology*, “The BCL-2 protein family: opposing activities that mediate cell death.”

[E] Together they tell the standard story. BCL-2, BCL-XL and MCL-1 keep a cell alive by holding BAX and BAK in check. BH3-only proteins act as “death sentinels” and tip the balance. When BAX and BAK win, they punch pores in the outer mitochondrial membrane, cytochrome c escapes, and caspases dismantle the cell. TOM40 is the main door through which proteins enter the mitochondrion.

[F] **Lesson.** Start with the consensus, not the frontier. A review with more than 4,000 citations is solid ground. You need firm footing before you can leap sideways, and the clippings did not need to be polished or complete. They only needed to set the scene.

Step 2. The lateral leap: does sulfur control cell death?

“does sulfur control cell death”

[E] Nothing in the clippings mentions sulfur. That is what made the question productive. I moved from the language of proteins to the language of atoms, and asked whether the whole pathway rests on one element.

[F] The answer came back as a qualified yes. Sulfur is not the switch, but the machinery that carries out the decision is soaked in sulfur chemistry. **Cytochrome c** holds its heme through two thioether bonds and binds the iron through the sulfur of Met80; when Met80 lets go, cytochrome c becomes a peroxidase and helps free itself. **BAX and BCL-2** carry cysteines that act as switches, and nitric oxide on a BCL-2 cysteine protects it from degradation. **Caspases**, the executioners, cut with an active-site cysteine. **Glutathione** falls before apoptosis.

[F] **Ferroptosis**, a separate form of cell death, is decided outright by sulfur supply: cystine comes in, glutathione is made, and GPX4 clears lipid peroxides.

[E] One detail in that answer became important four steps later: GPX4's active site uses selenium, not sulfur. The AI flagged it as a nuance. I filed it away.

[F] The answer also closed a loop with my own clippings. Cytochrome c enters through TOM40 without its heme, gets its sulfur bonds inside, and is trapped there until BAX and BAK open the door. The clipping I thought was a side note turned out to be part of the chain.

[F] **Lesson.** Ask a question from a different level of description: proteins to atoms, genes to chemistry, biology to accounting. A question from another level makes the AI reorganize what it knows, and that is where new connections come from.

Step 3. The pushback: master mechanism or shared thread?

“so it carries out the decision and is the how the cell death occurs. the master mechanism”

[E] I pushed the finding as far as it would go. This is a deliberate move: state the strongest version of the claim and see whether it breaks.

[F] It broke in useful places. The AI agreed that sulfur is the “how” at the caspase step, in cytochrome c, and in ferroptosis. Then it named where the claim fails. **The pore itself**, the point of no return, runs on protein folding and membrane insertion; BAX mutants with no cysteines are reported to still form pores. **Ferroptosis** is executed by iron-driven lipid peroxidation; sulfur is the brake, not the executioner. **Necroptosis** runs on phosphorylation of RIPK3 and MLKL and needs no caspases.

[F] It offered a version a reviewer would accept: sulfur chemistry is the most widely shared chemical thread through cell death, not a single master switch.

[F] **Lesson.** Push your hypothesis until the AI pushes back. If it never disagrees, you are not learning where the edges are. The correction here did not end the line of inquiry; it sharpened it, and it told me which reviewer objections to expect.

Step 4. Width: sorting the 18 sulfur functional groups

"which of 18 sulfur functional groups particates in this process"

[E] I attached the Wikipedia table of sulfur functional groups and asked the AI to sort every row. This turns a vague claim ("sulfur matters") into a checklist that can be tested one line at a time.

Role	Groups	Where they act
Central (5)	Thiol, thioether, disulfide, thioester, sulfoxide	Caspase active sites, glutathione, cytochrome c's heme bonds and Met80, BAX/BAK dimers, ubiquitin tagging of MCL-1, PUFA-CoA in ferroptosis
Minor (2)	Sulfinic acid, sulfonic acid	Over-oxidized cysteine; peroxiredoxin repair; taurine
Drugs or diet only (3)	Sulfonate ester, isothiocyanate, thiocyanate	Busulfan, sulforaphane, inorganic SCN^-
No known role (8)	Sulfone, thioketone, thial, thioic S-acid, thioic O-acid, thionoester, dithiocarboxylic acid, dithioate	None known

[F] The most valuable part of the answer was what the table left out. Four players that matter a great deal are not in a standard chemistry table: sulfenic acid (–SOH), S-nitrosothiol (–SNO, nitric oxide on a cysteine), persulfide (–SSH), and iron-sulfur clusters.

[F] A pattern also emerged. Most of the switching is one atom climbing a ladder of oxidation states: thiol, sulfenic, disulfide, sulfinic, sulfonic. The lower rungs can be reversed; the top one cannot. That ladder became the backbone of Step 7.

[F] **Lesson.** When a claim is fuzzy, hand the AI a complete list and ask it to classify every item. Exhaustive sorting exposes both the strong cases and the gaps, and the gaps are often where the next finding hides.

Step 5. Depth: TOM40, its gene neighbors, and public data

"what role does Tam40 and its gene neighbors play and gene switching data available"

[E] I typed "Tam40." The AI read it as TOM40 (gene TOMM40) and said so openly, noting I might instead mean yeast Tim40, now called MIA40. Stating the interpretation and moving on kept the session going instead of stalling on a clarifying question.

[F] **Function.** TOM40 is the main import pore. When import fails, PINK1 builds up on the TOM complex and flags the mitochondrion for destruction, so TOM40 acts as a sensor for whether a mitochondrion is repaired or removed.

[F] **Neighbors.** On chromosome 19 the order is BCAM, NECTIN2, TOMM40, APOE, APOC1. TOMM40 and APOE lie about 2 kb apart and share regulatory DNA. This is the strongest genetic risk locus for late-onset Alzheimer's disease. A proposed TOMM40 marker, the '523 poly-T repeat, is still disputed because its signal is hard to separate from APOE.

[E] **Data.** No dataset is built around TOMM40 switching, but the region is covered by free public resources: GTEx for expression and eQTLs, ENCODE and Roadmap for chromatin state, 4DN for 3D contacts, the AD Knowledge Portal for Alzheimer's brain data, and the GWAS Catalog.

[F] This step mattered for my own work. It showed that a theoretician can go from literature straight to public data without sequencing a single sample.

[F] **Lesson.** After a wide survey, pick the one object on the page that connects to a bigger system and ask about its neighborhood. Genes are never alone, and asking about neighbors is one of the cheapest ways to find hidden connections.

Step 6. The gold vein: selenium and the narrow window

"i recall selenium being very toxic and has a very narrow band of concentration usage. is that how apoptosis is finely tunned by nature using seleno not sufur cysteine"

[E] This was the intuitive jump. I went back to the nuance from Step 2, that GPX4 uses selenium, and connected it to something I already knew: selenium is safe only in a narrow range. A narrow range suggests tight control, and tight control suggests fine-tuning.

[F] The AI kept the core of the idea and corrected the mechanism. **The window is real**: adults need about 55 µg a day, and the upper safe limit is about 400 µg. The same reactivity that makes selenium a good catalyst makes it toxic when free.

[F] **Selenium buys robustness, not tuning.** Selenocysteine is ionized at the cell's pH and recovers from oxidation where cysteine would be stuck for good. In mice whose GPX4 carries cysteine instead, peroxide destroys the enzyme, certain neurons die by ferroptosis, and the mice have fatal seizures (Ingold et al., *Cell*, 2018).

[F] **The tuning is in the supply.** About 25 human selenoproteins share a ranked supply, and GPX4 and thioredoxin reductase are served first. Selenium travels in blood as selenoprotein P and enters cells through LRP8 (ApoER2), a receptor in APOE's family. That ties Step 6 back to the TOMM40/APOE locus of Step 5.

[F] **A direct apoptosis link.** Thioredoxin reductase is a selenoprotein. It keeps thioredoxin reduced, and reduced thioredoxin holds the death kinase ASK1 inactive. Lose the selenium and ASK1 is released.

[F] **Lesson.** The best questions often come from the human's own memory, not from the page. I recalled a fact about toxicity from outside the usual framing, and it opened the richest vein of the session. The AI then did the careful part: keeping what was right and replacing what was not.

Step 7. The reframe: sulfur as a supply chain

"what sulfur functional groups does the supply chain inventory management accounting"

[E] I borrowed a frame from engineering and business. Any system that must never run out of a critical part keeps books: what comes in, what is on the shelf, what is held in reserve, what gets repaired, and what is written off. The sulfur groups from Step 4 fell into that frame almost perfectly.

Ledger line	Sulfur form	Example
Intake	Thioether, disulfide, thiol	Methionine from diet; cystine through SLC7A11; cysteine through EAAT3
Internal production	Thioether to thiol (transsulfuration)	Methionine converted to cysteine by CBS and CSE, which also set the hydrogen sulfide (H_2S) supply
Working stock	Thiol	Glutathione (GSH), 1–10 mM; free cysteine kept low (~0.1 mM) because it is reactive
Balance sheet	thiol/disulfide ratio	GSH:GSSG about 100:1 in the cytosol, nearer 3:1 in the ER
Reserve	Protein thiols, persulfides	Protein cysteines hold the largest pool; persulfides act as deferred inventory

Ledger line	Sulfur form	Example
Fixed assets	Iron-sulfur clusters	Built with sulfur supplied by NFS1
Recycling	Disulfide, sulfoxide, sulfinic acid back to reduced form	Glutathione reductase, MsrA/B, sulfiredoxin
Write-off	Sulfonic acid, sulfate	Cysteic acid, taurine, excreted sulfate

[F] Seen this way, ferroptosis is an inventory failure. Cut cystine intake, block internal production, or drain the working stock, and GPX4 runs out of glutathione. Selenium is a second, smaller supply chain running beside the first, with its own delivery route and its own priority list.

[F] **Lesson.** Once the pieces are on the table, borrow a frame from a field you know well. A good analogy does not just decorate a finding; it tells you what to measure. The ledger view says to track ratios and reserves, not just totals.

Part III — Synthesis

Finding, Method, Limits — in that order

The finished chain

[F] The BCL-2 family makes the decision to die, and the mitochondrion carries it out by releasing cytochrome c. That protein entered through TOM40 and is held together by sulfur bonds. Caspases then cut the cell apart with an active-site cysteine. Across cell death, sulfur is the most widely shared chemical thread, though not the master switch. Most of its switching is one atom climbing a ladder of oxidation states, reversible at the bottom and permanent at the top. Where a permanent loss would be fatal, at GPX4 and thioredoxin reductase, nature swaps in selenium, which recovers from damage where sulfur cannot. Selenium supply is rationed by a ranked list of selenoproteins and delivered through an APOE-family receptor, and the gene for TOM40 sits beside APOE on chromosome 19. Keep the sulfur and selenium ledgers balanced and the cell lives; let them fail and it dies by ferroptosis or apoptosis.

Lessons for researchers

Seven prompts, averaging about fifteen words each, produced this chain. The short prompts worked because each one did a specific job.

1. **Anchor in the consensus.** Start from reviews and textbook material. You cannot recognize a surprise without knowing what is expected.
2. **Change the level of description.** Ask a protein question in the language of atoms, or a chemistry question in the language of genes. That forces a reorganization, and reorganization is where links appear.
3. **Go wide with a complete list.** Hand over a whole table and ask for every row to be classified. Exhaustive sorting shows both the strong cases and what the table leaves out.
4. **Overstate on purpose, then listen.** Push a claim until it breaks. The pushback tells you where the edges are and what a reviewer will say.
5. **Dig where things connect.** After a wide pass, pick the one item that touches a bigger system (here, a gene's neighbors) and go straight down.

6. **Trust your own memory.** The richest vein came from a fact I carried in from outside the conversation. The AI supplies breadth; the human supplies the hunch about where to dig.
7. **Reframe through a field you know.** An analogy from engineering or accounting can reorganize a whole finding and tell you what to measure next.
8. **Keep the loose threads.** A one-line nuance in Step 2 (selenium in GPX4) became the center of Step 6. Note the asides; they are often the next vein.

The division of labor is the whole method. The AI lays out the territory quickly and corrects overreach. The human decides where to dig.

Honest caveats and open questions

[E] No live web search was run during the session. The inputs were my eight clippings: Wikipedia's functional-group table, search-engine AI summaries, and the Youle and Strasser abstract. The AI's answers drew on its knowledge of the published literature. That was enough to build the chain, but not enough to publish it as fact; each claim below should be checked against a primary source.

[O] Does cysteine-free BAX still form pores? This supports “not a master mechanism.”

[O] Is TOM22 a receptor that targets BAX to mitochondria? The evidence is mixed.

[O] Does Met80 oxidation to a sulfoxide switch on cytochrome c's peroxidase activity?

[O] Is the TOMM40 '523 repeat an Alzheimer's marker independent of APOE? This is disputed.

[O] Do cancer cells depend on LRP8 for selenium, and undergo ferroptosis when it is lost?

[O] Concentration figures: glutathione 1–10 mM, free cysteine ~0.1 mM, and the GSH:GSSG ratios.

[O] Selenium intake figures (~55 µg/day needed, ~400 µg/day upper limit): check current guidance.

[O] The AI's pushback in Steps 3 and 6 is itself a claim, not a verdict, and deserves the same verification as everything else.

Reading ART: A Breaking-News Primer on a New CRISPR-Like Enzyme System

Dr. John Allen Berger, PhD

PP-2026-ART-01 v2 | 25 September 2026 | Licensed under CC BY-NC-ND 4.0.

Color Key

Color	Element	Base	Where it appears in this paper
	Hydrogen	Adenine	Ribose 3′-hydrogen abstracted by the thiyl radical; the 5′-deoxyadenosyl radical in radical-SAM chemistry (Part III).
	Carbon	Cytosine	The three carbons ligated to sulfur in S-adenosylmethionine's sulfonium center (Part III).
	Nitrogen	Guanine	The internal guanosine residue that primes retron msDNA synthesis (Part I).
	Oxygen	Hypoxanthine	The diiron-oxo/tyrosyl cofactor of Class Ia RNR; oxidative phosphorylation (Part II).
	Phosphorus	Uracil	The phosphodiester backbone (Part I); phosphorylation in Part II's oxidative-phosphorylation discussion.
	Sulfur	Thymine	The paper's main thread — thiol, disulfide, persulfide, sulfonium, and iron-sulfur clusters (Parts II–III).
	Selenium	Xanthine	Not referenced in this paper.
	Magnesium	Orotate	Not referenced in this paper.

House rule: color is a pale field behind the word, never colored type. Iron carries no key row and prints uncolored; a compound such as an iron-sulfur cluster therefore prints as its sulfur alone.

Part I — Molecular

The system, its parts, and its family

[E] On 24 September 2026, Anthropic announced that its Claude models had identified a previously uncharacterized enzyme system during an autonomous bioinformatic screen of bacteriophage genomes. Roughly 950 Claude agent instances ran in parallel for about 21 hours, consuming approximately 210 million tokens, to scan more than 200,000 candidate reverse transcriptase sequences drawn from public genomic databases. The screen narrowed that field to 3,500 promising systems, produced detailed reports on the twenty strongest candidates, and flagged one standout. Human scientists in Anthropic's own laboratory then confirmed the finding by hand.

[E] The standout has been named ART — Array-associated Reverse Transcriptase. It is built from three parts encoded next to one another in the phage genome: a reverse transcriptase drawn from a jumbo phage, a partner gene of unidentified function sitting beside it, and a long array of evenly spaced DNA repeats, written into the same phosphodiester backbone as the rest of the genome, that resembles a CRISPR array

in layout. Preliminary work indicates that array is transcribed into a set of distinct short RNAs — the same programmable logic a CRISPR array uses to generate its own guide sequences.

[F] Anthropic has stated plainly that ART's function inside the cell is not yet known. Its structure resembles CRISPR's, but nothing published so far demonstrates that it cuts, edits, or programs DNA the way CRISPR-Cas systems do.

[E] Reverse transcriptase belongs to a much older lineage: the “palm domain” catalytic fold shared by RT, DNA polymerases, RNA polymerases, and telomerase. The long-standing reading of that fold's phylogeny treats it as a molecular fossil of the era when every polymerase necessarily copied RNA onto RNA, because no DNA template yet existed to copy from. Telomerase — the enzyme that extends chromosome ends in ordinary human cells — is usually cited as the clearest living relic of that transition still running inside a modern nucleus.

[E] That same broad reverse-transcriptase lineage also produced group II introns, self-splicing bacterial elements that encode their own mobilizing RT; retrons, which pair an RT with an accessory protein and a templating noncoding RNA to build a branched DNA/RNA molecule (msDNA) used in bacterial antiviral defense; diversity-generating retroelements (DGRs), which use error-prone reverse transcription to hypervary a target gene; and the recently described defense-associated reverse transcriptases (DRTs) — ribonucleoprotein complexes built from an RT and a structured noncoding RNA that activate during phage infection.

[E] Retrons illustrate the underlying chemistry well. Their reverse transcriptase primes DNA synthesis directly off the 2′-hydroxyl on one specific internal guanosine residue of the template RNA, producing a branched RNA/DNA molecule linked at that single ribose position. It is the same class of reaction — a ribose hydroxyl acting as the nucleophile — that shows up elsewhere in RNA-catalyzed chemistry, including at the ribosome's peptidyl transferase center.

[F] ART's own layout — reverse transcriptase, adjacent partner gene, adjacent repeat array read out as short RNAs — matches the retron/DGR/DRT pattern far more closely than it matches the pattern eukaryotic non-LTR retrotransposons use. LINE-1's reverse transcriptase, carried in its ORF2 protein, is not encoded next to the element it mobilizes; it acts entirely in trans.

[E] LINE-1's ORF2 protein is exactly the enzyme that mobilizes Alu elements — short, non-autonomous, non-coding SINEs derived from the 7SL signal-recognition-particle RNA gene — throughout the human genome. An Alu element carries no reverse transcriptase of its own. LINE-1's endonuclease nicks genomic DNA at a target site, and the exposed 3′-hydroxyl primes reverse transcription directly off the Alu RNA, a mechanism called target-primed reverse transcription (TPRT).

[O] The open, testable question is which side of that architecture ART's repeat array falls on. If the array functions as a guide — read out and used, but not itself propagated — ART is closest kin to CRISPR, retrons, and DRTs: a defense system. If the array turns out to be self-templating, copied and reinserted the way group II introns and LINE elements copy themselves, ART sits structurally closer to a SINE/LINE pair such as Alu and L1 — array as cargo, reverse transcriptase as the engine that moves it. Anthropic's own phylogenetic placement work, described as ongoing, is what will answer this.

Part II — Cellular

Where the relevant chemistry actually happens in the cell

[F] Two separately ancient inventions had to exist, at roughly the same evolutionary moment, before a DNA-and-protein cell of the modern kind could work at all: a way to build deoxyribonucleotides, and a way to copy them into a templated polymer. Both are routinely discussed under the heading of the "RNA-to-DNA transition." They are not, however, the same enzyme lineage, and it is worth being precise about that rather than treating them as one story.

[E] Ribonucleotide reductase — RNR — is the only known chemistry that converts a ribonucleotide into a deoxyribonucleotide. Because nothing with a DNA genome can exist without that conversion, RNR is frequently treated in the origin-of-life literature as one of the oldest enzyme functions still running, plausibly present before the last universal common ancestor. Three structurally distinct RNR classes exist, each with its own metal cofactor, and all three converge on the same underlying strategy: generate a stable radical and relay it to the site where the bond is actually broken.

[F] Reverse transcriptase and RNR are not fold relatives. RNR's chemistry runs on an iron-centered, radical-based mechanism structurally unrelated to the RT/DNA-polymerase palm fold responsible for templated nucleotide addition. The two enzymes are contemporaries — both had to evolve for a DNA-based genome to become viable — but neither descends from the other, and there is no established common ancestral gene linking them.

[E] In human cells, RNR itself sits in the cytosol, supplying deoxyribonucleotides to nuclear DNA replication. Mitochondrial DNA draws most of its precursors from local salvage-pathway kinases (TK2, DGUOK) rather than from de novo reduction performed inside the organelle.

[E] What is genuinely mitochondrial is iron-sulfur cluster biogenesis. The ISC pathway — a cysteine desulfurase, a scaffold protein, frataxin, and ferredoxin — assembles iron-sulfur clusters inside the mitochondrial matrix, then exports a sulfur-carrying precursor to the cytosolic CIA pathway, which finishes building clusters for use elsewhere in the cell. That includes several enzymes involved in nuclear DNA replication and repair, and, in organisms carrying the anaerobic (Class III) form of RNR, the radical-SAM enzyme that activates it.

[E] That same mitochondrial cluster factory also supplies Complexes I, II, and III of the electron transport chain, which together carry on the order of a dozen iron-sulfur clusters.

[F] Oxidative phosphorylation is therefore a major client of mitochondrial sulfur-cluster biogenesis, drawing on the same factory that supplies certain genome-maintenance enzymes elsewhere in the cell. It is not, however, the pathway that runs RNR's own radical chemistry. The connective tissue between the two is the cluster factory itself, not a direct mechanistic link between the electron transport chain and deoxyribonucleotide synthesis.

Part III — Atomic

The eighteen sulfur functional groups, and which two are doing the work

[E] Organic sulfur chemistry is conventionally organized into eighteen functional-group classes: thiol, sulfide, disulfide, sulfoxide, sulfone, sulfinic acid, sulfonic acid, sulfonate ester, thiocyanate, isothiocyanate, thioketone, thial, thiocarboxylic S-acid, carbothioic O-acid, thiolester, thionoester, dithiocarboxylic acid, and dithiocarboxylic ester.

[F] Of those eighteen, exactly two are doing any of the work described in this paper. The thiol — the cysteine side chain — does double duty: its thiyl radical form is what abstracts the ribose 3′-hydrogen in RNR catalysis, and its deprotonated thiolate form is the actual ligand chemistry of an iron-sulfur cluster, donating the sulfur that coordinates each iron. The disulfide is the regeneration step: the two active-site cysteines end up bonded to each other after each turnover and have to be reduced back to free thiols by thioredoxin or glutaredoxin before the enzyme can run again.

[E] None of the other sixteen classes — sulfoxide, sulfone, the sulfinic acid/sulfonic acid family, thiocyanate and isothiocyanate, the thioketone/thial pair, or the thiolester and dithio-ester groups — appear anywhere in this mechanism.

[E] Two further sulfur species sit outside that eighteen-entry list entirely, because the list is organized around carbon-substituted sulfur rather than sulfur–sulfur or sulfur–metal centers. A persulfide — a cysteine carrying one extra terminal sulfur, written as a hydrodisulfide — is the actual sulfur-donor intermediate cysteine desulfurase builds on its own active site before handing that sulfur to the cluster-assembly scaffold. And the sulfonium center in S-adenosylmethionine — sulfur bonded to three separate carbons and carrying a positive charge — is the group a reduced iron-sulfur cluster attacks and homolytically cleaves in radical-SAM enzymes, the reaction that produces the 5′-deoxyadenosyl radical driving the anaerobic form of RNR.

[F] House convention in this paper carries no color for iron, which has no key row; a compound such as an iron-sulfur cluster therefore prints as its sulfur alone.

Part IV — Protocol

How this gets tested, and what would falsify each candidate function

[F] None of this needs to stay a mystery indefinitely. Every candidate function raised in Parts I through III is falsifiable with the same general toolkit that has already characterized other recently discovered CRISPR-adjacent systems — TnpB, IscB, Fanzor, retrons, and the DRTs ART most closely resembles architecturally. What follows is this author's own projection of how that playbook would likely be run on ART specifically, not a protocol Anthropic has announced.

[E] Comparative genomics comes first, because it is cheap and fast: survey how widely ART is distributed across sequenced phage and prophage genomes, whether its presence correlates with known phage-defense hotspots (“defense islands”) in host bacterial genomes, and whether hosts carrying ART show any measurable difference in phage susceptibility in existing metagenomic datasets.

[E] Structure prediction follows immediately, using AlphaFold-class modeling on the reverse transcriptase and the partner protein together. The question that matters most here is whether the partner protein's predicted fold contains a recognizable nuclease domain (an HNH, RuvC, or PD-(D/E)XK motif, the signature of a

CRISPR-style effector) or lacks one entirely, which would argue against a cut-and-edit function.

[E] In vitro reconstitution comes next: express the RT and partner protein, supply the repeat-array RNA, and test directly whether the complex reverse-transcribes the array into DNA, and separately whether it binds or cleaves a DNA target complementary to one of the short RNAs. This one experiment can distinguish ‘programmable nuclease’ behavior from ‘self-templating’ behavior in a test tube, before any cells are involved.

[E] Two in vivo assays then run in parallel, because they test mutually exclusive hypotheses. A phage-challenge assay expresses the ART locus in a host that naturally lacks it and measures whether it lowers plaquing efficiency — the standard test used to confirm retrons, CBASS, and DRTs as genuine antiviral defense systems. A retrotransposition-reporter assay does the opposite: it places a marker gene, interrupted so that it only lights up after a full copy-and-reinsert cycle, inside the repeat array itself — the same assay design used to prove that L1 elements truly retrotranspose. A positive result in the first assay paired with a negative in the second would argue for CRISPR's cousin; the reverse would argue for Alu's.

[E] A catalytically dead point mutant of the reverse transcriptase's active site, run through whichever assay produces a phenotype, establishes whether RT activity is actually required for that phenotype, or whether the partner protein is doing the real work on its own.

The Null Hypotheses

[F] Four null hypotheses fall out of the protocol above, one per candidate model. A careful test is built to reject or fail to reject each independently, rather than treating ‘ART does something’ as a single testable claim.

[E] H0 (defense): expressing ART in a naive host produces no reduction in phage plaquing efficiency relative to a host without it — no antiviral phenotype.

[E] H0 (mobility): the retrotransposition reporter shows no activation above assay background over extended passaging — no evidence the array copies and reinserts itself.

[E] H0 (RT-essential): the catalytically dead RT mutant produces the same outcome as wild type — RT activity is dispensable for whatever effect is observed, which would point to the partner protein as the actual functional unit.

[E] H0 (vestigial): none of the above phenotypes appear under any tested condition — ART is a structurally striking but functionally inert relict, the phage-genome equivalent of a pseudogene. This is the least glamorous outcome, and for that exact reason it is the one worth ruling out first rather than last.

[F] Rejecting H0 (vestigial) is the actual first hurdle. A structure that merely resembles CRISPR is not evidence of function on its own — the field has learned that lesson before, from repeat-associated systems that turned out to be inert. Everything else in this section only becomes interesting once that first null is rejected.

Part V — Impact

Where this could reach into gene and epigenetic editing, intended or not

[F] Assume, for the sake of this section, that ART turns out to do something. Its downstream reach into gene and epigenetic editing depends entirely on which candidate function wins, and the possibilities pull in genuinely different directions depending on the outcome.

[O] If ART resolves toward the CRISPR-cousin outcome — a programmable, RNA-guided effector — its main value would likely be size and simplicity rather than novelty of concept. The field's actual bottleneck for in vivo human gene editing is delivery, not cutting: compact effectors like TnpB and Fanzor became interesting specifically because they fit inside an AAV vector where Cas9 does not. An ART-derived effector, if one exists, would be judged on the same terms.

[O] If ART resolves toward the Alu-cousin outcome — a self-templating retroelement — the more interesting opportunity may not be in editing at all, but in reverse transcriptase engineering. Prime editing's practical limits are set largely by the processivity and fidelity of the reverse transcriptase it borrows from Moloney murine leukemia virus. A naturally evolved, phage-derived RT with different processivity or fidelity characteristics would be directly relevant to that bottleneck, independent of anything ART's own array turns out to do.

[O] If ART's short RNAs turn out to fold or process differently from a standard CRISPR crRNA, that scaffold itself could matter for epigenetic editing, where a dCas9- or dCas12-based effector's guide RNA needs to stay stably bound at a target locus for much longer than a cutting guide does. A more stable, naturally evolved scaffold would be a genuine, if incidental, contribution.

[O] If ART behaves more like a retron or a DRT — an antiviral system that disables an infected cell rather than editing its genome — its more likely relevance is to biocontainment and synthetic-biology kill-switch design, not to editing at all. Its partner protein of unknown function is the most likely candidate for the actual toxin or effector in that scenario, the same role proteins like CapV play in CBASS systems.

[F] The genuinely uncomfortable possibility, and the reason this section is titled ‘intended or not,’ is that any RT capable of copying and reinserting DNA in a genome is, by definition, capable of heritable change wherever it operates — that is exactly what Alu and L1 already do in every human genome, continuously, without anyone's authorization. A phage-derived system with the same capacity, if it is ever adapted for a laboratory or therapeutic context, would inherit that same germline-relevant concern before a single edit is designed on purpose. That is a regulatory and biosafety conversation, not just a technical one, and it starts well before ART's function is confirmed.

[F] None of this requires ART to be revolutionary to be worth tracking. Even the least glamorous outcome — a structurally interesting but functionally inert element — would recalibrate how much confidence the field places in CRISPR-like architecture as a predictor of CRISPR-like function, at a moment when AI-driven screens are about to make that kind of structural pattern-matching far more common. The follow-up game plan is simple: watch for Anthropic's phylogenetic placement of ART's RT domain, watch for a wet-lab phage-challenge result, and watch for a retrotransposition-reporter result. Any one of those three, on its own, would answer most of what this paper has had to leave open.

The Uncertain Glyph

A Curatorial Gap in Reactome's Spliceosome Assembly Pathway, the ATP-Driven Mechanism Behind It, the Purine Branch Point at IMP, and a Method Extended to the ADAR1 mRNA-Editing Editosome

Dr. John Allen Berger, PhD
PP-2026-SPLICE-01 v2 · Licensed under CC BY-NC-ND 4.0.

Color Key

Color	Element	Base	Where it appears in this paper
	Hydrogen	Adenine	ATP / AMP / ADP; adenine, adenosine — Parts II, III & V (adenosine, ADAR1's edited base)
	Carbon	Cytosine	Background element (C6 base) — not separately referenced
	Nitrogen	Guanine	GMP, guanine — Part III
	Oxygen	Hypoxanthine	IMP, inosine, hypoxanthine — Part III; inosine as ADAR1's edited product — Part V
	Phosphorus	Uracil	Not referenced in this paper
	Sulfur	Thymine	Not referenced in this paper
	Selenium	Xanthine	XMP, xanthine — Part III
	Magnesium	Orotate	Not referenced in this paper

Database, Mechanism, Context, Method, and mRNA Editing — in that order.

Part I — Database: The Uncertain Glyph

[E] Across Reactome's canonical human spliceosome-assembly pathway (R-HSA-72203, “Processing of Capped Intron-Containing Pre-mRNA”), every complex-to-complex transition in the core catalytic cycle carries the database's “Uncertain” reaction glyph — A complex to Pre-B, Pre-B to B, B to B^{act}, B^{act} to C, and the Intron Lariat Spliceosome step feeding into P complex. That is not a gap in one corner of the pathway; it is the entire assembly-to-catalysis arc, A complex through P complex, every step flagged the same way.

[E] What is not uncertain is the cast of characters at each junction: SRRM1, ALYREF and DDX39B feeding the U4/U6.U5 tri-snRNP into Pre-B; the DDX23/SNRNP27/SART1/USP39 cluster and the PRP19–CDC5L complex, alongside PPIL1, CCDC12, PPIL3, CWC22, PPIL2, CWC27, RNF113A, DHX16 and GPKOW, building B; UPF3B, DHX38, SYF2, PPIG, PPWD1, CASC3 and the Magoh–Y14 pair driving B^{act}; PRPF18, STEEP1, DHX8, CACTIN, FAM50A, SDE2, DDX41,

PRKRIP1, FAM32A and hSLU7 pushing into C; GCFC2, CWF19L2, DHX15 and TFIP11 dismantling the intron lariat spliceosome into P.

Sourcing note: this gene list was transcribed from the author's own Reactome screenshots, not independently re-pulled from the live diagrams. Verify symbol spelling and placement against R-HSA-72203 directly before this list is treated as final.

[F] Reactome, in other words, has curated with extraordinary precision who is present at every stage of splicing — and marked every door between the stages "uncertain."

[F] "Uncertain" here is not a claim that biochemistry doesn't understand splicing — cryo-EM structures exist for most of these complexes, and the DEAH-box ATPases threaded through this list are well-characterized as the motors driving each transition via ATP hydrolysis. What the glyph flags is narrower: within Reactome's own event model, the reaction type linking one fully-curated complex to the next hasn't been assigned to one of the database's defined mechanistic categories (association, dissociation, omitted process, transition). It is a completeness flag on one database's formal annotation layer, not a statement about the state of the science.

Part II — Mechanism: ATP and the DEAH-box Relay

[E] The reaction at each flagged transition is ATP hydrolysis, not RNA base chemistry: a DEAH-box ATPase burns ATP to ADP and inorganic phosphate to physically remodel the spliceosome. DHX16 (Prp2) acts at the B complex step; DHX38 (Prp16) at B^{act}; DHX8 (Prp22) near the C complex step; DHX15 (Prp43), with cofactor TFIP11, at the ILS-to-P step.

[E] DHX35, with cofactor GPATCH1, plays a distinct proofreading role — rejecting aberrant splicing substrates rather than driving forward progress — resolved structurally in Chen et al., *Cell Research* 2025 (PMID 40016598).

[F] The chemical entity doing the work at every uncertain gap in this pathway is ATP, spent by a rotating cast of closely related helicases performing distinct jobs, not a variation in which RNA base is present.

Part III — Context: IMP and the Purine Branch Point

[E] IMP (inosine monophosphate) is the first complete purine nucleotide built by de novo synthesis — a ten-step pathway on a PRPP scaffold — and serves as the branch point to both AMP (via adenylosuccinate synthetase/lyase) and GMP (via IMP dehydrogenase and GMP synthetase, through XMP). This is standard, conserved biochemistry (see, e.g., Nelson & Cox, *Lehninger Principles of Biochemistry*).

[O, explicitly closed] IMP/inosine has no established role in the spliceosome's uncertain transitions; that mechanism is ATP and the DEAH-box helicases (Part II). The link between IMP's base (hypoxanthine) and this paper's own color-key convention is a naming coincidence worth noting, not a biological finding — it connects the author's house style to a real fact about purine metabolism, not to the spliceosome gap.

Part IV — Method: From Speculation to Verification

Parts I through III were built by a process worth making explicit, because the process is the more reusable result. The exchange behind this paper began far more speculatively than it ended, and the steps that narrowed it are a teaching case in their own right.

Step 1 — Pattern versus mechanism. The starting proposal linked octonion algebra (an eight-dimensional number system), nuclear magic numbers, a claimed count of small-RNA species, and the visible light spectrum through a shared numeral, eight. Checked individually, none of these domains supplied a mechanism connecting it to any other — no published mapping from octonion multiplication to ribonucleotide chemistry, no privileged status for eight in nuclear shell structure, no canonical eight-species count in small-RNA taxonomy. The parallel was real as an observation and unsupported as a causal claim. Holding those two facts apart — real pattern, unproven mechanism — is the method's first move: an [O] tag, not an [E] one.

Step 2 — Redirecting to a domain with mechanistic substance. Ribonucleotide reductase and the RNA World hypothesis offered what the octonion material didn't: a documented biochemical mechanism (proton-coupled electron transfer, radical relay chemistry) connecting an ancient enzyme to the RNA-to-DNA transition. Distinguishing this enzyme family carefully from reverse transcriptase — a different protein family entirely, despite both acting on nucleic acids — caught an error before it propagated into a larger claim.

Step 3 — Verifying a claimed current event against primary sources. A reference to a recent enzyme-discovery announcement required checking publication dates against the working knowledge cutoff, then reading the original announcement and the original quotes rather than a secondhand paraphrase. A first citation used to characterize the discovery's reception turned out to be an unvetted source; it was replaced with a named, credentialed academic commentary making the same substantive point — upgrading a citation rather than defending a weak one.

Step 4 — Applying the same standard to a database claim. A question about symbols in a pathway-diagram screenshot was answered by locating Reactome's own published glyph specification, rather than inferring a meaning from context.

Step 5 — Finding a real pattern, then bounding its meaning. Checking the full spliceosome assembly pathway showed every complex-to-complex transition carrying the “Uncertain” glyph — a genuine, specific, checkable finding. The necessary next move was distinguishing what that finding does and doesn't show: a gap in one database's formal reaction-type annotation, not a gap in structural biology's actual knowledge of the spliceosome, which is independently well-documented by cryo-EM. Reporting the finding without that boundary would have reproduced the error in Step 1, dressed in real data instead of numerology.

Step 6 — Refusing to over-extend a real finding. When the same finding was generalized — to all Reactome pathways, to a causal claim about AI-assisted drug-design errors — the honest response was to name a concrete counterexample (a different Reactome pathway that isn't flagged uncertain) and decline the

causal claim as unsupported, while keeping the narrower finding intact.

Step 7 — Extending the method to a harder case with no built-in answer. The ADAR1 editosome has no equivalent Reactome pathway to read a glyph from at all — Reactome models it only as a standalone complex, with no assembly pathway behind it. That absence removes the shortcut the spliceosome case had. Part V is built directly from primary literature instead, tiered the same way, precisely because there is no glyph to lean on.

Part V — mRNA Editing: The ADAR1 Editosome Gap

[E] ADAR1 exists as two isoforms from the same gene: p150, interferon-inducible and predominantly cytoplasmic, and p110, constitutively expressed and localized mainly to the nucleolus. Both share a core deaminase catalytic domain and three double-stranded RNA-binding domains (dsRBD1–3); p150 additionally carries an N-terminal Zα domain that p110 lacks.

[E] The reaction ADAR1 performs is A-to-I mRNA editing: hydrolytic deamination of adenosine to inosine within double-stranded RNA, most often in noncoding, Alu-derived structures in introns and untranslated regions. This is a distinct enzymatic system from the A-to-I editing that produces wobble-position inosine at position 34 of certain tRNA anticodons: tRNA wobble editing is carried out by the ADAT enzyme family (ADAT1 acting at the wobble position itself; the ADAT2/ADAT3 heterodimer acting at other anticodon positions), not by ADAR1. Both processes deaminate adenosine to inosine and share the same underlying chemistry, but they act on different RNA substrates, by different enzyme families, for different biological purposes — decoding flexibility at the ribosome for tRNA wobble editing, versus recoding and self/non-self immune discrimination for ADAR1 mRNA editing.

[E] Isoform-specific localization is signal-driven: p110's nuclear/nucleolar retention is mediated by a nuclear localization signal within dsRBD3, while p150's cytoplasmic distribution, including recruitment to stress granules under oxidative stress, is mediated through its Zα domain, which also carries a nuclear export signal.

[E] The Zα domain binds left-handed Z-DNA/Z-RNA structures, including those formed by inverted Alu repeats, directing p150 to edit these elements and suppressing MDA5-triggered interferon signaling against the cell's own RNA; loss-of-function mutations in this domain cause Aicardi–Goutières syndrome type 6, a genetic inflammatory disease — direct clinical evidence for the domain's role (Rice et al., *Nature Genetics*, 2012).

[E] ADAR1 homodimerizes through dsRBD3, not through Zα or Zβ, across a roughly 1,150-square-angstrom symmetric interface on the domain's β-sheet face — the face opposite its RNA-contact surface, so a dimer's two dsRBD3 copies can each still engage a separate RNA duplex. Disrupting this interface does not abolish editing broadly; it changes editing efficiency at specific sites while leaving others unaffected (*Nature Communications*, 2024).

[F] Assembled into a stepwise picture — the author's synthesis, not a single citable source — isoform identity and its localization signal place the enzyme in a compartment (cytoplasm/stress granule for p150,

nucleus/nucleolus for p110); the Zα domain (p150) or intrinsic dsRBD affinity (p110) then targets a dsRNA structure, often Alu-derived; the dsRBDs engage the duplex; dsRBD3-mediated dimerization brings two catalytic units into proximity without excluding either monomer's own RNA contact; and the deaminase domain carries out the hydrolytic deamination of adenosine to inosine.

[O] Unresolved in the literature reviewed here: the order of operations between dimerization and substrate binding (whether one nucleates the other), and whether ADAR1 requires any obligate protein partner analogous to A1CF in the APOBEC-1 system — the evidence surveyed shows ADAR1 acting as a self-dimer directly on RNA, without a documented second-protein requirement, though this was not an exhaustive search for minor cofactors.

[F] This is the gap Part I's method predicts. Reactome's "Formation of the Editosome" pathway (R-HSA-75094) fully models the APOBEC-1/A1CF system as three explicit reactions: RNA stem-loop formation, A1CF binding, APOBEC-1 binding. ADAR1 has no equivalent build-up pathway — only the finished "A to I edited RNA:Editosome (ADAR1) complex" as a standalone entity. What the literature above supplies, and what a Reactome curator would need to formalize an equivalent pathway, is a comparable reaction sequence: isoform-dependent localization and targeting, dimerization, then catalysis — structurally parallel to the APOBEC-1/A1CF sequence, but with an isoform-selection step that system doesn't have.

This sequence is a literature synthesis, not an official Reactome pathway. Any citation of it should point to the primary papers in the References below, not to Reactome, since Reactome has not curated this pathway.

Author's Note on Sourcing and Confidence

Paragraphs tagged [E] draw directly on primary sources (Reactome's own pages and documentation, or a specific cited paper) and are held with high confidence. Paragraphs tagged [F] are the author's interpretive synthesis built on those [E] claims — reasonable, but not themselves a citable statement from any single source. Paragraphs tagged [O] mark a question left open or, in one case, explicitly considered and closed: no link was found, and none is claimed. Two items carry an additional sourcing note: the Part I gene list transcribed from screenshots should be checked against the live Reactome diagram, and the Part V assembly sequence is this author's synthesis of primary literature, not a Reactome-curated pathway, and should be cited accordingly.

COMPANION TO THE PAPER OUTLINE

The Eight Ladders

Base, nucleoside, mono-, di- and triphosphate for IXGA and UOCT, sorted from the volume

PP-2026-LADDERS-01 v1 · August 2026

Base, nucleoside, monophosphate, diphosphate, triphosphate — for IXGA and UOCT, sorted from the 1,081-page volume

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Every one of the eight symbols was traced through all five phosphorylation levels across eight hundred and eighty-six sections. Four families climb the ladder to the triphosphate and stay there. Four do not — and each of the four is stopped by a different mechanism, every one of them named, characterized, and already in this volume.

1. The Finding the Sort Produced

Four ladders complete. Four are cut.

A adenine -> adenosine -> AMP -> ADP -> ATP COMPLETE\nG guanine -> guanosine -> GMP -> GDP -> GTP COMPLETE\nC cytosine -> cytidine -> CMP -> CDP -> CTP COMPLETE\nU uracil -> uridine -> UMP -> UDP -> UTP COMPLETE\nI hypoxanthine-> inosine -> IMP -> IDP -> ITP CUT at the triphosphate\nX xanthine -> xanthosine -> XMP -> XDP -> XTP CUT at the triphosphate\nT thymine -> thymidine ->

dTMP -> dTDP -> dTTP DEOXY ONLY\nO orotate -> orotidine -> OMP -> ---- -> ----
TERMINATES at the monophosphate

The four families that complete the ladder without interference are adenine, guanine, cytosine and uracil — exactly the canonical RNA alphabet. The four that are cut are exactly the four symbols this volume adds. Nothing was arranged to make that come out. It is what the phosphates do.

And the four cuts are four different mechanisms

symbol	where it stops	what stops it	volume sections
I	at the triphosphate	ITPA hydrolyzes ITP and dITP back to the monophosphate	24, 40, 48, 60, 64, 65, 454, 465, 653, 659
X	at the triphosphate	the same enzyme — ITPA also takes XTP and dXTP	24, 48, 60, 64, 65, 454–459
T	never enters the ribo series	thymidylate synthase builds dTMP from dUMP at the deoxy level only	18, 24, 31, 33, 39, 118, 442, 586, 590
O	at the monophosphate	OMP decarboxylase removes the carboxyl and the molecule becomes UMP	118, 119, 442, 444, 584, 586–588, 595, 596

The purine pair is held by one enzyme

ITPA hydrolyzes ITP, dITP, XTP and dXTP — the deaminated purine nucleoside triphosphates — back to the corresponding monophosphate, releasing pyrophosphate. One enzyme, both gates, and it does not distinguish ribose from deoxyribose.

Inosine and xanthine are not absent from the triphosphate pool because the cell cannot make them. It makes them and then destroys them, with a conserved, dedicated, essential enzyme. That is a far stronger statement than absence.

And the pyrimidine gate is held by one of the fastest enzymes known

OMP decarboxylase achieves a rate enhancement approaching 10^{17} and provides roughly 31 kcal per mole of transition-state stabilization. Orotate does not linger at

the monophosphate. It is converted to uracil faster than almost any other reaction in the cell.

Sections 801 and 802 of this volume already record the correction to the "most proficient enzyme" claim — UroD overtook it in 2008 — and that correction stands. The 10^{17} figure does not.

---

2. The Eight Ladders, with the Volume's Own Sections

I — the inosine family

level	species	mentions	volume sections
base	hypoxanthine	183	15, 16, 19, 24, 32, 36, 40, 41, 56, 64 …
nucleoside	inosine	828	3, 15, 16, 18, 19, 20, 22, 24, 30, 31 …
monophosphate	IMP	307	16, 17, 18, 24, 31, 33, 38, 39, 40, 41 …
monophosphate	inosine monophosphate	46	3, 16, 38, 41, 118, 191, 278, 298, 343, 355 …
diphosphate	IDP	22	40, 135, 141, 456, 463, 464, 649, 651, 652, 653 …
triphosphate	ITP	62	24, 40, 48, 60, 64, 65, 141, 454, 455, 456 …
deoxy-triphosphate	dITP	30	24, 48, 60, 454, 455, 459, 463, 563, 569, 570 …
the sanitizer	ITPA / ITPase	70	24, 40, 48, 60, 64, 65, 454, 465, 563, 653, 659, 856, 860

828 mentions of inosine, 307 of IMP, and only 22 of IDP. The ladder is top-heavy at the monophosphate and thins immediately above it. That shape is the enzyme.

X — the xanthine family

level	species	mentions	volume sections
base	xanthine	400	8, 15, 16, 17, 19, 24, 32, 36, 38, 40 …
nucleoside	xanthosine	49	17, 40, 41, 65, 118, 137, 191, 279, 443, 451 …
monophosphate	XMP	115	16, 17, 18, 33, 39, 40, 41, 63, 64, 65 …
diphosphate	XDP	7	456, 463, 464, 651, 652, 661
triphosphate	XTP	24	24, 48, 60, 64, 65, 454–459 …
deoxy-triphosphate	dXTP	7	24, 48, 60, 563, 685, 856
the enzyme above	xanthine oxidase	14	8, 38, 40, 56, 103, 185, 186, 230

Seven mentions of XDP in eleven hundred pages. It is the thinnest rung on any of the eight ladders.

G — the guanine family

level	species	mentions	volume sections
base	guanine	331	3, 8, 15, 16, 17, 18, 19, 20, 30, 32 …
nucleoside	guanosine	100	16, 17, 30, 40, 41, 62, 64, 65, 66, 84 …
monophosphate	GMP	102	16, 17, 18, 33, 39, 40, 41, 63, 65, 117 …
diphosphate	GDP	15	135, 181, 277, 286, 463, 620, 622, 651, 652, 661 …
triphosphate	GTP	61	8, 18, 38, 39, 40, 41, 56, 65, 144, 454 …
deoxy-triphosphate	dGTP	5	144, 454, 455, 463, 685

A — the adenine family

level	species	mentions	volume sections
base	adenine	257	15, 16, 18, 19, 24, 30, 31, 32, 33, 35

level	species	mentions	volume sections
			…
nucleoside	adenosine	229	15, 16, 17, 24, 27, 30, 35, 36, 37, 38 …
monophosphate	AMP	112	16, 17, 18, 24, 33, 38, 39, 40, 41, 46 …
diphosphate	ADP	9	27, 135, 181, 277, 286, 685, 715
triphosphate	ATP	155	8, 16, 18, 27, 35, 36, 38, 39, 40, 41 …
deoxy-triphosphate	dATP	22	46, 65, 144, 183, 454, 455, 463, 651, 661, 685 …

Adenine is the only family whose triphosphate outnumbers its monophosphate. That is the energy currency showing up in the counts.

U — the uracil family

level	species	mentions	volume sections
base	uracil	162	6, 13, 15, 21, 24, 30, 31, 33, 40, 41 …
nucleoside	uridine	153	24, 30, 31, 33, 34, 38, 39, 40, 41, 54 …
monophosphate	UMP	53	18, 33, 39, 41, 65, 117, 118, 119, 132, 135 …
diphosphate	UDP	5	135, 181, 182, 554, 586
triphosphate	UTP	13	118, 144, 442, 444, 454, 463, 464, 613, 622, 651 …
deoxy-monophosphate	dUMP	11	31, 41, 48, 118, 442, 444, 586, 587, 590, 595

O — the orotate family

level	species	mentions	volume sections
precursor	dihydroorotate	24	118, 119, 124, 137, 138, 141, 143, 162, 164, 185 …

level	species	mentions	volume sections
base	orotate	131	117, 118, 119, 120, 124, 125, 131, 137, 138, 141 …
base	orotic acid	14	119, 146, 278, 588, 595, 801, 802, 808
nucleoside	orotidine	14	119, 137, 143, 191, 278, 587, 588, 594, 595, 596 …
monophosphate	OMP	46	118, 119, 442, 444, 584, 586, 587, 588, 595, 596 …
diphosphate	ODP	0	does not occur
triphosphate	OTP	0	does not occur

Zero and zero. Not thin — absent. The volume never mentions them because there is nothing to mention. Orotate is the only one of the eight whose ladder has no top three rungs at all.

C — the cytosine family

level	species	mentions	volume sections
base	cytosine	138	3, 15, 18, 19, 20, 21, 24, 30, 31, 32 …
nucleoside	cytidine	35	34, 41, 62, 132, 135, 183, 273, 278, 280, 328 …
monophosphate	CMP	16	18, 33, 39, 41, 65, 117, 132, 135, 683, 687
diphosphate	CDP	2	135, 181
triphosphate	CTP	17	118, 144, 442, 454, 463, 464, 586, 591, 595, 613 …
deoxy-triphosphate	dCTP	5	144, 454, 455, 651, 661

T — the thymine family

level	species	mentions	volume sections
base	thymine	117	6, 13, 15, 18, 21, 24, 31, 32, 33, 39 …
nucleoside	thymidine	18	18, 24, 31, 39, 132, 278, 823, 824, 825, 828 …

level	species	mentions	volume sections
ribo-monophosphate	TMP	4	117, 132
deoxy-monophosphate	dTMP	14	18, 24, 31, 33, 39, 118, 442, 586, 590
ribo-diphosphate	TDP	0	does not occur
ribo-triphosphate	TTP	2	651, 661
deoxy-triphosphate	dTTP	3	144, 454, 455
the RNA exception	ribothymidine	10	823, 824, 825, 834

Thymine is the mirror image of orotate. Orotate is cut off above the monophosphate; thymine is cut off from the ribose series entirely and lives only on deoxyribose — with one exception, the ribothymidine at position 54 of nearly every transfer RNA, which Part Ninety-Nine records.

3. The Completeness Table

	base	nucleoside	MP	DP	TP	status
A	yes	yes	yes	yes	yes	complete
G	yes	yes	yes	yes	yes	complete
C	yes	yes	yes	yes	yes	complete
U	yes	yes	yes	yes	yes	complete
I	yes	yes	yes	yes	made, then destroyed	suppressed
X	yes	yes	yes	thin	made, then destroyed	suppressed
T	yes	yes	deoxy	deoxy	deoxy	deoxy only
O	yes	yes	yes	none	none	truncated

Four complete. Two suppressed by one enzyme. One restricted to a different sugar. One truncated outright.

4. Sorted Into the Paper Outline

outline section	what the eight-ladder sort supplies
7 — the eight-symbol index	the completeness table above. It is the strongest available argument that the eight are an index and not an alphabet: half of them cannot hold a triphosphate, and a symbol that cannot be a triphosphate cannot be polymerized
3 — the rungs	the ladders themselves populate rungs 5, 6 and 7 with named species and section numbers
6 — the junction	ITPA, thymidylate synthase and OMP decarboxylase are all atomic-molecular-junction enzymes, and all three are already in the volume
10 — falsification	four sharp kill conditions, one per cut ladder — see below

Falsification conditions this sort generates

the claim	what would kill it
ODP and OTP do not occur	detection of either in any organism
ITPA suppresses ITP, dITP, XTP and dXTP	an ITPA-null cell with unchanged inosine and xanthine triphosphate pools
thymine is deoxy-only	a ribo-TTP pool at metabolically meaningful concentration
the four complete ladders are exactly A, G, C, U	any fifth family shown to hold an unsuppressed triphosphate

5. What the Sort Shows is Missing

gap	what is needed
XDP	seven mentions, all in late sections. The diphosphate rung of the xanthine ladder is nearly unwritten
IDP	twenty-two mentions. Almost nothing on why the diphosphate exists at all if the triphosphate is destroyed
orotidine	fourteen mentions for a nucleoside that sits at the pyrimidine fork
quantitative pool sizes	every count above is a count of mentions in the book, not a concentration in a cell. The claim that I and X are suppressed needs measured pool sizes, and those are in the literature

That last row is the same gap the sulfur sort found. The inventory is complete; the numbers beside it are not in this volume.

---

6. What This Delivers

Eight families, forty species, four thousand two hundred and sixty-one mentions across eight hundred and eighty-six sections — and the result is a single table with four rows that say "complete" and four that say why not.

The canonical four are the four that can be polymerized. The added four are each blocked, by a different named enzyme, at a different rung. That is not an argument that the notation should have eight letters. It is an argument that the notation has four letters for a reason, and that the other four are doing something else — which is what an index is for.

Berger, J. A. (2026). The Eight Ladders. Companion document, NovagonDNA, PP-2026-LADDERS-01 v1.

Unification of Central Dogma Theory

A Geometric Frame for DNA, RNA, and Wobble tRNA

Molecular, translational, synthesis - in that order

PP-2026-CDU-01 v20 · 26 September 2026 · Dr. John Allen Berger, PhD · NovagonDNA

[F] No single link above is new: every element assignment, every pairing rule, every enzyme and every pathway is drawn from established molecular biology. What has not been shown before is this — the geometry, the color-to-element key, the letter-by-letter atom translation of every codon, the sulfur chemistry of the start codon's own amino acids, the purine synthesis that supplies both the genetic code's broadest-wobble base and the stop codons' proposed energy signal, and the natural and engineered editing tools that act on all of it, held together as one chain rather than as separate topics in separate textbooks. That is the scale of the synthesis this paper is offering: not a new experimental result at any one link, but a chain connecting links that established biology has, until now, never stated as connected.

Reading order. The three Parts of this paper run, in order, Molecular, Translational, and Synthesis. Those are not decorative labels; each one names a different kind of question the Part is answering, and it is worth spelling out what each word means in plain English before getting into the material itself, so that nothing about the structure of the argument has to be guessed at along the way.

Molecular (Part I) is the physical, structural half of the paper — the actual molecules involved, and the exact geometric shape that their pairing rules trace out. This is where the octahedron itself is introduced: a regular solid with eight faces, twelve edges, and six vertices, and the six vertices are where the six bases A, T, G, C, U, and I sit. Part I is concerned with what the pieces are and how they physically fit together — which base can bond to which other base, why the twelve edges of the shape correspond to twelve pairing relationships, and how those relationships sort into the three pairing groups (standard DNA pairing, RNA's G–C pairing, and inosine's wobble) whose counts add up to 22. Nothing in Part I is about a sequence of events unfolding over time — it is a snapshot of structure, the way a floor plan is a snapshot of a building rather than an account of how the building was put up.

Translational (Part II) shifts from structure to process — specifically, the process by which the genetic message gets converted into protein. “Translation” is the standard biological term for exactly this step: reading messenger RNA and using it to assemble a chain of amino acids, and Part II is built around the machinery that carries that out. This is where inosine's special role at position 34 of the tRNA anticodon is explained — the reason a single tRNA carrying inosine can recognize more than one codon, which is a major source of the genetic code's redundancy. It is also where the paper draws a firm line between two events that are easy to run together: aminoacyl-tRNA synthetase charging a tRNA with its amino acid (an ester bond, formed out in the cytoplasm) and the ribosome actually forming the peptide bond that joins that amino acid onto the growing chain (a separate chemical event entirely, carried out by the ribosome's own rRNA acting as a ribozyme, not by any protein enzyme). Part II, in short, is about how the structure laid out in Part I gets put to work.

Synthesis (Part III) carries two meanings at once, and the paper is using both of them on purpose. In its narrow biological sense, “protein synthesis” is simply the end product of translation — the finished chain of amino

acids that translation was building all along — and Part III is where that output is named and counted. But "synthesis" also carries its older, more general sense: the act of drawing separate strands of evidence or argument together into one coherent whole. Part III does that too. It is where the base-pairing counts worked out geometrically in Part I — eight, plus eight, plus six — are shown to land on exactly 22, and where that number is reconciled against the real biological count of proteinogenic amino acids by adding the two recoded exceptions, selenocysteine and pyrrolysine, onto the twenty canonical ones. Part III is therefore doing two jobs simultaneously: reporting an outcome (the amino acids that actually get built) and performing a reconciliation (the point where the geometry from Part I and the biology from Part II are shown to agree with one another).

Part IV, which follows all three, does not introduce a fourth category alongside Molecular, Translational, and Synthesis. It simply walks back through the same three stages — structure, process, outcome — a second time, more slowly and in far greater step-by-step detail, following the pathway all the way from the gene itself through transcription, mRNA processing, translation initiation, aminoacyl-tRNA synthetase charging, wobble recognition, peptide bond formation, elongation, and termination, so that a reader coming to this material for the first time is not left to assume or fill in any step on their own.

Color Key

color	element	base	where it appears in this paper
RED	hydrogen · H 1	adenine	Watson-Crick A–T / A–U pairing (Part I)
BLUE	carbon · C 6	cytosine	background element; G–C pairing (Part I)
GREEN	nitrogen · N 7	guanine	G–C, G–U, and G–I pairing (Part I)
ORANGE	oxygen · O 8	hypoxanthine	inosine's three-way wobble (Part II)
PURPLE	phosphorus · P 15	uracil	RNA backbone; U in A–U / G–U pairing (Parts I–II)
YELLOW	sulfur · S 16	thymine	sulfur-containing residues among the 20 canonical amino acids (Part III)
INDIGO	selenium · Se 34	xanthine, orotate	selenocysteine, the 21st amino acid (Part III)

Every row is active in this paper. Color is a pale field behind the word, never colored type, and it names an element and nothing else.

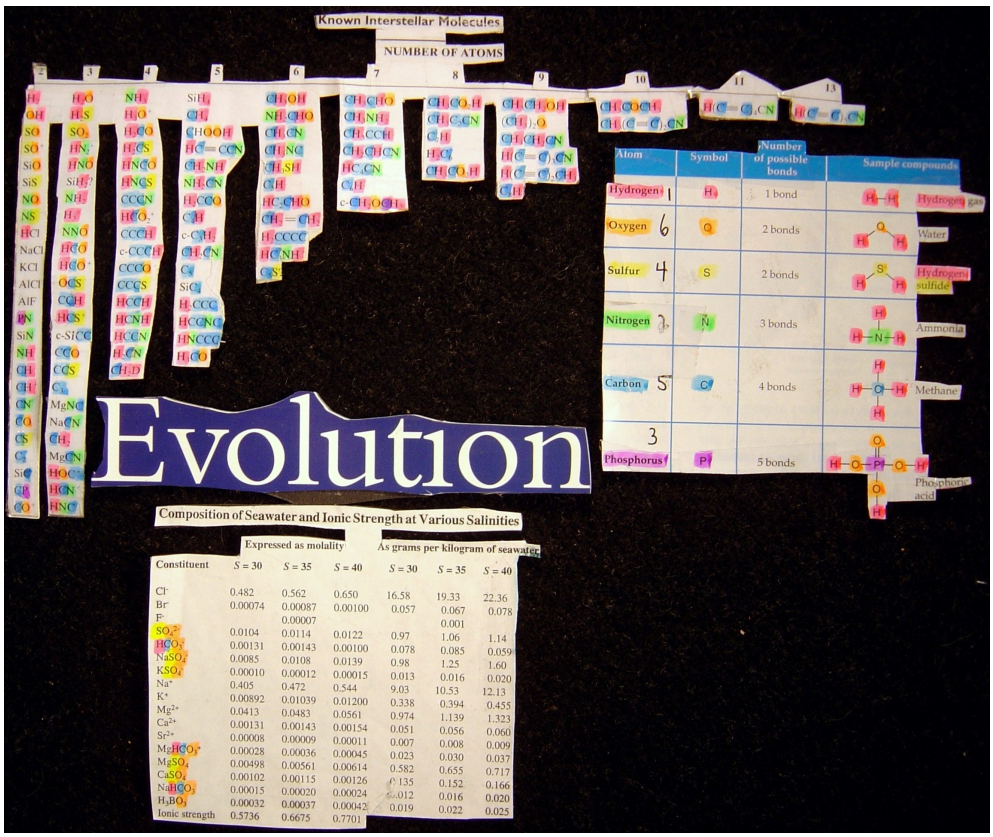

Figure 1. The six Color Key elements are not an arbitrary choice of six: hydrogen, oxygen, sulfur, nitrogen, carbon, and phosphorus are exactly the light, cosmically abundant elements whose ordinary bonding valence (1, 2, 2, 3, 4, and 5 bonds respectively) lets them build the base structures at all — the same handful of elements found across the known interstellar molecules and dissolved in seawater, source page from the author's own notes.

Abstract. A regular octahedron's 8 faces, 12 edges, and 6 vertices provide a single geometric frame for DNA base-pairing, RNA base-pairing, and tRNA wobble pairing, tying the transcriptional step (DNA → mRNA) to the translational step (mRNA → protein, via tRNA, aminoacyl-tRNA synthetase, and rRNA). The six vertices carry six bases (A, T, G, C, U, I); the twelve edges reduce to three pairing groups whose counts (8, 8, 6) sum to 22, matching the full set of proteinogenic amino acids once selenocysteine and pyrrolysine are counted alongside the twenty canonical ones. Inosine's three-way wobble (with A, C, and U) at tRNA position 34 accounts for much of the genetic code's redundancy; G–U wobble is a separate, second pairing at the same codon position. No prior model unifies the genetic code's octahedral geometry, its own color-to-atom translation of every base and codon, and the sulfur chemistry linking the RNA world's start codon to modern DNA replication and gene editing into one frame; that original synthesis, not new laboratory data, is this paper's contribution.

Paragraph tags. [E] established in the literature. [F] synthesized, reconciled, or argued here. [O] open question. All content is drawn from established molecular biology and a handwritten source page; no new experimental data is reported.

The Full Chain, Stated Once. Before Part I begins, the same claim this paper spells out section by section below is stated here once, end to end, so its full scale is visible before reading through all thirty sections one at a

time. Nothing in the list below is new on its own — every element assignment, every pairing rule, every enzyme and every pathway is drawn from established molecular biology, referenced here by the section that develops it in full. What is being shown for the first time is that these particular links connect into one chain at all.

1. **One geometric object carries three pairing systems.** A single regular octahedron (Part I) supplies the 8 + 8 + 6 = 22 count behind DNA pairing, RNA pairing, and tRNA wobble pairing at once — the same 22 that the amino acid count in Part III independently requires, before either count was compared to the other.
2. **Every base and pair gets one element, not a label.** The Color Key (page 1) does not decorate the six bases; it assigns each one a real element by atomic identity — adenine/hydrogen, cytosine/carbon, guanine/nitrogen, hypoxanthine/oxygen, uracil/phosphorus, thymine/sulfur — and Section 18 shows that hydrogen-bond count inside that key is a strength rule (3 for C–G, strict; 2 for A–U, wobble-tolerant), not bookkeeping.
3. **That element assignment turns every codon into an atom string.** Section 22 reads any codon letter for letter straight through the same key — AUG → HPN — so all 61 sense codons and all three stop codons translate into atomic-symbol strings by one fixed rule, not 64 separate lookups.
4. **The start codon's own amino acid carries the sulfur the codon atoms don't show.** Methionine's AUG translates to HPN with no sulfur in it, yet methionine is one of only two sulfur-bearing amino acids — its own side chain, not its codon, carrying the sulfur that becomes SAM, the methyl donor that finishes the mRNA guanine cap (Section 9) before Section 10's reading frame can begin.
5. **The same sulfur, in the second sulfur-bearing amino acid, builds the DNA it will be read into.** Cysteine's thiol supplies ribonucleotide reductase's thiyl radical, the reaction that turns RNA-type ribonucleotides into the deoxyribonucleotides Section 20's DNA → DNA replication runs on — the same sulfur chemistry that, as phosphorothioation, also stabilizes synthetic RNA and DNA against nuclease degradation (Section 22).
6. **The purine ring both ends of the pathway share is built, not copied, and inosine sits at its root.** De novo purine synthesis assembles adenine's and guanine's shared ring atom by atom into **IMP** — inosine monophosphate, the same base Section 18 already gives the broadest wobble tolerance of any base — before IMP branches to AMP or GMP (Section 22).
7. **The three stop codons translate into the same three molecules IMP branches toward.** Read through the identical atom key, UAA → PHH, UAG → PHN, and UGA → PNH (Section 21) carry two, one, and one hydrogen atoms respectively — read here as AMP, ADP, and ATP by hydrogen-bond count, the same purine-nucleotide family Section 22's de novo synthesis produces at the pathway's other end.
8. **That count is not arbitrary; it reproduces a hierarchy already known independently.** By Section 18's own strength rule, two hydrogen bonds is stricter than one — and UAA's two bonds track its being the one stop codon with no recoding exception anywhere in this paper, while UAG and UGA's one bond each track their being exactly the two stop codons recoded, to pyrrolysine and selenocysteine (Section 22), and the two most frequently reported to leak in the independent termination-efficiency literature (Section 21).

9 **The same particle is proposed to run both the start and the stop.** Section 19's open question about a hydrogen-bond proton tunneling inside a base pair, and Section 21's open question about a stop codon's hydrogen-count signaling ATP synthase — chemiosmotic ATP synthesis itself running on a hydrogen-ion gradient — are the same particle asked to do quantum-mechanical work at both ends of the chain, not two unrelated hypotheses that happen to share a word.

10 **Every one of the 22 amino acids inherits the same treatment at once.** Section 22 does not special-case methionine or cysteine; the identical codon-to-atom rule runs across all 22 amino acids and every codon that specifies them, alongside the independent hydrophobic/hydrophilic classification that governs protein folding (Part IV, Step 17) — two properties of the same table, computed by two unrelated rules, sitting side by side.

11 **The anticodon and tRNA structure obey the identical pairing and hydrogen-bond rules a second time.** Section 23's wobble position 34 and Section 18's codon pairing are the same rule read at the two ends of the same molecule; Section 24 then shows one deamination chemistry — adenine to hypoxanthine — underneath both natural wobble editing (ADAT) and human adenine base editors, and a second, mirror-image deamination underneath ADAR editing and cytosine base editors alike.

12 **Every failure mode and every fix run through the same links.** Section 25's mutation types and Section 26's disease mechanism describe specific ways this same chain breaks; Sections 27 and 28's gene and epigenetic editing are engineered insertions at specific links in it; Section 30's five small RNAs show the cell intervening at several of those same links on its own, by the same pairing rules, before any of it was engineered — one chain, failing, being repaired, and repairing itself, at named, specific points rather than in the abstract.

Part I. Molecular

1. The Octahedron Model

[E] A regular octahedron has 8 faces, 12 edges, and 6 vertices, satisfying Euler's formula (6 – 12 + 8 = 2). The model assigns the **6 vertices** to six bases: A, T, G, C, U, and I (adenine, thymine, guanine, cytosine, uracil, inosine).

[E] Each vertex of an octahedron connects to 4 of the other 5 vertices, skipping only its direct opposite (antipodal) vertex. With 6 vertices that gives 6 × 4 ÷ 2 = 12 edges — matching both the octahedron's 12 edges and the source page's “6 × 2 = 12” note — while the 3 antipodal (non-edge) pairs are excluded from the model.

[E] The source page's face labels read, top row then bottom row: I X G A / U O G T.

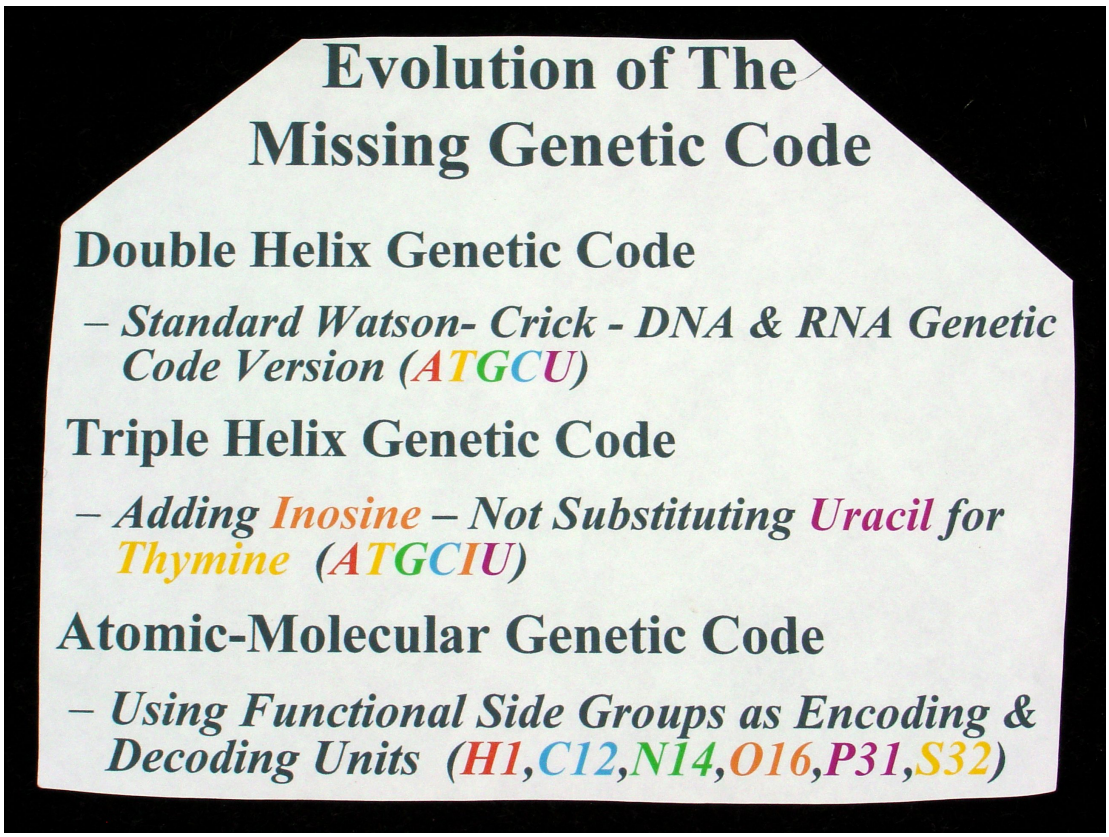

Figure 2. The three-stage progression this paper works from: the standard double-helix genetic code (A, T, G, C, U), the triple-helix code formed by adding inosine rather than substituting it for anything (A, T, G, C, I, U), and the atomic-molecular genetic code that reads each base by its own functional side groups as encoding and decoding units — the source of this paper's Color Key.

2. Base-Pairing Table

[F] The 12 edges group into three sets of pairings — standard DNA pairing, the RNA substitution of U for T, and inosine's wobble — which together account for the 22 proteinogenic amino acids (20 canonical + 2 recoded, see Part III).

Group	Pairs	Count
Watson-Crick (DNA)	A–T, T–A	4 (incl. reverse orientation: A–T, T–A, A–U, U–A)
Watson-Crick (G–C)	G–C, C–G	4 (incl. reverse orientation: G–C, C–G, G–U, U–G)
Inosine wobble	I–C, I–U, I–A	3

[E] Source-page note: an initial "A–U" entry was crossed out and replaced with "I–C" in the base-pair list, and the wobble group total (originally written as "6") reconciles with reverse-orientation counting above.

[F] **Total: 8 + 8 + 6 = 22**, matching the 22 amino acids used in protein synthesis (Part III).

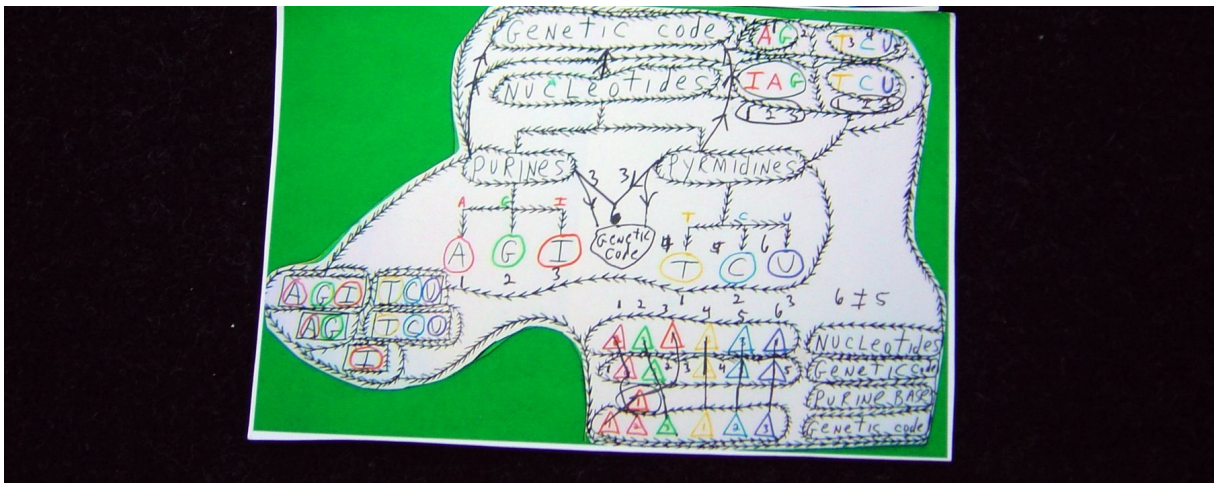

Figure 3. The genetic code's own hierarchy, from the author's source notes: nucleotides split into purines (A, G, I) and pyrimidines (T, C, U), the same six-base split the base-pairing table above and the Color Key both run on.

Part II. Translational

3. Inosine and tRNA Wobble Position 34

[E] Inosine (I) is the only base able to wobble-pair with three others — A, C, and U — per Crick's wobble hypothesis. This versatility is why inosine sits specifically at **position 34** of the tRNA anticodon (the codon's third, “wobble” position): a single tRNA carrying inosine at this position can read several synonymous codons that differ only in their third base, which is a major source of the genetic code's redundancy (and of “silent” mutations at that position).

[E] G–U is a second, separate wobble pair (distinct from inosine's three-way wobble) that also occurs at this third codon position.

4. From Codon to Protein: Two Separate Steps

[E] These are two distinct stages, not one:

1. **Charging (cytoplasm).** Aminoacyl-tRNA synthetase attaches (esterifies) an amino acid onto its matching tRNA's 3′ CCA end, producing an aminoacyl-tRNA. No peptide bond forms at this stage.
2. **Peptide bond formation (ribosome).** The charged tRNA delivers its amino acid to the ribosome, where the peptide bond is formed between that amino acid and the growing polypeptide chain. This step is catalyzed by the ribosome's peptidyl transferase center — which is itself ribosomal RNA acting as a ribozyme, not a separate protein enzyme.

Part III. Synthesis

5. Amino Acid Count: 22, Not 20

[F] The base-pairing table in Part I totals 22, which matches the full set of proteinogenic amino acids once the two recoded ones are included:

#	Amino acid	How it's incorporated
1–20	The 20 canonical amino acids	Standard codon table
21	Selenocysteine	UGA recoded, directed by a SECIS stem-loop element
22	Pyrrolysine	UAG recoded (found in some archaea and bacteria)

[F] So the model's Watson-Crick + wobble pairing accounts for the 20 canonical amino acids, and the two stop-codon-recoding cases bring the total to 22 — matching the 8 + 8 + 6 count from the base-pairing table.

6. Silent Mutations and G-U Wobble

[E] Third-position wobble changes, including G-U, are frequently synonymous at the amino-acid level and therefore silent: because the genetic code is degenerate (Section 21), a substitution at a codon's third base often still specifies the same amino acid.

[O] The source page separately distinguishes an oxo-form G-U pairing, noted as not directly observed experimentally, from the ordinary G-U wobble pair, which is well documented in tRNA anticodon pairing. The two are kept distinct here rather than treated as interchangeable.

Part IV. The Full Pathway, Step by Step

[F] Parts I–III established the geometry and reconciled the amino acid count. This Part walks the same ground a second time, slower, as a teacher would with a student: every stage from gene to finished protein, in order, with no stage skipped — including the processing and elongation stages the source page never mentioned, and with the aminoacyl-tRNA synthetase step and the amino acids themselves named explicitly at each point they act.

7. The Gene: DNA as the Starting Template

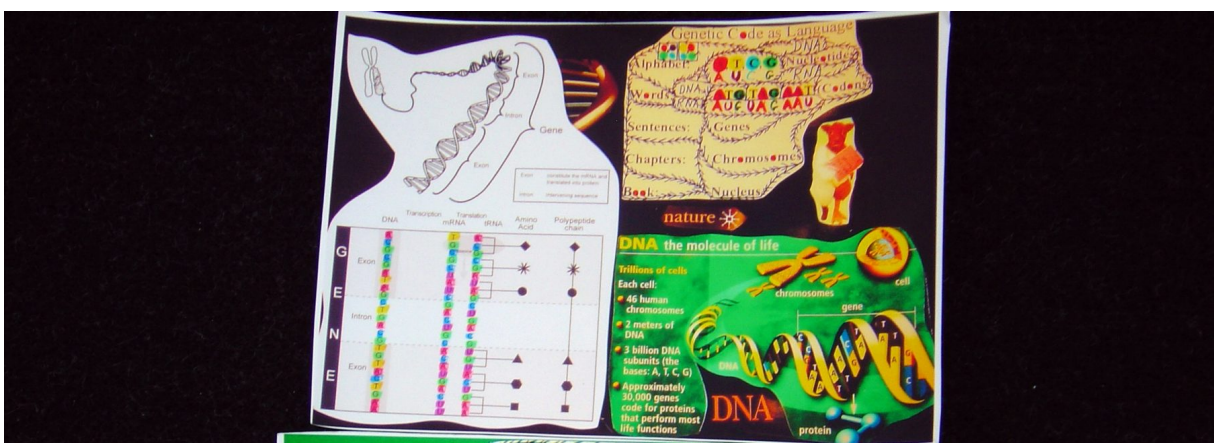

Figure 4. The gene-to-protein pathway this Part walks step by step, alongside the language analogy the author has used to teach it: nucleotides as an alphabet, codons as words, genes as sentences, chromosomes as chapters, the nucleus as the book.

[E] Every protein begins as a gene: a stretch of double-stranded DNA built from four bases, A, T, G, and C. One strand, the **template strand**, is what gets read; its partner, the **coding strand**, already carries the same sequence the mRNA will end up with, except that RNA always writes U where DNA would have written T. A short template-strand triplet reading 3′-TAC-5′, for example, will be copied into the mRNA triplet 5′-AUG-3′ — the very start codon this pathway reaches again in Step 4.

8. Transcription: DNA Becomes mRNA

[E] An enzyme called RNA polymerase binds a promoter sequence just upstream of the gene, unwinds the DNA double helix, and slides along the template strand in the 3′→5′ direction while it builds a new mRNA strand in the 5′→3′ direction. Each incoming ribonucleotide is chosen by strict Watson-Crick pairing with the template base across from it: A pairs with U, T pairs with A, G pairs with C, and C pairs with G. Because the polymerase reads DNA but writes RNA, every T on the template becomes A on the mRNA, and every A on the template becomes U on the mRNA — the single substitution (U for T) that runs through this entire pathway. This whole product is called **pre-mRNA** in eukaryotes, because it is not yet finished.

9. mRNA Processing: From Pre-mRNA to Mature mRNA

[E] Before it can be translated, the pre-mRNA is processed in three ways:

1. **5′ capping.** A modified guanine nucleotide is added to the 5′ end, protecting the message from degradation and later marking where the ribosome should attach.
2. **Splicing.** The pre-mRNA contains alternating **introns** (non-coding stretches) and **exons** (coding stretches). A large RNA-protein machine called the spliceosome cuts out the introns and joins the exons into one continuous coding sequence.
3. **3′ polyadenylation.** A long tail of adenine nucleotides (a poly-A tail) is added to the 3′ end, which further stabilizes the molecule and assists its export.

[E] Only once capped, spliced, and tailed is the molecule **mature mRNA**, ready to leave the nucleus for the cytoplasm, where translation happens.

10. Reading the Message: Codons and the Reading Frame

[E] In the cytoplasm the mature mRNA is read three bases at a time. Each three-base unit is a **codon**. The first codon read is always AUG (the start codon, coding for methionine), which fixes the **reading frame** — the grouping of every following triplet — for the rest of the message. Reading continues codon by codon until one of three **stop codons** is reached: UAA, UAG, or UGA. (Part III already showed that UAG and UGA are sometimes recoded rather than read as stops — Step 16 below returns to that exception.)

11. Translation Initiation: Assembling the Ribosome

[E] Translation begins when the small ribosomal subunit — itself built from ribosomal RNA (rRNA) plus proteins — binds the mature mRNA near its 5′ cap and scans downstream until it finds the start codon AUG. A special initiator tRNA, already carrying methionine and bearing the anticodon UAC (read 3′→5′, so that it pairs antiparallel with AUG), base-pairs with the start codon. The large ribosomal subunit then joins, completing the ribosome and opening up three working locations inside it: the **aminoacyl site**, where each newly charged tRNA will arrive; the **peptidyl site**, which holds the growing chain; and the **exit site**,

where spent tRNA leaves before it is released.

12. Charging tRNA: Aminoacyl-tRNA Synthetase

[E] No tRNA can be used until it has been **charged**. Each of the amino-acid-specific aminoacyl-tRNA synthetases recognizes exactly one amino acid together with the tRNA (or tRNAs) whose anticodon corresponds to it, and spends one ATP to attach that amino acid onto the tRNA's 3′ CCA end through an ester bond. This reaction — esterification, not peptide-bond formation — produces an **aminoacyl-tRNA**, charged and ready to enter the ribosome. This is the step named explicitly and reiterated here so it is never left out: without aminoacyl-tRNA synthetase charging every tRNA before it arrives, no amino acid could ever reach the ribosome at all.

13. Codon-Anticodon Recognition and the Wobble Position

[E] Each charged aminoacyl-tRNA enters the ribosome's aminoacyl site and tests its three-base anticodon against the mRNA codon sitting there. The first two positions of the codon must satisfy strict Watson-Crick pairing (A with U, G with C), but the third position tolerates **wobble**: inosine at anticodon position 34 can pair with A, C, or U, and G–U forms a second, separate wobble pair — exactly as set out in Part II, Section 3. A correct match locks the amino acid in place for the next step; a mismatch causes the aminoacyl-tRNA to be rejected and released.

14. Peptide Bond Formation: The Peptidyl Transferase Center

[E] Once the match is confirmed, the ribosome forms a new **peptide bond** between the amino acid held in the aminoacyl site and the growing polypeptide chain held in the peptidyl site. This bond is made at the **peptidyl transferase center**, which is built entirely from rRNA acting as a ribozyme — not from any protein enzyme — and which depends on Mg^{2+} ions to stabilize its active site. This is the point, first flagged in Part II, Section 4, where the chemistry actually diverges from the charging step: aminoacyl-tRNA synthetase built the ester bond in the cytoplasm; the ribosome's own rRNA builds the peptide bond here.

15. Elongation and Translocation

[E] With the new peptide bond formed, the ribosome **translocates**: it moves exactly one codon further along the mRNA. This shifts the tRNA that was in the peptidyl site into the exit site, where it is released back into the cytoplasm to be recharged; it shifts the tRNA that was in the aminoacyl site into the now-vacant peptidyl site, carrying the whole polypeptide chain with it; and it opens the aminoacyl site to receive the next charged aminoacyl-tRNA specified by the next codon. This three-part cycle — recognition, peptide bond, translocation — repeats once for every codon in the message, adding one amino acid to the chain each time.

16. Termination and Release

[E] Elongation continues until a stop codon (UAA, UAG, or UGA) occupies the aminoacyl site. No ordinary tRNA carries an anticodon that matches a stop codon, so instead a **release factor** binds there, which triggers hydrolysis of the bond holding the finished chain to its last tRNA. The polypeptide is released, and the ribosome's two subunits separate to be recycled. The exception, reconciled in Part III, Section 5, happens when a gene carries a SECIS or PYLIS stem-loop element: that structure recodes UGA or UAG

before a release factor can act, so selenocysteine or pyrrolysine is inserted as the 21st or 22nd amino acid instead of the chain being terminated.

17. The Finished Polypeptide

[F] The released chain of amino acids — drawn from the same 22-member set reconciled in Part III (the 20 canonical amino acids plus selenocysteine and pyrrolysine) — folds into a functional protein. Read start to finish, the pathway is unbroken: the octahedron's six vertices (Part I) fix which bases can pair; DNA is transcribed into mRNA (Steps 7–8) and matured (Step 9); the ribosome, itself built from rRNA, reads the message codon by codon (Steps 10–11); aminoacyl-tRNA synthetase charges every tRNA before it can be used (Step 12); wobble pairing, including inosine's three-way match, lets the code tolerate redundancy at the codon's third base (Step 13); the ribosome's own rRNA — not a protein enzyme — forms every peptide bond (Step 14); and the cycle of recognition, bonding, and translocation (Step 15) repeats until termination or recoding (Step 16) ends the chain. Nothing in this Part introduces new biology; it only walks the same unification, one step at a time, without skipping any of them.

Part V. Coding and Decoding: The Rule Set Behind Gene and Epigenetic Editing

[F] Parts I through IV built and then narrated one coherent pathway. This Part steps back and writes the rules of that pathway down explicitly, as a rulebook rather than a narrative — every base-pairing rule, every rule the genetic code itself obeys, every way the chain can break and produce disease, and the two different repair strategies, gene editing and epigenetic editing, that modern biology uses to fix each kind of break. Nothing here is new biology; it is the existing rules, spelled out in full rather than assumed.

18. The Complete Base-Pairing Rule Set

[E] Every pairing used anywhere in this paper — DNA replication, transcription, translation, an RNA molecule folding against itself, and, later in this Part, a gene-editing guide molecule finding its target — reduces to one of the following rules. None of these are new; collecting them in one table is the point.

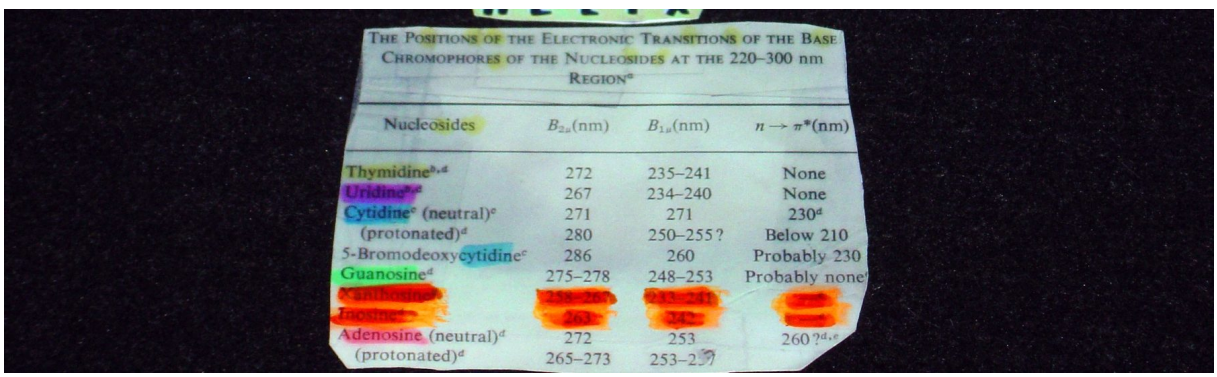
Pairing type	Bases	Hydrogen bonds	Where it governs
DNA Watson-Crick	A–T	2	the two strands of the double helix, antiparallel and fully complementary
DNA Watson-Crick	G–C	3	the two strands of the double helix, antiparallel and fully complementary
RNA Watson-Crick	A–U	2	replaces DNA's A–T pairing whenever T is transcribed as U
RNA Watson-Crick	G–C	3	unchanged from DNA; also governs RNA folding back on itself (tRNA, rRNA secondary structure)

Wobble (codon pos. 3)	G–U or G–C	—	anticodon G tolerates either mRNA base at the third codon position
Wobble (codon pos. 3)	U–A or U–G	—	anticodon U tolerates either mRNA base at the third codon position
Inosine wobble	I–A, I–C, or I–U	—	anticodon I tolerates any of three mRNA bases — the broadest tolerance of any base
Strict, no wobble	C–G only	3	anticodon C accepts no substitute
Strict, no wobble	A–U only	2	anticodon A accepts no substitute (rare at this position)

[E] That table's hydrogen-bond column reduces to a single governing rule, worth stating on its own rather than leaving it buried in a table: every Watson-Crick pair is held together entirely by hydrogen bonds, and the bond count is fixed by which two bases are paired. G–C is always a **triple bond** — three hydrogen bonds. Every other Watson-Crick pair used in this paper — A–T and A–U alike — is a **double bond**, two hydrogen bonds. No standard Watson-Crick pairing in this paper uses any count other than two or three, and the extra bond in G–C is exactly why G–C pairing is more thermally stable than A–T pairing.

[E] Two directionality rules govern every row of that table and are easy to state but easy to forget: pairing is always **antiparallel** (one strand runs 5′→3′ while its partner runs 3′→5′ alongside it), and pairing is always **complementary**, meaning the identity of one base fully determines the small set of bases allowed opposite it — never an open choice.

19. Proton Tunneling, Hydrogen Bonds, and an Open Question at Thymine's Methyl Group



THE POSITIONS OF THE ELECTRONIC TRANSITIONS OF THE BASE CHROMOPHORES OF THE NUCLEOSIDES AT THE 220–300 nm REGION[a]

Nucleosides	B_{2u}(nm)	B_{1u}(nm)	$n \rightarrow \pi^*$(nm)
Thymidine[b,d]	272	235–241	None
Uridine[b,d]	267	234–240	None
Cytidine[c] (neutral)[e]	271	271	230[d]
(protonated)[d]	280	250–255?	Below 210
5-Bromodeoxycytidine[c]	286	260	Probably 230
Guanosine[d]	275–278	248–253	Probably none[f]
Xanthosine[d]	258–261	233–241	[illegible]
Inosine[c]	263	242	[illegible]
Adenosine (neutral)[d]	272	253	260?[d,e]
(protonated)[d]	265–273	253–257	

Figure 5. Each base's hydrogen-bonding chemistry leaves a measurable signature: the positions of the electronic transitions of the base chromophores of the nucleosides, 220-300 nm — including inosine's and hypoxanthine's, highlighted on the source page — a distinct, physically measured identity for every base in Section 18's table, independent of the tunneling question below.

[E] A separate and long-studied line of quantum-biology research asks whether the hydrogen bonds in Section 18's table can occasionally misbehave. The idea, first proposed by Löwdin in 1963, is that a proton sitting in one of those N–H···N or N–H···O hydrogen bonds can, with some small quantum-mechanical probability, tunnel across the bond to the atom on the other side, momentarily flipping the base into an unusual tautomeric form — cytosine's ordinary amino form shifting to a rarer imino form, or thymine's or guanine's ordinary keto form shifting to a rarer enol form. If that tunneled, mismatched shape happens to persist

through the next round of DNA replication (Section 20's DNA → DNA rule), it can pair with the wrong base and produce a point mutation with no external mutagen involved at all — a purely quantum-mechanical entry point into Section 24's mutation types. Whether this happens often enough, and the tunneled form survives long enough, to matter at the scale of a whole genome remains an active and unsettled question in the literature, not a settled mechanism.

[O] The established version of that hypothesis places the tunneling proton inside the hydrogen bond itself, at the N–H position joining the two paired bases — not at thymine's methyl (CH_3) group attached at carbon 5, whose three C–H bonds sit outside the Watson-Crick pairing face and are not part of any hydrogen bond in Section 18's table at all. An open question raised here, distinct from that established picture, is whether the methyl group nonetheless plays an indirect role — whether its electron density or vibrational motion could act as a kind of antenna, feeding energy toward the adjacent N–H···O hydrogen bond that sits close to thymine's methyl-bearing carbon 5 position, and in doing so lowering the effective barrier for a proton to tunnel across that particular bond — even though the methyl group's own C–H bonds would not be the ones that actually tunnel. This is offered as an open question, not a synthesis: it has not been established in the literature reviewed for this paper, and confirming or ruling it out would need its own dedicated treatment — vibrational spectroscopy of the thymine base pair, or a quantum-chemical calculation comparing the tunneling barrier with and without the methyl substituent present — before it could move from an open question to a reconciled finding.

20. The Central Dogma's Directional Rules

[E] Base pairing tells you which bases can sit next to which. The central dogma adds a second, separate rule: the direction information is allowed to move. There are three ordinary routes and one recognized exception:

1. **DNA → DNA (replication).** Before a cell divides, DNA polymerase copies each strand of the double helix using the same Watson-Crick rules from Section 18, producing two identical double helices. This is called **semiconservative** replication because each new helix keeps one original strand and pairs it with one newly built strand.
2. **DNA → RNA (transcription).** Covered in full in Part IV, Step 8: RNA polymerase reads the template strand and writes mRNA using the same pairing rules, with U standing in for T.
3. **RNA → Protein (translation).** Covered in full in Part IV, Steps 10–17: the ribosome reads mRNA codon by codon and, through charged tRNA and the peptidyl transferase center, builds a polypeptide.
4. **RNA → DNA (reverse transcription) — the recognized exception.** Certain viruses (retroviruses such as HIV) and one of the body's own enzymes (telomerase, which extends chromosome ends) carry an enzyme, reverse transcriptase, that runs transcription's pairing rules backward, building a DNA strand from an RNA template. This does not violate the central dogma as Crick originally stated it — his rule was narrower than “RNA never becomes DNA”; it was that sequence information can never flow from protein back into a nucleic acid. Protein → RNA and protein → DNA are the only directions that remain absolutely forbidden.

21. The Genetic Code's Own Rules

[E] Separately from how bases pair and which direction information flows, the genetic code that maps codons to amino acids follows its own six rules:

1. **Triplet.** Codons are read three bases at a time, never one or two.
2. **Non-overlapping.** Each base belongs to exactly one codon; the ribosome never re-reads a base as part of the next triplet.
3. **Comma-less and continuous.** There is no punctuation between codons; the reading frame set at the start codon (Part IV, Step 10) is the only thing that tells the ribosome where one codon ends and the next begins.
4. **Degenerate (redundant).** Most amino acids are specified by more than one codon, almost entirely because of the wobble tolerance at the third position set out in Section 18.
5. **Unambiguous.** The redundancy runs only one way: a single codon never specifies more than one amino acid, even though a single amino acid can be reached by several codons.
6. **Nearly universal.** The same code is used across almost all known life, with a small number of documented exceptions (for example, in mitochondrial genomes, where UGA codes for tryptophan instead of acting as a stop codon).

[E] The start codon AUG and the three stop codons UAA, UAG, and UGA (Part IV, Steps 10 and 16) are not exceptions to these six rules; they are how the six rules get applied to a real strand of mRNA — where to start counting triplets, and where to stop.

[F] Translated through the same Color Key as any other codon (Section 22 spells out the letter-by-letter rule), the three stop codons become: UAA → PHH, UAG → PHN, and UGA → PNH. UAG and UGA are the same two codons recoded for pyrrolysine and selenocysteine in Section 22's table (numbers 22 and 21); UAA is the one stop codon with no recoding exception anywhere in this paper.

A stop-codon energy-state hypothesis.

[E] Three facts already established elsewhere set up the question. First, Section 18's pairing table already treats hydrogen-bond count as a strength rule, not just a bookkeeping number: C–G carries three hydrogen bonds and pairs strictly, with no wobble, while A–U carries two and tolerates wobble at the third codon position. Second, ATP synthase itself runs on hydrogen: Mitchell's chemiosmotic mechanism drives ATP synthesis from a hydrogen-ion (proton) gradient across a membrane, the same particle Section 19 asks whether a base pair can tunnel. Third, the three stop codons are not interchangeable in the literature on translation termination: UAA is widely reported as the strictest, most efficient stop, least prone to ribosomal readthrough, while UGA is the most frequently reported to leak — read through, suppressed, or, as Section 22's table already shows, recoded outright to selenocysteine.

[O] Reading each stop codon's own atom translation for hydrogen-count and position against the three adenine-nucleotide phosphate states lines up with that same hierarchy rather than cutting across it. UAA → PHH carries two hydrogen atoms, at positions 2 and 3 — read here as AMP, two hydrogen bonds, the same two-bond count Section 18 already assigns A–U pairing generally. UAG → PHN carries one hydrogen atom, at the middle position — read as ADP, one hydrogen bond. UGA → PNH carries one hydrogen atom, at the last position — read as ATP, one hydrogen bond, in the position taken here as the signal telling ATP synthase to stop making ATP. By Section 18's own strength rule, more hydrogen bonds means a stricter, harder-to-break signal: two hydrogen bonds for UAA tracks its position as the strictest stop with no recoding exception anywhere in this paper (Section 21 above); one hydrogen bond each for UAG and UGA tracks their being exactly the two stop codons this paper's own model recodes, to pyrrolysine and

selenocysteine respectively (Section 22, entries 22 and 21). On this reading, the weaker signal is not a coincidence of two codons sharing a letter; it is the same hydrogen-bond-strength rule already governing Section 18's base pairs, applied one level up to whether a stop is obeyed or overridden.

[O] If real, this would be more than a naming convention: it would mean translation termination and cellular energy state share one physical signal, carried by the same particle. Section 19 already asks whether a hydrogen-bond proton can tunnel across a base pair; this hypothesis asks whether the number and position of those protons in a stop codon's own translated atoms is read out, downstream, as the difference between AMP, ADP, and ATP — making a stop codon's identity, and not just its presence, the first quantum-mechanical signal proposed in this paper for when protein synthesis and ATP synthesis each stop. That is a claim about mechanism, not just correlation, and it is not established here or anywhere in the literature reviewed for this paper.

[O] It is also, as stated, falsifiable rather than merely suggestive. If the coupling is real, the known termination-efficiency hierarchy (UAA strictest, UGA leakiest) should track measurable shifts in local ATP:ADP:AMP ratio or proton-motive force at the ribosome — for instance, termination fidelity at each stop codon shifting by a different amount under an energy-stress condition that changes the cell's ATP:ADP:AMP balance (the same ratio AMPK-type energy sensors already read), or UGA's recoding to selenocysteine being sensitive to that ratio in a way UAA never is. A quantum-chemical calculation of the tunneling barrier at each stop codon's hydrogen-bond, parallel to the one Section 19 calls for at thymine's methyl group, would be the direct test. Absent that evidence, the pattern above is an open question raised here, not a reconciled finding: it is offered because the numbers line up with a hierarchy already known independently, not because that alignment has been shown to reflect a shared mechanism.

22. The Codon Table in Full: All 22 Amino Acids, Color-Coded, and Their Hydrophobicity

[E] Section 21 stated the genetic code's rules in the abstract. This section is the same code made concrete: every one of the 22 amino acids reconciled in Part III, Section 5, together with every codon that specifies it (color-coded per Section 18) and whether that amino acid's side chain is hydrophobic (nonpolar, tending to bury itself away from water) or hydrophilic (polar or charged, tending to face water) — the property that governs how the finished polypeptide from Part IV, Step 17 folds into a working three-dimensional protein.

[F] Reading each codon straight through the Color Key also translates it directly into atoms, letter for letter: A is hydrogen (H), U is phosphorus (P), G is nitrogen (N), C is carbon (C), T is sulfur (S), and I is oxygen (O). Methionine's single codon, AUG, becomes HPN — hydrogen, phosphorus, nitrogen — the same translation applied to every codon below.

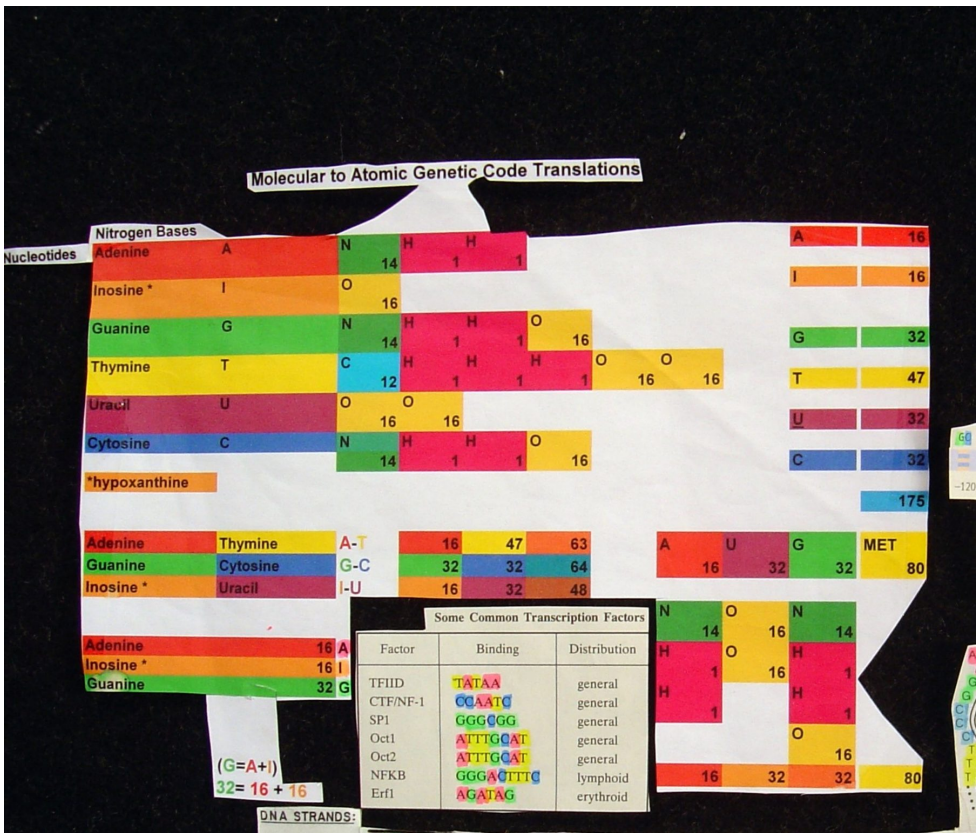


Figure 6. The earlier, atomic-mass version of the same translation, from the author's source notes: each base assigned the mass numbers of the atoms in its functional side groups, summing to adenine=16, inosine=16, guanine=32, thymine=47, uracil=32, cytosine=32 — with A-T=63, G-C=64, I-U=48, and the start codon AUG (Methionine) summing to 16+32+32=80. The letter-based key this paper uses throughout is the same rule carried one level down, from mass to atomic symbol.

[E] Two of the 22 amino acids below carry a sulfur atom in their own side chain that this letter-by-letter translation does not show, because the translation runs on the base, not the finished amino acid: methionine's only codon, AUG, translates to HPN (hydrogen, phosphorus, nitrogen), and cysteine's two codons, UGU and UGC, translate to PNP and PNC — none of the four carry the sulfur (S) this Color Key ties to thymine. The sulfur in methionine's thioether and cysteine's thiol is real, established chemistry; it is just carried by the amino acid's own side chain rather than by any base in its codon.

[E] That sulfur does real work at both ends of the pathway this paper traces. Methionine is the cell's universal precursor of S-adenosylmethionine (SAM), the methyl donor that installs the mRNA guanine 5′ cap described in Section 9 — so the start codon's own amino acid supplies the methyl group that finishes mature mRNA before Section 10's reading frame can even begin. Cysteine's thiol, separately, is the source of the thiyl radical that ribonucleotide reductase uses to reduce ribonucleoside diphosphates to deoxyribonucleoside diphosphates — the reaction that supplies the dNTPs Section 20's DNA → DNA replication runs on, so every new DNA double helix is built from precursors a cysteine-dependent enzyme first pulled out of the ribonucleotide pool. A closely related sulfur chemistry, phosphorothioation — a sulfur atom substituted for one non-bridging oxygen in the phosphate backbone — occurs naturally as a genome modification in some bacteria and is used deliberately to stabilize the synthetic RNA and DNA

oligonucleotides that include several of Section 30's small RNAs against nuclease degradation.

[E] The purine ring shared by adenine, guanine, and hypoxanthine is not modified from an existing base; de novo purine synthesis builds it atom by atom on a ribose-5-phosphate scaffold, and the first complete purine nucleotide produced is **IMP** — inosine monophosphate, the same base this paper's Color Key already gives the broadest wobble tolerance of any base (Section 18). IMP is the trunk the pathway branches from: one route converts it to AMP, the other to GMP.

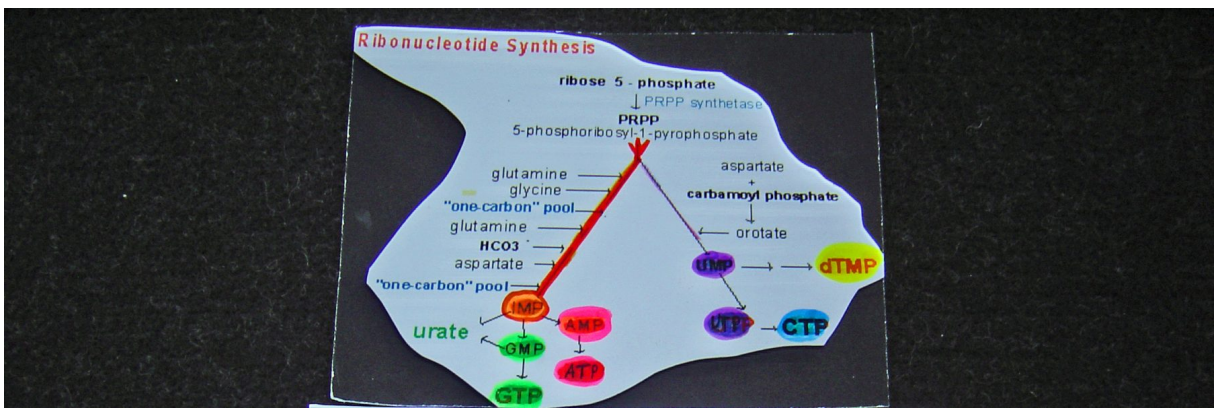

Figure 7. Ribonucleotide synthesis in full, from the author's source notes: ribose 5-phosphate to PRPP to IMP, then branching to AMP/GMP/ATP/GTP on one side and, via orotate, to UMP/dTMP/UTP/CTP on the other — the same IMP branch point Section 21's stop-codon hypothesis and this section's atom translation both run on.

[O] Read together, this puts sulfur chemistry — methionine's SAM finishing mRNA, cysteine's thiyl radical turning ribonucleotides into the deoxyribonucleotides DNA is built from — at the start of the pathway this paper traces, and hydrogen/oxygen chemistry — IMP's purine ring branching to the AMP that Section 21's stop-codon hypothesis needs, and the hydrogen bonds that hypothesis reads out at the stop codon itself — at its end. Where, if anywhere, sulfur and oxygen chemistry meet directly inside that span — a shared carbonyl intermediate, for instance — is raised here as an open question, not answered: nothing in the literature reviewed for this paper establishes such a step, and this paragraph does not claim one.

#	Amino acid	Codon(s)	Atoms	Hydrophobicity
1	Alanine (Ala, A)	GCU, GCC, GCA, GCG	NCP, NCC, NCH, NCN	Hydrophobic (nonpolar, small aliphatic chain)
2	Arginine (Arg, R)	CGU, CGC, CGA, CGG, AGA, AGG	CNP, CNC, CNH, CNN, HNH, HNN	Hydrophilic (polar, basic — positively charged)
3	Asparagine (Asn, N)	AAU, AAC	HHP, HHC	Hydrophilic (polar, uncharged)
4	Aspartate (Asp, D)	GAU, GAC	NHP, NHC	Hydrophilic (polar, acidic — negatively charged)
5	Cysteine (Cys, C)	UGU, UGC	PNP, PNC	Hydrophobic (nonpolar by most scales; reactive thiol)

6	Glutamate (Glu, E)	GAA, GAG	NHH, NHN	Hydrophilic (polar, acidic — negatively charged)
7	Glutamine (Gln, Q)	CAA, CAG	CHH, CHN	Hydrophilic (polar, uncharged)
8	Glycine (Gly, G)	GGU, GGC, GGA, GGG	NNP, NNC, NNH, NNN	Hydrophobic (nonpolar; smallest side chain)
9	Histidine (His, H)	CAU, CAC	CHP, CHC	Hydrophilic (polar, basic — partially charged)
10	Isoleucine (Ile, I)	AUU, AUC, AUA	HPP, HPC, HPH	Hydrophobic (nonpolar, branched aliphatic)
11	Leucine (Leu, L)	UUA, UUG, CUU, CUC, CUA, CUG	PPH, PPN, CPP, CPC, CPH, CPN	Hydrophobic (nonpolar, branched aliphatic)
12	Lysine (Lys, K)	AAA, AAG	HHH, HHN	Hydrophilic (polar, basic — positively charged)
13	Methionine (Met, M)	AUG	HPN	Hydrophobic (nonpolar; start codon, Part IV Step 10)
14	Phenylalanine (Phe, F)	UUU, UUC	PPP, PPC	Hydrophobic (nonpolar, aromatic)
15	Proline (Pro, P)	CCU, CCC, CCA, CCG	CCP, CCC, CCH, CCN	Hydrophobic (nonpolar; rigid ring side chain)
16	Serine (Ser, S)	UCU, UCC, UCA, UCG, AGU, AGC	PCP, PCC, PCH, PCN, HNP, HNC	Hydrophilic (polar, uncharged)
17	Threonine (Thr, T)	ACU, ACC, ACA, ACG	HCP, HCC, HCH, HCN	Hydrophilic (polar, uncharged)
18	Tryptophan (Trp, W)	UGG	PNN	Hydrophobic (nonpolar, aromatic; largest side chain)
19	Tyrosine (Tyr, Y)	UAU, UAC	PHP, PHC	Borderline (aromatic hydrophobic; polar –OH weakly hydrophilic)
20	Valine (Val, V)	GUU, GUC, GUA, GUG	NPP, NPC, NPH, NPN	Hydrophobic (nonpolar, branched aliphatic)
21	Selenocysteine (Sec, U*)	UGA	PNH	Hydrophilic (polar; selenol more acidic than thiol) — recoded stop
22	Pyrrolysine (Pyl, O*)	UAG	PHN	Hydrophobic (large, nonpolar ring) — recoded stop

[F] Two patterns fall directly out of Section 18's rules once the table is laid out in full. First, degeneracy is not spread evenly: amino acids reached by four or six codons (Alanine, Arginine, Glycine, Leucine, Proline,

Serine, Threonine, Valine) are exactly the ones whose codons differ only at the wobble-tolerant third position; amino acids reached by only one or two codons (Methionine, Tryptophan, and the eight two-codon amino acids) are exactly the ones where the third position still carries real information, or is followed by a strict, no-wobble pairing (Section 18's C-G only and A-U only rows). Second, hydrophobicity does not track the color key by base at all — it is a property of the amino acid's side chain, not of the codon's bases — so two codons differing by a single wobble-tolerant base (a silent mutation, Section 24) never change hydrophobicity, while a single missense change to a non-synonymous codon can flip a residue from hydrophobic to hydrophilic outright, which is exactly why a single misfolded residue at the wrong position in a protein can be enough to cause disease.

23. Codons, Anticodons, and the 76-Base tRNA: Where Wobble Position 34 Sits

[E] A codon and its anticodon pair the same way any two complementary strands do (Section 18), except that the anticodon is only three bases long, is read 3′→5′ against the codon's 5′→3′, and lives inside a single folded tRNA molecule rather than a second full strand. Three worked examples show every strictness level from Section 18's table at once:

1. **Strict pairing, no wobble.** The codon 5′-CCC-3′ (Proline) pairs with the anticodon 3′-GGG-5′ position by position — C–G three times over — because anticodon C accepts no substitute (Section 18's C-G only row).
2. **G–U wobble.** The codons 5′-GUC-3′ and 5′-GUU-3′ (both Valine) differ only at the third position. A single anticodon 3′-CAG-5′, with G at position 34, reads both: G pairs with C normally and with U by wobble (Section 18's G-U or G-C row), so one tRNA covers two codons.
3. **Inosine three-way wobble.** Alanine's four codons — GCU, GCC, GCA, and GCG — need only two tRNAs between them. An anticodon 3′-CGI-5′, with I at position 34, wobble-pairs with all three of U, C, and A at the codon's third position (Section 18's broadest row), covering the first three codons in a single tRNA; the fourth, GCG, still needs its own strict-pairing tRNA with C at position 34.

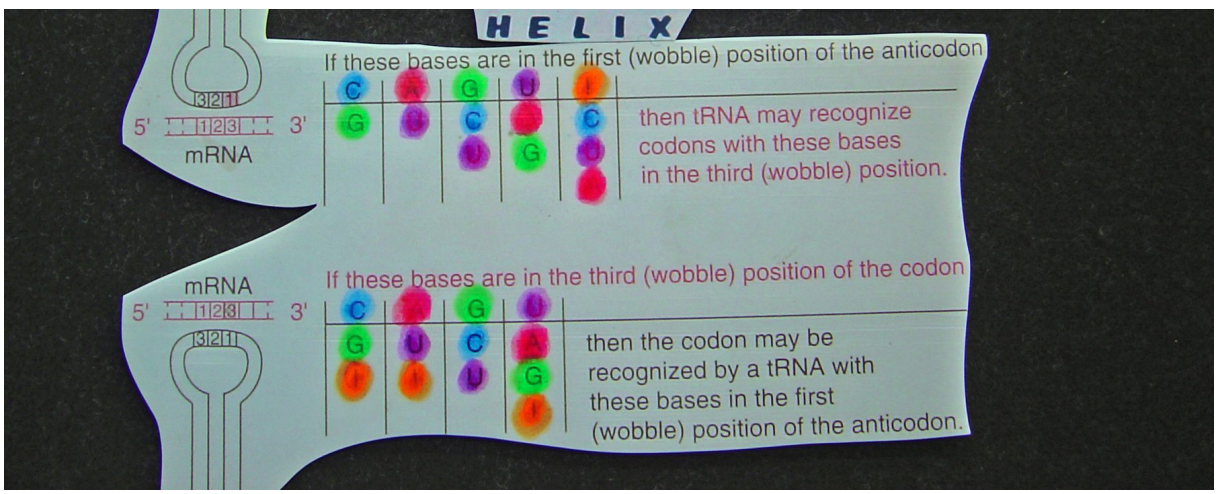

Figure 8. The author's own wobble rule tables, stated both directions: which anticodon first-position bases read which codon third-position bases, and the reverse — the same correspondence the three worked examples above are drawn from.

[E] Position 34 is not a free-floating base; it sits at a fixed address inside the tRNA molecule's own folded structure, which is built from approximately 76 bases arranged as a cloverleaf of four arms around a central

junction:

Arm / region	Approx. size	Contents and role
Acceptor stem	7 base pairs + 4-base NCCA overhang	single-stranded 3′ CCA end is where aminoacyl-tRNA synthetase esterifies the amino acid (Part IV, Step 12)
D-arm	≈3–4 bp stem + ≈8-base loop	loop contains dihydrouridine (“D”), an unusual base that helps the molecule fold correctly
Anticodon arm	5 bp stem + 7-base loop	the anticodon occupies loop positions 34-35-36; **position 34 is the wobble position**, pairing against the codon's third base (Section 18; Part II, Section 3; Part IV, Step 13)
Variable loop	4–21 bases (varies by tRNA)	length differs across tRNA classes; contributes additional synthetase-recognition surface
T-arm (TΨC arm)	5 bp stem + 7-base loop	loop carries the near-invariant sequence T-Ψ-C (ribothymidine–pseudouridine–cytosine); folds back against the D-arm to fix the molecule's 3-D shape
Total	≈76 bases (canonical/reference length)	folds from this 2-D cloverleaf into an L-shaped 3-D molecule, with the acceptor stem and the anticodon loop at opposite ends of the L

[E] The T-arm's T-Ψ-C sequence is one of the only places actual thymine ever appears in RNA at all. It does not come from an exception to Part IV, Step 8's U for T substitution rule — transcription still writes ordinary U at that position — but the finished tRNA is then chemically modified after transcription, methylating that U into ribothymidine. The rule from Part IV is about what RNA polymerase writes; this is a separate, later, well-documented modification step, not a violation of it.

[F] Read together with Section 18, this is the point where the model in Part I stops being only geometry: inosine's three-way wobble and G–U's two-way wobble are not abstract edges on an octahedron, they are the specific chemistry sitting at one fixed position — position 34, inside the anticodon loop, inside a 76-base folded molecule — of a real tRNA carrying out Part IV, Step 13 inside a real cell.

24. Deamination Chemistry: ADAR, ADAT, and the Adenine and Cytosine Base Editors

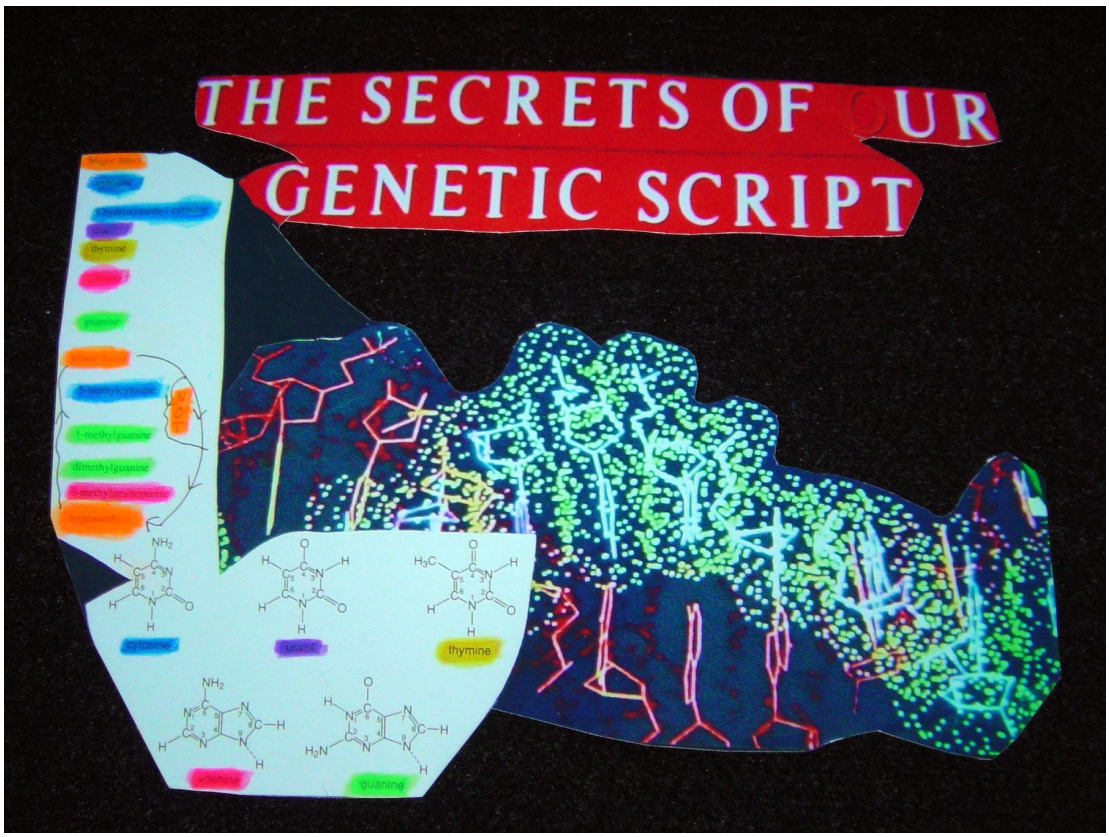

Figure 9. The chemical structures behind this section, from the author's source notes: the major and minor bases of the genetic script, including hypoxanthine itself, the product this section's deamination chemistry runs on, alongside its methylated relatives (5-methylcytosine, 1-methylguanine, and the rest) that mark natural base modification more broadly.

[E] One single chemical reaction — deamination, the hydrolytic removal of an exocyclic amino group and its replacement with a keto (oxo) group, releasing ammonia — is responsible for both natural wobble editing and the two most widely used base editors, depending only on which base it is run on. Deaminating adenosine converts it into inosine — Section 18's wobble base, not a separately synthesized molecule but adenosine itself, one amino group removed. Deaminating cytidine converts it into ordinary uridine. Every enzyme and every tool in this section is a variation on one of those two conversions.

[E] **ADAT** (adenosine deaminase acting on tRNA) is the natural enzyme that installs the wobble I at position 34 described in Section 23. In eukaryotes, a two-subunit ADAT2/ADAT3 complex deaminates the A already sitting at position 34 of an eligible tRNA's anticodon loop, converting it to I directly on the finished molecule; a related single-subunit enzyme, ADAT1, instead edits a different tRNA position (37) that plays no role in wobble. Bacteria carry a simpler single-subunit ancestor of this enzyme family, TadA, which performs the same A-to-I deamination on a narrower set of tRNAs — and which reappears, engineered, later in this section.

[E] **ADAR1, ADAR2, and ADAR3** (adenosine deaminases acting on RNA) run the identical A-to-I deamination, but on double-stranded regions of mRNA and other RNAs rather than on the tRNA anticodon loop of Section 23. Because both the ribosome (Part IV) and reverse transcriptase (Section 20) read inosine as though it were guanine — consistent with Section 18's pairing table, where I pairs most readily with C —

an A-to-I edit inside a codon is read downstream as an A-to-G change, letting a cell alter its own protein sequence after transcription without ever touching the DNA. ADAR1 has a constitutively expressed nuclear form and a second, interferon-inducible form, and edits broadly, including a role in helping the cell distinguish its own double-stranded RNA from a virus's. ADAR2 performs one of the best-studied edits in biology, the “Q/R site” of a glutamate-receptor subunit, where near-complete editing recodes a single codon and is required for normal neurons to function. ADAR3 is largely catalytically inactive, is expressed mainly in the brain, and is thought to act as a competitive inhibitor of ADAR1 and ADAR2 rather than as an editor of its own.

[E] The overwhelming majority of documented human A-to-I editing sites are not spread evenly across the genome; they cluster inside one family of repeated sequences called **Alu elements**. An Alu element is a short (roughly 300-base) retrotransposon — a sequence that copies itself by being transcribed into RNA and then reverse-transcribed back into DNA at a new genomic location, borrowing the reverse transcriptase of a second, unrelated element rather than encoding its own. Alu copies have inserted themselves at more than one million locations across the genome, and by total sequence they make up roughly **10% of the entire human genome** — on the order of 300 million of its approximately **3.1 billion base pairs**, essentially all descended from repeated copying of the same short ancestral sequence. Because Alu copies are so numerous and land in either orientation, two copies frequently end up near each other and inverted relative to one another within the same transcribed region — typically inside an intron or a 3′ untranslated region. When that region is transcribed, the two inverted Alu copies fold back and pair with each other by ordinary Watson-Crick rules (Section 18), run intramolecularly exactly as Section 23 described for a folded tRNA, forming a long double-stranded RNA hairpin. ADAR1 and ADAR2 require exactly this kind of double-stranded substrate, so inverted-Alu hairpins become their preferred target — which is why the large majority of catalogued human editing sites sit inside Alu sequences rather than inside protein-coding codons.

[F] This Alu-heavy editing load is not incidental to disease. ADAR1's editing of the cell's own inverted-Alu double-stranded RNA is one of the ways a cell marks that RNA as “self,” preventing innate-immune sensors from mistaking an ordinary inverted-Alu transcript for double-stranded viral RNA; when ADAR1 itself is mutated and that editing fails, the result is a real disease, Aicardi-Goutières syndrome, in which the immune system mounts a chronic interferon response against the body's own unedited Alu-derived RNA as though it were a persistent viral infection. The scale established above — roughly one-tenth of the entire 3.1-billion-base-pair genome given over to one repeated element — is therefore not incidental to this section's deamination chemistry; it is the reason that chemistry has as large a job to do in humans as it does, and the reason its failure (Section 26) can be a disease in its own right, independent of any single point mutation.

[F] **Adenine base editors (ABEs)** move this same chemistry from RNA onto DNA. An ABE fuses a Cas9 nickase (Section 27) to a laboratory-evolved TadA — the same bacterial tRNA adenosine deaminase described above, directed-evolved in the laboratory until it can act on single-stranded DNA instead of only tRNA. Guided to its target by ordinary Watson-Crick complementarity (Section 18), it deaminates a targeted A to I inside the single-stranded DNA loop the guide RNA exposes; because DNA polymerase reads I as G during the next round of replication or repair, the edit resolves into a permanent A-T → G-C base-pair change, with the opposite strand's T becoming C to match under Section 18's complementarity

rule. This is Section 18's inosine wobble tolerance and Section 23's ADAT-installed tRNA wobble base, redirected into a tool that corrects one specific class of point mutation (Section 25) directly at the DNA level.

[F] **Cytosine base editors (CBEs)** run the mirror-image reaction with a different deaminase family. In place of an adenosine deaminase, a CBE fuses the same Cas9 nickase to a cytidine deaminase (typically from the APOBEC or AID families), which deaminates a targeted C to U within the exposed single-stranded DNA loop. Because DNA polymerase reads U as T upon replication, the edit resolves into a G-C → A-T base-pair change — the reverse of the ABE's conversion. CBEs are typically built with a second added component, a uracil glycosylase inhibitor, because the cell's own base-excision repair machinery would otherwise recognize the newly created U as damage and remove it before it could be read as T.

[F] Taken together, ADAT, ADAR1/2/3, and the two base editors show that this Part's entire rulebook rests on a very small number of underlying chemical reactions, reused at different scales: the same deamination a cell runs naturally on one tRNA base at position 34 (Section 23) is the same reaction it runs naturally on double-stranded mRNA (ADAR1/2/3, above), and is the same reaction an engineered enzyme now runs deliberately on a single chosen base of double-stranded DNA (the adenine and cytosine base editors, above) — three different substrates, one chemistry, with Section 18's base-pairing and wobble rules still deciding, in every case, where the edit is chemically allowed to land.

25. Where the Chain Breaks: Mutation Types

[E] A mutation is any change that breaks one of the rules above, or that changes a base without breaking any rule at all. They sort into a small number of kinds:

1. **Silent mutation.** A single base changes, but the resulting codon is a wobble-tolerant synonym for the same amino acid (Section 18) — the protein is unaffected.
2. **Missense mutation.** A single base changes and the resulting codon specifies a different amino acid, altering one link of the protein chain.
3. **Nonsense mutation.** A single base changes and the resulting codon becomes one of the three stop codons prematurely, truncating the protein before it is finished.
4. **Frameshift mutation.** A base is inserted or deleted in a number not divisible by three, which shifts the triplet grouping (Section 21's non-overlapping rule) for every base downstream — garbling the rest of the message, usually into an early stop.
5. **In-frame insertion or deletion.** Bases are inserted or deleted in a multiple of three, adding or removing whole amino acids without shifting the frame for the rest of the sequence.
6. **Larger structural variants.** Duplications, larger deletions, inversions, and translocations move or remove entire stretches of the coding chain rather than single bases; repeat expansions (extra copies of a short repeated codon, as in Huntington's disease) are a specific case of duplication.
7. **Epigenetic dysregulation — not a sequence error at all.** The base sequence can be entirely correct while the chemical marks that control whether a gene is read (Section 28) are wrong — a gene silenced that should be active, or the reverse. This is not a mutation in the sequence, which is exactly why it needs a different correction strategy.

26. How a Coding Error Becomes a Disease

[E] Each mutation type in Section 25 propagates forward through the same pathway laid out in Part IV, and disease is what shows up at the far end of that propagation. A missense or nonsense mutation in the gene (Part IV, Step 7) is copied faithfully into the mRNA by transcription (Step 8), because RNA polymerase has no way to know the template is wrong — it only applies the pairing rules in Section 18. The ribosome then translates that mRNA exactly as written (Steps 10–16), producing a protein that is misfolded, non-functional, missing entirely past a premature stop, or, in some cases, actively harmful in a new way (a "gain-of-function" mutation, as opposed to the more common "loss-of-function"). Because none of the machinery in Parts I–IV is able to check the DNA's meaning, only its shape, an error introduced once at the gene keeps being faithfully reproduced at every step downstream until something intervenes at the level of the DNA itself.

[E] An epigenetic error propagates differently: the DNA sequence, mRNA, and protein could all be entirely normal, but the cell simply never transcribes the gene in the first place (or transcribes it when it should not), because the chemical marks controlling access to that gene are set wrongly. Some cancers, some imprinting disorders (where the copy of a gene inherited from one parent is supposed to be silenced and the other active), and some developmental conditions trace back to this second route rather than to any change in the coding rules themselves.

27. Gene Editing: Correcting the Sequence Itself

[E] When the disease-causing error is a genuine sequence mutation (Section 25's first six categories), the correction has to rewrite the DNA itself. All three major tools do this by using the same base-pairing rules from Section 18 to find the error before acting on it:

1. **CRISPR-Cas9.** A short guide RNA locates its target purely by Watson-Crick complementarity (Section 18) against the DNA, next to a short flanking sequence the Cas9 protein also requires (the PAM). Once bound, Cas9 cuts both DNA strands. The cell's own repair machinery then closes the break — either by simple, error-prone rejoining (non-homologous end joining, often used deliberately to disable a gene) or, if a correct template sequence is supplied, by copying that template across the break (homology-directed repair, used to correct a specific mutation).
2. **Base editors.** A Cas9 that has been disabled from cutting both strands is fused to a second enzyme (a deaminase) that chemically converts one base into another directly, without ever creating a double-strand break — for example, converting a mismatched C back to T, or A to G, at a single targeted position. Section 24 gives the full deamination chemistry behind both directions of this conversion, and the natural ADAR/ADAT enzymes it was engineered from; here it is enough to note that this is the most direct application anywhere in this Part of the base-pairing rules in Section 18 to therapy: it edits the pairing itself, one base at a time.
3. **Prime editing.** A further-modified Cas9 is fused to a reverse transcriptase (Section 20's RNA → DNA exception, repurposed as a tool) and guided by an extended guide RNA that both marks the target and carries the corrected sequence within itself. This "search-and-replace" approach can correct insertions, deletions, and any of the twelve possible single-base substitutions without a double-strand break and without a separate repair template.

[F] All three tools inherit the same limitation that Part II attached to inosine's wobble: a guide RNA that tolerates a near-match rather than a perfect one can bind and act at the wrong location in the genome.

Off-target editing is, in this sense, the same wobble tolerance from Section 18 showing up as a liability rather than a feature.

28. Epigenetic Editing: Correcting Expression Without Correcting Sequence

[E] When Section 26's second route is the cause — a correct sequence that is wrongly silenced or wrongly activated — cutting or rewriting the DNA would fix nothing, since nothing in the sequence is broken. The correction instead targets the chemical marks layered on top of the DNA and its packaging:

1. **DNA methylation.** A methyl group attached to cytosine, usually at C-G dinucleotides clustered in a gene's promoter, typically switches that gene off without changing a single base in its coding sequence.
2. **Histone modification.** DNA is wound around histone proteins; adding or removing chemical tags on those histones (acetylation, methylation, phosphorylation, and others) loosens or tightens how accessible the underlying DNA is to being transcribed at all.
3. **Chromatin remodeling.** Larger-scale repositioning of how DNA is packaged, shifting whole regions between an open, readable state (euchromatin) and a closed, silenced one (heterochromatin).
4. **Epigenome-editing tools.** The same Cas9 used to find a target by base pairing in Section 27 is disabled from cutting altogether (“dead” Cas9, or dCas9) and fused instead to an enzyme that writes or erases one of the marks above at that one location — for example, a methyltransferase to silence a gene that is wrongly active, or a demethylase together with an activating enzyme to switch on a gene that is wrongly silenced. The targeting step is still ordinary Watson-Crick base pairing from Section 18; only the payload delivered once the target is found has changed.

29. Choosing Between Gene Editing and Epigenetic Editing

[F] Sections 27 and 28 are not competing techniques; they answer two different questions, and the diagnosis in Section 26 decides which one applies. If the base sequence itself contains the error — a missense, nonsense, frameshift, or structural mutation — the coding rules in Sections 18, 20, and 21 are being violated, and only gene editing rewrites the sequence back into compliance with them. If the sequence is correct and the fault lies in which genes get read, the coding rules were never broken, and gene editing would have nothing to correct — the fault lies one level above the code, in the marks that regulate it, and only epigenetic editing addresses that level. A small number of conditions involve both — a sequence variant that also disrupts a regulatory mark — and those require both tools applied together, in either order, since the two corrections do not interfere with each other.

30. The Five Small RNAs Behind Gene and Epigenetic Editing, and the 8 + 8 + 6 Underneath All of Them

[F] Part I's octahedron reduced DNA, RNA, and wobble pairing to three groups whose counts — 8, 8, and 6 — sum to 22, matching the 22 amino acids reconciled in Part III. That count describes the destination of the pathway in Part IV: the finished amino acid chain. The same base-pairing and wobble rules that produced it (Section 18) are also, unchanged, what let a short RNA molecule find one specific target out of an entire genome or transcriptome and nothing else — which is why one family of pairing rules underlies not only how the 22 amino acids get built, but also every one of the small RNA tools available to intervene in that build, naturally or deliberately, at any point along the way.

[E] Five small RNA classes account for nearly all of that intervention, three of them the cell's own and two of them borrowed or engineered:

1. **siRNA (small interfering RNA).** A short (20–24 base) RNA duplex, perfectly complementary to its target by Section 18's strict Watson-Crick rules, processed by the enzyme Dicer and loaded into the RISC/Argonaute complex, which then cleaves any mRNA fully matching it — the standard natural and laboratory tool for silencing one specific gene's expression after transcription (Part IV, Step 8) without touching the DNA itself.
2. **miRNA (microRNA).** Similar in size to siRNA but encoded by the cell's own genome and typically only *partially* complementary to its target, usually a site in the 3′ untranslated region of an mRNA. Where wobble (Section 18) tolerates a mismatch at one fixed codon position, a miRNA duplex tolerates several mismatches spread across a longer stretch, which shifts the outcome from clean cleavage to translational repression or gradual mRNA decay — the cell's own built-in dial for how much of a given protein gets made.
3. **piRNA (Piwi-interacting RNA).** A longer (24–31 base) small RNA, paired with a Piwi-family protein rather than Argonaute, expressed mainly in the germline, whose job is silencing transposons — including the Alu and related retrotransposon elements from Section 24 — largely by directing C-G methylation (Section 28) onto the transposon's own DNA sequence rather than by cleaving its RNA. Of the five, piRNA is the one that is genuinely epigenetic rather than post-transcriptional: it changes which DNA gets read, not merely which RNA survives.
4. **sgRNA (single guide RNA).** The one fully synthetic entry on this list, and the guide molecule behind both Section 27's CRISPR-Cas9 gene editing and Section 28's dCas9-based epigenetic editing. Unlike the three natural RNAs above, its sequence is not inherited or transcribed from a gene built for the purpose; it is chosen deliberately, by Section 18's ordinary complementarity rules, to match whatever DNA site actually needs correcting.
5. **snoRNA (small nucleolar RNA).** Rather than silencing anything, a snoRNA base-pairs only transiently with a site on rRNA or snRNA and recruits an enzyme that chemically modifies that one position (typically 2′-O-methylation or conversion to pseudouridine) — the cell's natural mechanism for fine-tuning the very ribosomal and spliceosomal machinery that Part IV, Steps 9 and 11, depend on to process mRNA and build protein in the first place.

[F] Despite reaching entirely different targets — an mRNA for silencing, a transposon's DNA for permanent shutdown, a chosen genomic site for correction, or a ribosomal RNA for chemical fine-tuning — all five succeed or fail by the same single test: whether their sequence satisfies Section 18's base-pairing and wobble rules against the intended target, and nowhere else. Seen this way, this paper's central count, 8 + 8 + 6 = 22 (Part I, Part III), and the 22 amino acids it reconciles, describe only the destination of the pathway in Part IV. These five small RNAs are five different places along that same pathway, upstream of and alongside it, where the identical pairing rules are being read a second time — once by the cell itself, for its own natural regulation (miRNA, piRNA, snoRNA), and once by an experimenter or clinician supplying a deliberately chosen sequence (siRNA in the laboratory, sgRNA in the clinic).

Status. Transcribed and annotated from a handwritten source page, with corrections made through discussion (U in place of an initially misread V; G–U wobble as a separate pairing from inosine's; the 22-amino-acid

reconciliation with selenocysteine and pyrrolysine). Version 2 added Part IV, a full step-by-step walkthrough from gene to finished polypeptide — transcription, mRNA processing, translation initiation, aminoacyl-tRNA synthetase charging, wobble recognition, peptide bond formation, elongation, and termination — so that no stage of the pathway is left unstated. Version 3 added the up-front Reading order note glossing Molecular, Translational, and Synthesis in plain terms; version 4 expanded that note into a full plain-English explanation of each term, at length, rather than a compressed summary. Version 5 adds Part V, a full coding-and-decoding rulebook: the complete base-pairing rule set and its hydrogen-bond counts, an open question about proton tunneling at thymine's methyl group, the central dogma's directional rules, the genetic code's own rules, the full 22-amino-acid codon table with hydrophobicity, the 76-base tRNA structure and wobble position 34, the deamination chemistry shared by ADAR, ADAT, and the adenine and cytosine base editors, the role of Alu elements in human A-to-I editing, mutation types and how a coding error becomes a disease, gene editing and epigenetic editing as two different repair strategies, and the five small RNAs (siRNA, miRNA, piRNA, sgRNA, snoRNA) that carry out natural and engineered editing by the same pairing rules. Versions 6 and 7 tried to fix reported color problems by re-engineering the palette for more distinctness between hues; version 8 found the actual issue instead: pixel-sampling his own reference paper ("Unit Quaternions as Photonic Unitaries," PP-2026-SU2MZI-01) showed the intended colors were never a distinctness problem to begin with, so the palette is restored here to the exact hex values sampled from that reference. Version 8 also closes every remaining gap found by re-auditing every spelled-out base name in the paper — a missed inosine in Section 24, guanine in Section 9, selenocysteine in the Abstract, adenine, cytosine, and uracil across Section 24, and hydrogen itself wherever "hydrogen bond" appears — and removes the source-page transcription commentary from Section 6, stating its two substantive points — silent third-position wobble changes, and the oxo-form G-U pairing as a distinct, unobserved case — directly. Version 9 brightened orange alone. Version 10 brightens all seven colors to match, by his direct instruction, and drops magnesium from the Color Key entirely — indigo now covers only selenium, xanthine, and orotate. Version 11 finishes the atom pass — every remaining hydrogen and carbon mention, and the last column of the base-pairing rules table, where several anticodon letters had been left plain. Version 12 adds an Atoms column to Section 22's codon table, translating every codon straight into the atoms its bases stand for — Methionine's AUG becomes HPN — the same translation carried through all 22 amino acids and every codon that specifies them. Version 13 extends that same atom translation to the three stop codons in Section 21 (UAA, UAG, UGA), color-coded alongside their atom sequences the same way. Version 14 added a first pass at an open question reading those three atom translations against AMP, ADP, and ATP by hydrogen-count and position. Version 15 spells that hypothesis out in full in Section 21: the established background it rests on (Section 18's hydrogen-bond strength rule, chemiosmotic ATP synthesis running on the same hydrogen ion Section 19 asks about, and the known UAA-strictest/UGA-leakiest termination hierarchy), the hypothesis itself — that hierarchy reproduced by each stop codon's own hydrogen-bond count, tying translation termination and ATP synthesis to one physical signal — and the falsifiable predictions that would confirm or rule it out. Offered throughout as an open question, not an established finding. Version 16 adds the sulfur side of the same pathway to Section 22: methionine's SAM finishing the mRNA cap and cysteine's thiyl radical supplying DNA's deoxyribonucleotide precursors, bracketed against de novo purine synthesis converging on IMP — the AMP that Section 21's hypothesis needs, closing the loop from start codon to stop codon. Version 17 corrects the closing framing itself and states the full chain explicitly, link by link — geometry, color key, atom translation, start-codon sulfur chemistry, purine synthesis, the stop-codon energy hypothesis, the full amino acid table, tRNA structure, deamination chemistry,

and every editing tool, natural and engineered. Version 18 moves that full-chain statement from the paper's close to its front matter, right after the Abstract, so its scale is visible before Part I rather than only after Section 30. Version 19 moves the single closing sentence of that statement — the "no single link above is new" paragraph — further still, verbatim, to stand before even the Reading order note, so the claim of original synthesis is the first thing read in the paper. Version 20 adds nine figures, each a photograph of the author's own source notes placed at the point in the text its content bears on directly: the interstellar-molecule and seawater-composition context for the Color Key's six elements; the three-stage evolution from the standard code through the triple-helix code to the atomic-molecular code; the purine/pyrimidine hierarchy; the gene-to-protein pathway and language analogy; the UV absorption bands underlying Section 19's tunneling question; the atomic-mass version of the atom translation in Section 22; ribonucleotide synthesis through IMP; the wobble rule tables of Section 23; and the base chemistry behind Section 24's deamination editing. Every individual fact drawn on throughout is established; the frame connecting them into one chain has not been assembled this way anywhere in the literature reviewed for this paper. That original synthesis, not new laboratory data, is what this paper offers.

APPENDIX A · THE WORKING LIBRARY

1744. The Library Behind the Argument ↩

What was bought, over five years, to build this

This appendix is the reading list from which the twenty-nine years of work in this volume were assembled. It is reproduced because the question a reader is entitled to ask of a single-author volume of this scope is where the knowledge came from, and this is the answer.

The list was kept on paper in three separate printings, made at different times and numbered independently. The three do not agree on numbering. Fire Under the Sea is item 316 in one run, 326 in another and 350 in a third, so the merge below is keyed on the title and each run number is carried as its own column in the accompanying spreadsheet.

item	figure
what was counted	figure
raw line items transcribed from the three printings	1,411
duplicate line items collapsed	242
distinct titles in the integrated list	1,169
titles appearing in two or more of the three printings	235
years of acquisition	1998 to 2003

What the distribution shows

field	titles	share
Biology and Genetics	168	14.4%
Chemistry and the Molecular World	91	7.8%
Minerals, Crystals and the Earth	53	4.5%
Mathematics and Geometry	178	15.2%
Computing and Software	190	16.3%
Color, Light and Optics	47	4.0%
Mind, Language and Symbol	72	6.2%
Business and Management	52	4.4%
Cosmos and Physics	26	2.2%
General and Reference	292	25.0%

Ten fields, and no single one of them holds a quarter of the shelf. The volume's method — reading a chemical claim through a geometry, a geometry through a notation, and a notation through a color — is visible in what was bought before it is visible in what was written.

1745. The Vowel O Across the Whole Shelf ↩

A count, not an impression

The author has held for years that the vowel O binds oxygen to a family of words that recurs across unrelated fields. The shelf can be counted, and the count is given here without interpretation.

measure	count
titles whose head word begins with O	63
titles carrying an O-rooted scientific morpheme	256
titles matching either test	292
share of the whole library	25.0%
fields those titles fall across	10 of 10

The morphemes counted were oxy, organ, molecul, color, code, geometr, order, proto, photo, polygon, polyhedr, polymer, cosmo, holo, chromo, topol, morpho, logic, onto, opto, solid, form, orbit and oscill.

One title in four on a shelf of eleven hundred and sixty-nine, spread across every one of the ten fields. What is claimed here is the count. What it means is argued in Part Fifty-Five.

1746. Why the Titles Themselves Are Not Reproduced ↩

An earlier version of this appendix printed all one thousand one hundred and sixty-nine titles, sorted into the ten fields, across thirty-five tables. They have been removed.

A list of titles is not evidence and it is not analysis. It is inventory. What bears on the argument is the distribution - ten fields, no single one holding a quarter of the shelf - and that distribution is given in section 1427 as a count. Printing the titles underneath it added eighty pages and no information the count did not already carry.

The full list is kept as a spreadsheet alongside this volume for anyone who wants to audit the count. It does not belong in the argument, and a reader who wants the claim checked is better served by a file that can be sorted than by eighty pages that cannot.

1747. What This Appendix Evidences and What It Does Not ↩ ↩

Stated plainly, as everywhere else in this volume

It evidences that the material behind this volume was gathered across ten fields over five years, and it makes the breadth checkable rather than asserted.

It does not evidence that every title was read cover to cover, and the author does not claim that. A working library is consulted, not consumed.

It does not stand in for the citations. Where this volume rests on a measurement, a mechanism or a dated publication, that source is named at the point of use, and this appendix is separate from it.

— Show that the three printings are one printing rather than three, and the merge of 1,411 line items into 1,169 titles is an artifact of transcription rather than a real de-duplication.

— Color or count the same shelf independently and reach a materially different field distribution, and section 1094 does not reproduce.

— Show that the morpheme set counted in section 1095 was chosen after the count rather than before it, and that section is a selection effect.

Combined Register of the Berger 816 Subjects

This register unites Appendix B of Book I, the Register of the Berger 816 Subjects (§1748–§1751, formerly pages I-2466 to I-2502), with items 17 and 18 of Book II, the 816 Subject Matter Index of 188 subjects and the 816 Master Subject Matter Index of 1,063 subjects (formerly pages II-833 to II-861). Each subject has one row, keyed by its 816 number. The Book I column gives the subject's tier and reference from Appendix B; the Book II column gives its entry in item 18 and, where present, in item 17, with each reference and source tag. Where the two books word a subject differently, both wordings are printed. The one subject of item 17 that has no counterpart in item 18 has its own row at the end. The text before and after the table is carried word for word from both books.

From Book I · Appendix B

APPENDIX B · REGISTER OF THE BERGER 816 SUBJECTS

1748. What This Register Is, and What It Admits ↩

↩

All one thousand and sixty-three subjects of the Berger 816 Master Subject Index, each given a destination or declared open

The Berger 816 Master Subject Index lists one thousand and sixty-three subjects the author has investigated. This Register places every one of them on the record here, in the author's own numbering, and gives each a live destination where one exists. It does not give any subject a reference that does not exist, and the count of those is printed below rather than buried.

Every subject string was matched against the typeset text of this edition. Three outcomes were possible and all three are reported.

tier	subjects	the meaning
Tier A	97	the subject appears verbatim in the text. It receives a primary section and its secondary sections, all live links.
Tier B	327	the subject is a compound whose head term is an Index entry with references of its own. It receives a cross-reference to that entry rather than a list of several hundred sections, which would not be an index.
Tier C	639	no reference of any kind exists in this volume. The subject is declared open. It is listed, numbered and bookmarked, and it links to nothing, because there is nothing to link to.

Six hundred and thirty-nine of the author's own subjects have no treatment in one thousand five hundred pages. That is the number this Register exists to state plainly. It is not a defect of the index and it is not a defect of the matching; it is the size of the work still to be written, and printing it is the only honest way to carry a subject list of this length.

The three registers below are in the author's index order. A section number in any register is a live link into the text. A term in the cross-reference column is a live link to that term's own Index entry, which carries its pages.

1749. Tier A · The Ninety-Seven Subjects With Their Own Reference References ↩

Present verbatim in the text, with a primary section and secondary sections

1750. Tier B · The Three Hundred and Twenty-Seven Subjects Carri Subjects Carried by Cross-Reference ↩

Compound subjects whose head terms carry the references

Each of these is a phrase built on one or more terms that already hold references in the Index. Listing every section in which the head term appears would put four hundred or a thousand numbers against a single line, which is not an index but a concordance. The cross-reference is given instead and it is live.

1751. Tier C · The Six Hundred and Thirty-Nine Open Subjects ↩ Subjects ↩

Investigated by the author, not yet written in this volume

These are listed and bookmarked so that they can be cited, assigned and closed one at a time. No section reference is given because none exists. A subject leaves this register by being written about, not by being relabeled.

From Book II · items 17 and 18

17. The 816 Subject Matter Index — 188 subjects

Alphabetical, numbered, no duplicates. The reference column is the page range in Volume 816, or ARCHIVE where the subject stands in the corpus but not yet in the volume. 144 subjects carry pages; 44 are ARCHIVE.

18. The 816 Master Subject Matter Index — 1,063 subjects

The same instrument widened to the whole corpus of 6,600 files and 20.37 GB: 160 subjects carry pages in Volume 816 and 903 are ARCHIVE. Duplicates were removed by token-similarity matching at a 0.70 threshold.

Six hundred and thirty-nine subjects. The volume states the number rather than implying coverage it does not have.

[F] 187 of the 188 subjects in the shorter index reappear here, and 145 of those carry page references in both. The master index therefore adds 875 subjects to the record, of which 15 are written into the volume and the rest are the frontier.

APPENDIX C · THE DERIVATIVE PAPERS

1752. What a Derivative Is, and Which Way the Dependence Ru Dependence Runs ↩

A register, kept here because the derivatives will outnumber the volume

A derivative paper is a document drawn out of this volume for a reader who will not read the volume. It takes a Part, or a thread running across several Parts, and sets it out on its own — sometimes verbatim, sometimes re-sequenced, sometimes retold in plainer language for an audience that has no reason to care about the framework.

The dependence runs one way and the volume states it plainly. Every derivative depends on the volume. The volume depends on none of them. Nothing is argued in a derivative that is not argued here at greater length and with its qualifications attached, and no derivative is a citable source for anything. A reader who finds a claim in a derivative and wants to test it should come to the Part named beside it in the register below.

The distinction matters because the two kinds of document are built to different rules. The volume orders its evidence by argument, states its boundaries at full length, prints its corrections, and assumes a reader who intends to check. A derivative orders the same evidence by attention, states the boundaries once, and assumes a reader deciding whether to begin. Both are honest. Only one is the record.

The rule this volume follows when it makes one

— A derivative introduces no claim that is not in the volume. If a derivative needs a new claim, the claim is written into a Part first, and the derivative is rebuilt.

— A derivative carries the same numbers as the volume. Where the volume prints a rate, a ratio or a count, the derivative prints the same one from the same source, and does not round it into a headline.

— A derivative carries the boundaries. Every refusal stated in the parent Part is stated in the derivative, in the derivative's own words and at the derivative's own length, but never dropped.

— A derivative is dated and versioned, and superseded versions are not circulated. Where an error has gone out, an errata document is issued rather than the file being quietly replaced.

1753. The Register as It Stands ↩

Papers drawn from the Parts of this volume, with the Part each one answers to

The register below lists the derivatives drawn from the Parts of this volume that the author can account for line by line. It is open and it is not complete: earlier documents exist in the working archive that predate the Part numbering now in use, and they are recorded in Appendix A rather than here. A document belongs in this register when it is drawn from a numbered Part and can be traced back to it.

the paper	pp	the content	the Part it answers to
Why the Color Yellow Shines Brightly on Atomic Element 16	15	the sulfur spine, for a reader with no chemistry	Parts One through Thirteen
The Telling	13	the same material as oral narrative, without scaffolding or section apparatus	the sulfur spine, retold
The Particle That Fathered the Transposon	11	7SL RNA, the SRP54 methionine-rich domain, and the origin of the Alu element	Part One Hundred and Fifty
The Bar Code Has Two Channels	16	color and hydrogen-bond count as two independent channels of the same notation	Part One Hundred and Fifty-One
Nine Billion Letters, Four Characters	23	the AlphaGenome Atlas, its construction rule, and what its scale does and does not establish	Part One Hundred and Fifty-Two
The Unit Is a Nucleotide, Not a Letter	11	base, sugar and phosphate as the unit of variation; the 63+1 accounting	Part One Hundred and Fifty-Three
The Arabinose Test	16	six questions with published answers, offered as a benchmark rather than a critique	Part One Hundred and Fifty-Four
Read as Guanosine	15	inosine in subacute sclerosing panencephalitis, and why the wobble is not the mechanism	Part One Hundred and Fifty-Five
Two Hands, One Signal	18	inflammation switching on an enzymatic and a chemical deaminase together	Part One Hundred and Fifty-Six
A Fatal Child's Brain Disease after Contacting the Measles	18	the same evidence re-sequenced for a general reader, disease first	Parts One Hundred and Fifty-Five and Fifty-Six

the paper	pp	the content	the Part it answers to
		and chemistry second	
Errata: ANA Chemistry	4	four corrections to chemistry circulated under the author's name, issued as a standing correction	not drawn from a Part; a correction to documents that were
From a Star to a Wrinkle	14	glycine and sulfur from stellar nucleosynthesis to an enzyme built on a glycine oxidase scaffold	Part One Hundred and Fifty-Eight
The Berger Two-Channel Color Genetic Code	19	the notation written across all sixty-four codons and their anticodons, and the 39.3 percent it produces	Part One Hundred and Fifty-Nine
The Currency Is a Letter	15	phosphorus, the ADP-ATP cycle as a phosphate transfer, and the bond that pays for metabolism being the bond broken to write the message	Part One Hundred and Sixty
QT Is the Marker. Calcium Is the Trigger.	12	a missing node in a published adverse outcome pathway, and the experiment in which a longer action potential abolished the arrhythmia	Part One Hundred and Sixty-One
The Gene That Broke Twice	11	uricase lost independently in two primate lineages, and the disulfide that turns a dehydrogenase into a radical source	Part One Hundred and Sixty-Two
Adenosine for Inosine	12	the sixteen permitted characters, the parent-letter rule, and the substitution the primary record makes without a flag	Part One Hundred and Sixty-Three
One Chemistry, Two Addresses	15	base editing safety: the intended product and the principal off-target as one molecule, with a null hypothesis and the power	Part One Hundred and Sixty-Four
Two Deaminations No Sequence File Can Write	17	the two deamination channels, the lipoprotein the cytidine family is named after, and the decoy hypothesis	Part One Hundred and Sixty-Five
Six Experiments and a Laptop	15	six protocols from this volume whose primary endpoints are computable from public data on a desktop computer	drawn from the experiment sections of many Parts, not from one
Eight Papers, Eight Claims	5	the front door: each paper stated as its claim, with a reading route, the color key and the house rules	an index to the derivatives; not drawn from a Part

Twenty-one documents, two hundred and ninety-five pages between them, every one of them a window cut into a wall that is seventeen hundred pages thick. None of them is the wall.

the paper	pp	the content	the Part it answers to
What Would Settle It	32	every experiment generated across the eighty-nine proposals of this volume, grouped by what it tests, each carrying the Part and the section that produced it	drawn from the experiment sections of forty-eight Parts, not from one
Two Deaminations No Sequence File Can Write — through — The Derivative Papers	95	the two deamination channels carried whole, with the working library, the register of subjects and the derivative register standing behind them	Part One Hundred and Sixty-Five, with Appendices A, B and C

Twenty-three documents, four hundred and twenty-two pages between them, every one of them a window cut into a wall that is seventeen hundred pages thick. None of them is the wall.

Two of the nine most recent entries do not answer to a single Part, and the register says so rather than inventing one. Six Experiments and a Laptop is drawn from the experiment sections of many Parts, selected on one criterion — that the primary endpoint can be computed from public data on a desktop computer — and it belongs to no one Part because it belongs to dozens. Eight Papers, Eight Claims is an index to the derivatives themselves, which makes it a derivative of derivatives and the only document here that points inward rather than outward. Holding both forms, and saying which is which, is the reason the register exists.

What the register is not

It is not a publication list. Several of these were written to be sent to one correspondent and no further. It is not a claim of priority: the priority of everything in them belongs to the Parts they are drawn from, and the priority of the underlying measurements belongs to the laboratories that made them. And it is not closed — the author expects the derivatives to outnumber the Parts, because a volume of this length produces more windows than walls.

NovagonDNA

The Scientific Arc of Man's Evolution from the Big Bang to the Human Genome

Frame, alphabet, charging systems, record, sulfur, network; the themes, the weave, the registers; the count, the listing, the indexes — merged in that order

Merged desktop edition · PP-2026-VTI-01 · merging PP-2026-VOL-01 v1 (19 October 2026), PP-2026-THEMES-01 v1 (17 October 2026) and PP-2026-INVENTORY-01 v2 (16 October 2026) · Dr. John Allen Berger, PhD · NovagonDNA

Editorial note. This edition reproduces the text of the three source papers verbatim, arranged by subject rather than by source. Every passage carries its origin tag — [VOL p.N], [THEMES p.N] or [INV p.N], where N is the page of the source PDF. Running heads, footers and repeated title lines have been removed; the per-source front matter (color keys, abstracts, tag definitions) is kept in Section 1. Pages carrying plates, figures or drawn tables are also reproduced as 150 dpi images directly after their text. The volume's own table of contents (VOL pp.7–26) is superseded by the contents below and is not reproduced. One new plate is added (Plate N-1, Section 4), marked [H] as new material by JAB. Paragraph tags [E] [F] [H] [O] are as in the sources.

Merged color / element table (identical in all three sources)

color	element	base
red	hydrogen · H 1	adenine
blue	carbon · C 6	cytosine
green	nitrogen · N 7	guanine
orange	oxygen · O 8	hypoxanthine · inosine
purple	phosphorus · P 15	uracil
yellow	sulfur · S 16	thymine
indigo	selenium · Se 34	xanthine · orotate

Each source's own "where it appears" column for this table follows verbatim with its front matter in Section 1.

Contents

1. Front matter, color keys, abstracts and the full chains 3
2. Method and the record: the count, the run, the listing 12
3. The frame and the arc in twelve stages 27
4. The nucleotide and the alphabet (with new Plate N-1, the nucleotide octahedron) 93
5. The charging systems and the twenty-one plates 155
6. What the record cannot carry 218
7. Sulfur in command 271
8. The network, the fan and the clinic 348
9. The thirteen themes, the weave and the six threads 405
10. The documents entered into the record, and the chapters item by item 424
11. Appendices of the volume (A–AC) 458
12. Claims, hypotheses, predictions and falsifiers 614
13. Consolidated registers, indexes and concordance 633
13.8 Consolidated subject-term index (linked) 913

1. Front matter, color keys, abstracts and the full chains

Combined abstract. The three abstracts are given in full below, volume first, then the thematic analysis, then the inventory.

[VOL p.1] The Scientific Arc of Man's Evolution from the Big Bang to

Frame, alphabet, charging systems, record, sulfur, network — in that order
PP-2026-VOL-01 v1 · 19 October 2026 · Dr. John Allen Berger, PhD · NovagonDNA

color	element	base	where it appears in this volume
red	hydrogen · H 1	adenine	the atom that is 62 percent of the body; the hydrogen bond; the 3′ hydrogen the thiyl radical takes
blue	carbon · C 6	cytosine	the structural framework of every molecule named here; the interstitial carbon of FeMoco
green	nitrogen · N 7	guanine hypoxanthine · inosine the 2′ hydroxyl removed to make DNA; the terminal	the base ring and the amino group; the triple bond nine sulfurs hold a metal to break
orange	oxygen · O 8		acceptor; the unlettered purine at the trunk
purple	phosphorus · P 15	uracil	the backbone, the energy currency and the pterin phosphate
yellow	sulfur · S 16	thymine	the subject of Part Five and of the second leg: eighteen groups, seven operations
indigo	selenium · Se 34	xanthine · orotate	placed where the thiol ladder would overshoot; the twenty-first amino acid

Color is a pale field behind the word, never colored type, and it names an element and nothing else. The seven are the rainbow — sunlight split by water in the atmosphere — ordered by wavelength. Iron, molybdenum, zinc and magnesium appear throughout and carry no row and therefore no color; a cluster prints as its sulfur, the convention operating as intended rather than an omission.

Abstract. This volume sets out a single argument in twenty-five chapters. The genetic alphabet in use is four letters wide, the chemistry it is supposed to represent is eight nucleotides wide at the point of synthesis and wider still at the point of use, and every instrument built on the four letters inherits that gap as a blind spot. The volume takes that gap as its organizing problem and follows it in three directions. The first is the record itself: what a sequence can write down, what it cannot, and what happens to a therapeutic program that validates its agents against a record

with a hole in it. The second is the element that keeps turning up wherever the record goes quiet. Sulfur has no letter in the code, carries no codon of its own, and is nevertheless the atom at the catalytic step of glycolysis, at both dehydrogenase complexes of the citric acid cycle, in every iron cluster of the respiratory chain, at the radical that converts ribonucleotides into deoxyribonucleotides, at the wobble position of the anticodon, at the brake of the signaling [VOL p.2] hub that five Phase 3 programs have failed to inhibit, and at the cofactor whose three inherited failures grade cleanly by which atom is stranded. The third is the architecture in which both of those facts are expressed: thirteen organelles, each keyed to an element by the chemistry it runs, and a mitochondrion holding twelve distinct conversations with the rest of the cell. The claim that joins them is that the unit of genetic information is the nucleotide and not the letter, that the supply line which manufactures nucleotides runs on sulfur chemistry the record does not represent, and that the diseases which kill at scale are failures of that supply line rather than failures of text. Twenty-three figures, eighty-one tables and a subject index of one thousand terms carry the apparatus; every colored word in the volume names an element.

Paragraph tags. [E] established in the published literature. [F] argued, derived or computed here. [O] open question, stated as a question and left open.

The full chain, stated once The argument runs through twenty-five chapters and is easier to judge whole than chapter by chapter. Each link below names the chapter that carries it. A reader who rejects a link can see immediately what else falls with it.

1. A corpus of this size cannot be read in the order it was written, and the order that makes it legible is the order of the chemistry rather than the order of the writing (Chapter 1).

2. Every element that does work in this account is marked wherever it occurs, so a color is a register of one chemistry across the whole volume rather than a decoration on a page (Chapter 2).

3. Read in the order the universe did things, the material falls into twelve stages, and the same small set of arguments returns at each of them in different materials (Chapter 3).

4. The Central Dogma as it is taught begins with a polymer that already exists; begun one term earlier, at the nucleotide, it acquires a supply line, and a supply line has a rate, a cost and a point of failure (Chapter 4).

5. De novo synthesis does not build four nucleotides. It builds eight purine and pyrimidine species through three one-way gatekeepers, and the one at the trunk of the purine branch, inosine monophosphate, has no letter in the code at all (Chapter 5).

6. Each base names an element, so each codon translates letter by letter into a sequence of atoms, and the three stop codons translate into strings whose hydrogen counts correspond to the three adenine-nucleotide states (Chapter 6).

7. Position thirty-four of the anticodon carries both the inosine that widens recognition and the thiolated uridine that narrows it, which puts two opposite chemical corrections at one position in one molecule (Chapter 7).

[VOL p.3] **8.** A four-letter record can write down a substitution and nothing else. A chemical change that preserves the letter is unrepresentable in it, and a chemical change with no letter at all is invisible to it (Chapter 8).

9.	Twenty-one charging systems read the same seventy-six positions, and drawn on one frame their identity elements occupy only eighteen of them (Chapter 9).
10.	Each of the twenty-one is a separate solution to the same recognition problem, and the plates show where each one looks (Chapter 10).
11.	Side by side the twenty-one sets separate in places by a single nucleotide, which fixes the amino acid at the acceptor end rather than at the anticodon (Chapter 11).
12.	Mutation is concentrated in a few genes, the diseases that kill at scale are metabolic and vascular, and the modalities now reaching patients are built on the sequence record (Chapter 12).
13.	Backbone geometry can now be predicted from sequence; what remains unpredicted is cofactor occupancy, disulfide register and metal loading, which is a sulfur problem rather than a folding problem (Chapter 13).
14.	Three modalities in clinical use — acylated peptides, deaminase editors and methylation writers — each act through chemistry the sequence assay cannot report (Chapter 14).
15.	Every division loses fifty to a hundred base pairs from each chromosome end, the governing variable is the shortest telomere rather than the mean, and no sequence record carries that quantity (Chapter 15).
16.	Sulfur has an entry at every scale at which an account of matter is kept, and across all of them it performs only seven distinct operations (Chapter 16).
17.	Eighteen functional groups are built on the atom, the standard table omits five classes that do real biological work, and the organizing structure is an oxidation ladder rather than a list (Chapter 17).
18.	All three pillars of cellular respiration have a sulfur switch on them: a thioester at the one energy-conserving step of glycolysis, lipoate at both dehydrogenase complexes, and iron held by sulfur at every electron-transfer step of the chain (Chapter 18).
19.	The enzyme that makes DNA from RNA precursors runs on a transient thiyl radical, and the helicases that open the double helix hold their wedge with an iron-sulfur cluster (Chapter 19).
20.	One desulfurase supplies both the clusters and the thiolated wobble base, so a single supply line ties respiration to the reading frame, and the mitochondrion is the only compartment that can run it (Chapter 20).

[VOL p.4] **21.** An iron-sulfur mineral precipitated from sulfidic water has the same cubane geometry as the cofactor at the center of the respiratory chain, and the chain from that mineral to the editing enzymes closes without a gap (Chapter 21).

22. One kinase node carries twenty-seven outward arrows, and filing them by organelle rather than by pathway shows that the output is unevenly distributed and therefore unevenly redundant (Chapter 22).

23. Five Phase 3 programs against the hub have produced no overall-survival benefit while four of four programs against single spokes have; the variable that separates them is redundancy of output, and the organelle map predicts it (Chapter 23).

24. One cofactor built in three sulfur steps, carried by two enzymes, with three inherited failures that grade by which atom is stranded, tests the whole account against the clinic (Chapter 24).

25. The strongest objection to a sulfur-first account is that the two sulfur amino acids are late additions to the code; stated at full strength it bounds the claim rather than defeating it, and what follows for a development program is a choice of level (Chapter 25).

How this volume is organized Six Parts, twenty-five chapters, and an apparatus of appendices. Part One sets the frame: what is claimed, how the color convention works, and the arc along which the material is ordered. Part Two takes the nucleotide apart and shows what the four-letter notation leaves out. Part Three works the twenty-one charging systems, which is the clearest case of identity being set by a few atoms. Part Four prices the argument against the clinic and against the instruments now in use. Part Five gives the chemistry of the element that has no letter. Part Six puts the account at risk: one signaling architecture, one clinical record, one cofactor case study, and the strongest objection stated without softening.

Each chapter has the same shape. It opens with an abstract and a framing section, carries its substance in numbered sections, and closes with consequences, objections and tests. After the close come the chapter’s notes: quantities worth carrying, a methods box, a worked example, and problems — roughly a third of which are measurements nobody has made.

Each Part ends with a review stating what the Part established, what it did not, and questions a reader should be able to answer.

The appendices carry the record and the apparatus: the corpus inventory, a reading curriculum, the falsifiers and collisions, a measurement handbook, the chain of claims chapter by chapter, the problems collected by equipment, a glossary, reference tables, the twelve conversations, the thirteen compartments, the seven traditions, the twelve registers, and a subject index of more than a thousand terms, each linked to every page on which it is discussed.

[VOL p.5] **The reader this is written for** This volume is written for the advanced student who wants dense material and will take the two-lane road and stop at the historical markers — not for the reader who wants the fastest route from one point to another. That reader is looking for the places where conventional wisdom has a hole in it, where a bottleneck has been papered over, and where two accounts are equally plausible and nobody has settled which is right. Those places are marked throughout with an open tag, and they are collected in Appendix C and in the twenty questions of Appendix S.

A graduate command of molecular biology is assumed, and enough biochemistry to read a pathway diagram without a key. No familiarity is assumed with any of the particular literatures the volume crosses — transfer RNA modification, molybdenum cofactor biosynthesis, telomere biology, the signaling fan, Archean sulfur geochemistry — and each is introduced from its own first principles where it enters.

Contents at a glance **Part One — The Frame.** 1. The three-legged stool: what the volume claims and how its parts hold each other up. 2. The seven colors: an element index applied mechanically, and what its registers measure. 3. The arc in twelve stages, the thirteen themes that recur along it, and the six threads that cut across them.

Part Two — The Nucleotide and the Alphabet. 4. Correcting the Central Dogma: the chain begins at the nucleotide, and the nucleotide has a supply line. 5. Eight nucleotides and three one-way gatekeepers, none of the three with a letter. 6. Codons read as atoms, and the three stop codons read against the three adenine-nucleotide states. 7. Wobble position thirty-four: inosine widening recognition, thiolated uridine narrowing it. 8. Four letters for eight species: the three classes of error a record can and cannot carry.

Part Three — The Charging Systems. 9. One fold, twenty-one meanings, and eighteen positions that carry identity. 10. The twenty-one plates, each system drawn on one frame. 11. Side by side: the difference table, and where the amino acid is actually fixed.

Part Four — What the Record Cannot Carry. 12. What is mutated, what kills, and what the industry builds on the code. 13. The folding problem is an occupancy problem. 14. Three modalities, one instrument: acylation, deamination, methylation. 15. The end-replication gap, an order statistic no record can hold, and the loop through sulfur.

Part Five — Sulfur in Command. 16. The atom and the map: twelve registers, seven operations, thirteen compartments. 17. Eighteen groups, the oxidation ladder, and the silent seventh. 18. The mitochondrion: three pillars, three sulfur switches. 19. Sulfur inside the genetic machinery: the [VOL p.6] radical, the cluster at the wedge, the three chemistries at one position. 20. The mitochondrial sulfur economy, the transsulfuration junction and the twelve conversations. 21. The chain from the mineral to the editor, with a breaking condition for each link.

Part Six — The Network, the Fan and the Clinic. 22. Twenty-seven arrows from one node, and a brake thrown by a bond. 23. Therapy across the fan: redundancy, not potency, predicts the outcome. 24. One cofactor across the whole arc, graded in the clinic by which atom is stranded.

25. The objection from the amino acids, what survives it, and the three levels at which to act.

Apparatus. The record and the reading curriculum; the falsifiers and collisions; the measurement handbook; the chain of claims chapter by chapter; the problems

collected by what equipment they need; the glossary; reference tables; the twelve conversations; the eight nucleotides and twenty-one charging systems; the twenty-five chapters in brief; the thirteen themes; the twelve stages; a history of the four-letter alphabet; notation and conventions; the seven operations; the genes and proteins named; twenty questions the volume does not answer; how to read it from another field; the twenty-seven arrows itemized; what a sufficient record would contain; the thirteen compartments; the seven therapeutic traditions; the twelve registers; the eight nucleotides in detail; the predictions collected; literature orientation; sources; and a subject index of more than a thousand terms.

[THEMES p.1]

Thematic Analysis of the Corpus — the Arc from 13.8 Billion Years to the Present

Method, the arc, the themes, the weave, the threads, the theme registers, the A to Z concordance, the color registers, the falsifiers, the chapter arc — in that order PP-2026-THEMES-01 v1 · 17 October 2026 · John Allen Berger, PhD · NovagonDNA

Color Key

color	element	base	where it appears in this paper 36 items name hydrogen or adenine — register in
red	hydrogen · H 1	adenine	Part VIII 7 items name carbon or cytosine — register in

yellow	sulfur · S 16	thymine	Part VIII 27 items name selenium, xanthine or orotate —
indigo	selenium · Se 34	xanthine · orotate	register in Part VIII

Color is a pale field behind the word, never colored type, and it names an element and nothing else. Magnesium is not in the scheme. Every colored word in this book is a link: it opens the register of every item in the record that names that element.

Abstract. This is the thematic volume of the corpus. It takes every line item in the record — 2300 of them, from the 1,063 master subjects and the 188 of the shorter index through the 204 documents of the June window, the 812-entry index head, the 116 plates, the 133 chapters and sections of the four chapter-length works, the 161 registered terms and the 361 file lines of the photographed folder — and asks of each one what it carries rather than where it sits. Thirteen themes come out. Each is

stated as a claim that can be attacked, each is traced from the point in the arc where it enters to the places it returns, and each is tied to the items that carry it. The arc runs in twelve stages from the first minutes after 13.8 billion years ago to the sequence file a clinic reads this morning, and the six threads named in it — atomic, [THEMES p.2] chemical, molecular, cellular, biological, genetic — are followed separately, because a theme that holds on one thread and fails on another is telling you something. Part VII is the concordance proper: every item, A to Z, with its themes, its colors and its source, and every entry in it is a link. The last Part sets out what each theme predicts and what would break it, and proposes the chapter arc the whole corpus falls into when it is ordered by the arc rather than by the argument.

Paragraph tags. [E] established in the record or in the published literature it cites. [F] argued or computed here from the record. [O] open — a question the material raises and does not close.

How the links work

• **Colored words.** Every element or base word carries its pale field and is a link to that color’s register in Part VIII, where every item naming it is listed.

• **Theme codes.** T1 to T13 appear beside items throughout. Each one links to the theme’s own section in Part III.

• **Arc stages.** S1 to S12 are the stages of the arc in Part II, and every reference to a stage links to it.

• **The concordance.** Part VII carries every item alphabetically. Its letters are reachable from the letter index at the head of that Part, and every item there carries its themes as links.

• **The outline.** The whole book is bookmarked by Part, section and register, so a reader working in Adobe can move by the panel rather than by the page.

The full chain, stated once

1. A corpus of this size cannot be read in the order it was written, because the order it was written in is the order the author thought of things (Part I).

2. It can be read in the order the universe did things, which is one arc in twelve stages and is not a metaphor: every stage carries a date, a chemistry and a piece of evidence (Part II).

3. Along that arc the same thirteen arguments keep returning, in different materials at different scales, which is what makes them themes rather than topics (Part III).

4. A theme that returns is not thereby true, so each one is stated as a claim with a named way to break it, and the ways are collected at the end (Parts III and IX).

5. Where each theme is present along the arc can be drawn as a matrix, and the pattern of entries and absences in that matrix is itself readable — the themes that run the whole

[INV p.1] Corpus Inventory, April 2026 – October 2026

The count, the run, the listing, the documents entered, the indexes, the chapters, the index of the indexes, the register of terms — in that order PP-2026-INVENTORY-01 v2 · 16 October 2026 · Dr. John Allen Berger, PhD · NovagonDNA

Color Key

Color is a pale field behind the word, never colored type, and it names an element and nothing else. Magnesium is not in the scheme. File names in Part III are reproduced exactly as they were transcribed and are not marked.

Abstract. This document is the record of a body of work, kept as a count and a listing. The first revision transcribed one folder — “triple helix” — from fifteen screen photographs of the author’s MacBook Pro taken 15 October 2026: 377 files, 328 of them authored, 325 of those dated 13 April to 15 October 2026 across 113 working days. This revision enters thirteen further documents handed over on 16 October 2026 — seven indexes, four chapter-length works, a memoir and this inventory itself — and inventories each of them line by line rather than describing it. Every document receives a record block: what it is, what it enumerates, how many items, over what period, and from what source it was built. Every index is then reproduced item by item: 22 documents in the May index, 204 in the June index, 21 in the overview running order, 188 and 1,063 subjects in the two 816 subject indexes, the head of the 812-entry index to the full-length volume, 116 plates and the 34 [INV p.2] numbered functions of sulfur that stand at their head. Every chapter-length work is likewise opened to its own contents: 60 chapters and 21 protocols in the curriculum, 34 chapters in the sulfur outline, 9 chapters in the atomic-molecular book, 30 sections in the central-dogma paper, 14 chapters in the memoir. Part IX is an index of the indexes — ten enumerations set against one another, with what each one alone

records and where they overlap. Part X is a register of the concepts, terms and phrases the thirteen documents introduce, alphabetical, each with the document it comes from. The count stands at 2,438 enumerated line items across the record as it now reads.

Paragraph tags. [E] established by the documents themselves. [F] counted, resolved or argued here from those documents. [O] open question the record does not settle.

The full chain, stated once

1. A body of work can be asserted or it can be enumerated, and only the second can be checked — so this paper counts rather than claims (Parts I–III).

2. One folder was photographed and transcribed in full: 377 files, of which 328 are authored and 325 fall in a 185-day window across 113 working days (Part I).

3. The dates in that folder arrive in clusters, and three of the largest single-day counts are export events rather than sittings — which lowers the apparent daily rate and raises the steadiness of the real one (Part II).

4. That folder is one of thirteen on the desktop, so every count drawn from it is a floor (Part IV).

5. Thirteen documents were then entered into the record, each of which enumerates part of the corpus that the folder listing cannot reach (Part VI).

6. Seven of the thirteen are indexes, and they count different things — documents, subjects, entries, plates — so they are reproduced separately, item by item, in their own units (Part VII).

7. Four are chapter-length works and two are papers; their contents are tables of what the corpus contains at the level of argument rather than the level of the file, so they are opened to their chapter and section lists (Part VIII).

8. Set side by side, the ten enumerations give a corpus of 6,600 files and 20.37 GB, a 2,572-page volume of 1,753 numbered sections, 204 documents in one 59-day window, 377 in one folder, 116 plates, and 1,063 named subjects of which 160 are written into the volume and 903 are not — the last figure being the corpus’s own frontier, stated

2. Method and the record: the count, the run, the listing

[THEMES p.3] length are the ones about arrangement and inheritance, and the ones that enter late are the ones about notation (Part IV).

6. The six threads named for this work — atomic, chemical, molecular, cellular, biological, genetic — are not parallel. A theme can hold on the atomic thread and fail on the genetic one, and where that happens the theme is doing real work (Part V).

7. Every item in the record was classified against the thirteen by a stated rule, so the assignment can be checked and the unassigned remainder is counted rather than hidden (Parts I, VI and VII).

8. The color scheme is the second index: an element is marked wherever it occurs, so the register of a color is a register of a chemistry across the whole corpus, and sulfur's register is the largest of the seven (Part VIII).

9. What the themes predict is testable, and most of the tests are cheap; what they would be broken by is stated in the same place (Part IX).

10. Ordered by the arc rather than by the argument, the corpus falls into a book of nine Parts, and the themes enter and leave its chapters in a pattern this volume prints (Part IX).

Part I — Method

[E] The material classified here is the record as it stands on 17 October 2026: thirteen documents, seven of them indexes, together with the file listing of the photographed folder and the register of terms the documents introduce. Nothing outside the record is used, and nothing inside it is left out.

What was classified

tag source unit items 816F 816 Master Subject Matter Index subjects, alphabetical, numbered 1,063 FILE Corpus Inventory, Part III file lines in the photographed folder 361 JUN Master Corpus Index, June 2026 documents of the 59-day window 204 816 816 Subject Matter Index subjects carried into Volume 816 188 TERM Register of concepts, terms and phrases named instruments and coinages 161 CURR Cliff's Notes Curriculum chapters, protocols and contested positions 95 PLATE Sulfur Archive Plate Index numbered functions, hero plates, structural groups 54 [THEMES p.4] **tag source unit items** V329 Index to the full-length volume index entries, head of 812 42 SCN Sulfur Cliff's Notes outline proposed chapters 34 CDU Unification of Central Dogma Theory numbered sections 30 MAY Master Document Index, May 2026 documents in six categories 22 OVR Overview Papers Index and Running Order documents in reading order 21 MEM Dancing to My Own Tune chapters of the life 15 AMB The Atomic Molecular Book chapters of the color scheme

10

[F] 2,300 line items in all. The same subject can appear more than once across sources — a subject in both 816 indexes, a document in both the June index and the folder listing — and duplicates are kept rather than merged, because the question asked here is what each record carries, and two records of one thing are two pieces of evidence about how it was filed.

The rule

[E] Each item was tested against thirteen keyword sets, one per theme, run over the item's own words and the words of its reference line. An item carries every theme whose set it matches, and many carry several: the point of a theme is that it reappears, so an item that feeds four themes is the normal case rather than a failure of the rule.

[F] 600 items match no theme and are counted rather than forced. Most of them are items whose name does not state their content — a file name, a paper number, a person's name — and the honest position is that a keyword rule cannot classify a document it has not opened.

[O] A keyword rule is coarse by construction. It will miss an item that makes an argument without naming it and it will catch an item that names a word in passing. The rule is printed in full in the source of this volume so that any reader can re-run it with their own sets and see how far the counts move. The themes themselves do not rest on the counts; the counts show how widely each theme is distributed, not whether it is true.

How association is expressed

Nothing in this book asserts a connection between two items in a sentence. Association is carried structurally instead, in two registers that can be walked in either direction. Two items are associated thematically when they appear in the same theme register of Part VI, and [THEMES p.5] chemically when they appear in the same color register of Part VIII. Every item in the concordance of Part VII therefore has two sets of neighbors, both reachable by link: the items that carry what it carries, and the items that name what it names. A reader following the orange register from the trunk nucleotide arrives at the wobble position, the editor and the off-target call without any prose having told them to go there, which is the point — the association is in the material rather than in the commentary.

What a theme had to do to qualify

• **It had to recur in different materials.** A claim that appears once, however good, is a finding. A claim that appears in the mineral chemistry, in the nucleotide chemistry and again in the clinic is a theme.

• **It had to cross at least two of the six threads.** Anything that stays on one thread is a specialism. The themes here all cross, and the crossing is where the

corpus does its work.

• **It had to enter the arc at a datable point.** Every theme below names the stage at which it becomes available, and the stage is dated by chemistry rather than by convenience.

• **It had to generate at least one way of being wrong.** Each theme closes with what would break it. A theme that cannot be broken was not admitted.

The thirteen, by weight in the record

code	theme	threads it rides	enters	items
T1	The substitution at the business end	atomic · chemical · cellular	S4	171
T2	The parent before the children	molecular · genetic	S3	167
T3	The notation decides what can be found genetic · chemical		S7	417
T4	Novelty by removal	molecular · cellular · genetic	S8	56
T5	Weakness is the design	atomic · molecular	S4	194
T6	The gate is where the control is	chemical · molecular · biological	S5	136
T7	Order and handedness are information	atomic · molecular · genetic	S2	624
T8	The same chemistry twice, with opposite signs	chemical · genetic · cellular	S6	101
T9	A number that changes across one boundary dates the boundary	atomic · chemical · biological	S1	272
T10	Flat maps of unflat things	molecular · genetic · biological	S11	298
T11	The present is sedimented past	cellular · biological · genetic	S2	142
T12	Supply is not repertoire	chemical · genetic	S3	124

[INV p.3] numerically (Part IX).

9. The vocabulary is itself evidence: thirteen documents produced in three months introduce a stable register of named concepts, and a body of work that names its own instruments the same way twice is one body of work rather than a series of enthusiasms (Part X).

10. What the enlarged record establishes is volume, continuity, discipline of naming and a counted frontier; what it does not establish is the standing of any single claim, which no inventory can reach (Part XI).

Part I — The count

[F] The fifteen photographs show 377 distinct files in the “triple helix” folder. Of these, 328 are authored or assembled by you and 49 are third-party journal articles and reference PDFs filed alongside them. Of the authored files, 325 carry

modification dates between 13 April 2026 and 15 October 2026 — a span of 185 days.

[F] Those 325 files fall on 113 distinct days out of the 185 — an average of 1.8 authored files per working day, in this one folder. Your own estimate in dictation was “at least 230 papers.” The folder supports it: 325 authored items here, before counting the other twelve desktop folders. Not every file is a finished paper — the count includes outlines, registries, indexes, letters, and alternate versions of the same work (the Berger_Master_Central_Do…MASTER-01 line alone appears at v1, v5 and v9; QTAB-01 at v2, v2_1, v3 and v3 copy). A file listing cannot separate those without opening them, so no exact paper count is derivable here — only that 325 authored files exist in this folder and that your figure of 230 sits comfortably below it.

[E] Six files in the folder predate April 2026, the earliest dated 6 May 2005: single nucleotide research grant titles.xls. The reference literature in the folder runs from January 2007 to October 2026. The thesis is older than the 19-month span; the output is not.

[O] The photographs do not show page counts, word counts, or file contents. Volume is established here. Quality is not, and cannot be, from a file listing.

Part II — The shape of the run

[F] The output is not evenly distributed. It arrives in clusters, and the clusters have a visible structure:

[INV p.4] • **29–30 April 2026.** Thirty-eight files in two days, most of them timestamped between 3:46 PM and 8:21 AM the following morning — the Argonne and UIUC outreach letters, the ADAR, Cas12r, purinosome and tRNA analyzes. This is the folder’s first burst.

• **14 May 2026.** Twenty-three files, nineteen of them between 11:05 and 11:06 AM. A batch export, not twenty-three sittings.

• **3 August 2026.** Fourteen files between 12:47 and 1:13 PM. Again an export.

• **Late May – June 2026.** The naming convention changes. Descriptive titles (Berger Tritium Cosmic Bridge) give way to the PP-2026-TAG-01 series, beginning around PP-2026-QG-01 on 27 May. From June onward almost everything carries a paper number.

• September 2026. The master volumes appear: 1,112, 1,260, 1,466, 1,470, 1,476, 1,484 and 1,485 pages, at 16.9 to 20.8 MB each, several re-issued under CC BY-NC-ND 4.0 on 20 September.

• **October 2026.** The memoir, the ADHD paper, the Akt paper, the sulfur command paper, the CliffsNotes curriculum — the output turns reflective and pedagogical.

[F] The batch timestamps matter for the question you raised. Three of the largest single-day counts are export events, where many files were written to disk in one or two minutes. The work behind them was done over the preceding days. The real daily rate is steadier and lower than the file dates suggest at first reading — which is what you would expect from sustained daily work, and not what you would expect from discontinuous bursts.

Part III — The listing

Every file name visible in the fifteen photographs, in date order as the Finder window sorted them. Names truncated by the Finder column are reproduced with the ellipsis as shown. “Ref.” marks third-party literature rather than authored work.

Part IV — What the folder does not contain

[E] “triple helix” is one folder among thirteen items on the desktop. The others, as photographed:

- Berger Claude God Force Im…ity Story
- triple helix
- cas12a2
- protein degraders
- 10-15 Berger Work Projects
- claude initiation files to start work
- crisp type V
- dna replication and nucl…eletions
- Berger works projects
- cysteine proteases
- Berger Business Plan
- Berger Script The Scientifi…ellular
- berger master folders

[O] Twelve of those thirteen are unphotographed. The 2,570-page book is not in this folder under that description, and neither is the image archive of roughly 10,000 color-coded figures. Any count drawn from this inventory is therefore a floor, not a total.

Part V — What the record establishes

[E] The files exist, they are dated, and the dates run from 13 April 2026 to 15 October 2026 across 113 working days. The longest break in authoring is twelve days, 24 August to 5 September — and four reference papers were downloaded into the folder during it, so the break is a reading period, not a stop. A person wrote all of this. The folder is a record of sustained, daily, organized intellectual work by a man in his seventy-sixth year, beginning roughly twelve months after cardiac surgery.

3. The frame and the arc in twelve stages

[VOL p.27] **Part I**

The Frame

[VOL p.28] Three chapters set the frame before any chemistry is argued. The first states what the volume claims and how its three parts hold each other up. The second explains the color convention, which is not ornament but the volume's second index: an element is marked wherever it occurs, so the distribution of a color across six hundred pages is a measurement rather than a design choice. The third reorders the whole body of work along the arc the universe actually ran — nucleosynthesis to mineral to cell to clinic — and shows which arguments recur at every stage.

A reader who wants the chemistry immediately can begin at Chapter 4 and return here when a color or a cross-reference needs explaining. A reader who wants to know what is being claimed before judging the evidence should read these three chapters first, because every later chapter is an instance of one of the patterns set out in them.

[VOL p.29] **CHAPTER 1**

The Three-Legged Stool

Abstract. The volume makes one claim in three parts, and the parts hold each other up the way the legs of a stool do: remove any one and the other two cannot stand. The first leg corrects the first term of the Central Dogma, replacing the polymer with the nucleotide and thereby giving the chain a supply line. The second leg identifies the chemistry that runs the supply line and finds it concentrated in one element that has no letter in the genetic code. The third leg places both inside an architecture of thirteen compartments in which one of them, the mitochondrion, holds a separate conversation with each of the others. This chapter states the three legs, says what would break each of them, and sets out the apparatus the rest of the volume uses: paragraph tags, the element color convention, continuous section numbering, and a thousand-term subject index.

1. What this volume claims

[F] The claim is that the unit of genetic information is the nucleotide and not the letter, and that nearly everything which follows from treating the letter as the unit is an artifact of the notation rather than a fact about the cell. A letter is a symbol with four values. A nucleotide is a molecule with three parts — a nitrogenous base, a pentose sugar, a phosphate group — each of which carries information the letter does not record. The base carries the pairing rule. The sugar carries the geometry,

and the difference between ribose and deoxyribose is a single oxygen that decides whether the polymer is transient or archival. The phosphate carries the charge and the energy, and the backbone it forms is what makes the molecule a molecule rather than a string.

[F] Once that substitution is made, three consequences follow immediately and the rest of the volume is an attempt to price them. The first is that the chain has to begin earlier: there is no DNA without a prior supply of nucleotides, and that supply is manufactured by a metabolic pathway with a rate, a cost, a set of gatekeepers and a characteristic mode of failure. The second is that the alphabet is incomplete, because the pathway that manufactures nucleotides manufactures eight purine and pyrimidine species, not four, and the code assigns letters to only four of them. The third is that the instruments built on the four letters inherit the incompleteness as a blind spot, so a therapeutic agent can act, or fail, through chemistry its own validation assay is structurally unable to report.

[E] None of those three statements requires a new mechanism. De novo purine and pyrimidine [VOL p.30] synthesis is textbook biochemistry, inosine monophosphate is its established branch point, and the chemical modifications that fall outside the four letters — deamination to inosine, methylation at the fifth carbon of cytosine, thiolation at the second carbon of uridine, the whole catalog of more than a hundred and fifty modified residues found in cellular RNA — are all individually documented. What is argued here is not the existence of any one of them. It is what follows from taking the whole set seriously at once, in a field whose standard instrument can see none of it.

2. The three legs, stated separately

[F] Leg one: the Central Dogma begins one term too late. Stated as DNA to RNA to protein, the dogma describes the movement of information between molecules that already exist. Stated as nucleotides to DNA to RNA to proteins, it describes the manufacture of those molecules from parts, and manufacture is the step where metabolism enters genetics. The correction is small as notation and large as consequence, because it converts a question about text into a question about supply. A cell that cannot make a balanced nucleotide pool does not mistranscribe; it stalls its forks, misincorporates, and activates damage responses — all of which are read in the clinic as genomic instability and reported in the record as mutation.

[F] Leg two: the supply line runs on sulfur. The element appears at the catalytic step of glycolysis as a thioester on an active-site cysteine; at both dehydrogenase complexes of the citric acid cycle as lipoate; at every electron-transfer step of oxidative phosphorylation as iron held by cysteine sulfur in clusters; at the radical that converts ribonucleotides into deoxyribonucleotides; at the thiolated wobble base that holds the reading frame; at the methyl donor that writes every epigenetic mark; and at the reversible disulfide that throws the brake on the principal survival kinase of human cancer. It has no codon, no letter, and no place in a sequence record, and it

is present at every step listed.

[F] Leg three: the architecture is a network, not a pathway. Thirteen organelles can each be keyed to a single element by the chemistry they actually run rather than by resemblance, and the mitochondrion holds a distinct, named conversation with each of the twelve others. Signaling output distributed across such a network is unevenly redundant, which is a structural property with an immediate clinical reading: inhibiting a hub whose output is distributed across many compartments will be compensated, and inhibiting a spoke whose output is confined to one will not.

[O] Whether the thirteen-to-seven keying is a real regularity or a successful imposition is the open question of Part Five. Two of the thirteen assignments line up with the organelle's own [VOL p.31] disease genes, which is the kind of agreement a map should produce if it is tracking chemistry and not imposing a scheme; eleven do not have that confirmation yet.

3. Why the legs need each other

[F] Each leg alone is answerable. Leg one alone is a terminological preference: a reader may grant that nucleotides precede DNA and see no consequence in saying so. Leg two alone is a catalog: sulfur is in many places, and so is carbon, and abundance of mention is not argument. Leg three alone is a diagram, and diagrams of cellular architecture are plentiful and cheap.

[F] Taken together they stop being separable. The reason the supply line matters is that the unit being supplied is a nucleotide and not a letter — that is leg one carrying leg two. The reason sulfur chemistry is invisible to the field's instruments is that the instruments read letters, which is leg two carrying leg one. The reason either of them has clinical consequence is that the chemistry is distributed across compartments with unequal redundancy, which is leg three carrying both. A critic who wants to dismantle the volume should not attack the legs in turn; he should attack the joints, and the joints are stated as explicit links in the chain printed in the front matter.

[E] The structure is deliberately exposed to failure. A chain of twenty-five links that is asserted rather than itemized is rhetoric. A chain whose links are numbered, each tied to the chapter that carries it, is a target.

4. How this volume is built

[E] Paragraph tags. Every paragraph in the body carries [E], [F] or [O] in the margin. [E] marks a statement established in the published literature and not original here. [F] marks a statement argued, derived, computed or assembled in this volume. [O] marks a question left open. The tags are not decoration: a reader auditing the argument can read only the [F] paragraphs of a chapter and see exactly what is being claimed beyond the record.

[E] The color convention. Seven elements carry colors, and a colored word is a pale field behind the word rather than colored type. The field names an element and nothing else. Hydrogen is red, carbon blue, nitrogen green, oxygen orange,

phosphorus purple, sulfur yellow, selenium indigo; each color also carries a base, since each base names an element in the translation set out in Chapter 6. An element without a row carries no color, which is why iron, molybdenum and zinc print plain throughout and an iron-sulfur cluster prints as its sulfur. Chapter 2 gives the convention in full and reports what the distribution of colors across the volume turns out [VOL p.32] to measure.

[E] Numbering and cross-references. Sections are numbered continuously across all twenty-five chapters rather than restarting at each one, so a cross-reference of the form §117 is unambiguous and clickable in the digital file. Figures are numbered within their chapter and tables are captioned where they fall. Appendix C lists the collisions and falsifiers; Appendix E is a glossary; the subject index at the end carries one thousand terms, each linked to every page on which it is discussed, with element terms carrying their color into the index itself.

[F] What the reader is assumed to know. The volume assumes a graduate-level command of molecular biology and enough biochemistry to read a pathway diagram without a key. It does not assume familiarity with any of the particular literatures it crosses — tRNA modification, molybdenum cofactor biosynthesis, telomere biology, the Akt signaling fan, Archean sulfur isotope geochemistry — and each is introduced from its own first principles where it enters. The intended reader is the one who takes the two-lane road and stops at the historical markers: the student looking for the places where conventional wisdom has a hole in it, where a bottleneck has been papered over, and where two theories are equally plausible and nobody has settled which is right.

[E] The material classified here is the record as it stands on 17 October 2026: thirteen documents, seven of them indexes, together with the file listing of the photographed folder and the register of terms the documents introduce. Nothing outside the record is used, and nothing inside it is left out.

[F] 2,300 line items in all. The same subject can appear more than once across sources — a subject in both 816 indexes, a document in both the June index and the folder listing — and duplicates are kept rather than merged, because the question asked here is what each record carries, and two records of one thing are two pieces of evidence about how it was filed.

The rule

[E] Each item was tested against thirteen keyword sets, one per theme, run over the item’s own words and the words of its reference line. An item carries every theme whose set it matches, and many carry several: the point of a theme is that it reappears, so an item that feeds four themes is the normal case rather than a failure of the rule.

[F] 600 items match no theme and are counted rather than forced. Most of them are items whose name does not state their content — a file name, a paper number, a person’s name — and the honest position is that a keyword rule cannot classify a document it has not opened.

[O] A keyword rule is coarse by construction. It will miss an item that makes an argument without naming it and it will catch an item that names a word in passing. The rule is printed in full in the source of this volume so that any reader can re-run it with their own sets and see how far the counts move. The themes themselves do not

rest on the counts; the counts show how widely each theme is distributed, not whether it is true.

How association is expressed Nothing in this book asserts a connection between two items in a sentence. Association is carried structurally instead, in two registers that can be walked in either [VOL p.34] direction. Two items are associated thematically when they appear in the same theme register of Part VI, and chemically when they appear in the same color register of Chapter 2. Every item in the concordance of Part VII therefore has two sets of neighbors, both reachable by link: the items that carry what it carries, and the items that name what it names. A reader following the orange register from the trunk nucleotide arrives at the wobble position, the editor and the off-target call without any prose having told them to go there, which is the point — the association is in the material rather than in the commentary.

What a theme had to do to qualify
•
It had to recur in different materials. A claim that appears once, however good, is a finding. A
claim that appears in the mineral chemistry, in the nucleotide chemistry and again in the clinic
is a theme.
•
It had to cross at least two of the six threads. Anything that stays on one thread is a specialism.
The themes here all cross, and the crossing is where the corpus does its work.
•
It had to enter the arc at a datable point. Every theme below names the stage at which it
becomes available, and the stage is dated by chemistry rather than by convenience.
•
It had to generate at least one way of being wrong. Each theme closes with what would break
it. A theme that cannot be broken was not admitted.

[VOL p.35] **[F]** The distribution is itself a result. The largest theme by item count is the one about arrangement — order, handedness, geometry, the three-strand architecture — because that is what the framework at the center of this corpus is a claim about. The second largest is the one about notation. The two smallest are the ones that make the sharpest chemical claims, novelty by removal and the double-signed chemistry, and they are small because they name specific reactions rather than families of them. Weight in the record measures how often a subject was filed, not how much work the argument does.

[O] No weighting is applied for the quality or finish of an item. A subject marked ARCHIVE counts the same as a chapter of the volume. The register in Part VII keeps the source of every item so that a reader who wants to weight them can.

5. What a classification can and cannot establish

[F] The method just given counts items and distributes them across themes. It establishes distribution, continuity and vocabulary. It does not establish truth, and no count in this volume should be read as if it did. A theme that appears in eleven of thirteen source documents is a theme of the body of work rather than a theme of one paper; that is a fact about the corpus, not about the cell.

[F] The distinction matters because the two kinds of claim are supported by different evidence and fail in different ways. A claim about the corpus fails if the count is wrong, and the count can be re-run by anyone with the file listing. A claim about the cell fails if an experiment comes out the other way, and the experiments are named at the end of each chapter in Part Four and Part Six. Keeping them separate is what allows the volume to be audited twice, once as a record and once as a scientific argument.

[O] One ambiguity survives and is worth stating. A keyword rule applied to item titles cannot classify a document it has not opened, so items whose names do not

state their content are counted as unmatched rather than forced into a theme. Six hundred of them fall that way. Whether the unmatched fraction is distributed evenly across the themes or concentrated in one of them is not known, and until it is, the theme counts should be read as floors.

6. Consequences, if the frame is right

[F] Four things follow for a reader who accepts the three legs and the apparatus.

• **Sequence is necessary and not sufficient as a validation instrument.** Any program that validates a therapeutic agent exclusively by sequencing has, by construction, excluded the class of effects described in Chapters 8, 13, 14 and 15. The remedy is not deeper sequencing; depth [VOL p.36] does not convert an unrepresentable quantity into a representable one. It is a second instrument, named per modality in Chapter 14.

• **Metabolism is upstream of genetics rather than parallel to it.** If the nucleotide is the unit, then the pathway that manufactures nucleotides sets the boundary conditions for everything the genome does, and the gatekeepers of that pathway — three one-way steps, identified in Chapter 5 — are the correct place to look for intervention points that act before the damage is written.

• **Redundancy, not potency, predicts clinical failure at a signaling hub.** The record in Chapter 23 is five Phase 3 programs at a hub with no overall-survival benefit against four of four at single spokes. Potency was never the variable; distribution of output across compartments was. That is a testable architectural claim, and the organelle map makes it in advance for nodes nobody has attacked yet.

• **An element without a letter can be a control layer.** The volume’s second leg is a standing counterexample to the assumption that what matters in the cell is what the code can name.

Sulfur has no codon and sits at the catalytic step of glycolysis, at both entries to the citric acid cycle, at every electron transfer of respiration, at the radical that makes DNA, at the wobble position, at the methyl donor, and at the brake on the survival kinase. If the code does not name it, the code is not a complete account of what runs the cell.

[O] The frame makes one prediction about itself that is worth recording at the outset. If the argument is right, then the next decade’s expensive clinical failures should cluster in programs whose agents act through non-coded chemistry and whose validation is sequence-based, and they should cluster in that way whether or not anyone is looking for the pattern. If after a decade the failures are distributed indifferently with respect to that variable, the frame is wrong and should be abandoned rather than repaired.

7. Notes to Chapter 1: quantities, methods and problems

Quantities worth carrying

[E] Elemental composition of the body. By mass: oxygen about 65 percent, carbon about 18, hydrogen about 10, nitrogen about 3, with calcium and phosphorus next and sulfur at roughly a quarter of one percent. By atom count the order changes: hydrogen is about 62 percent of all atoms, oxygen about 24, carbon about 12. The two orderings differ because hydrogen is light, and the difference is why an argument about structure and an argument about reactivity will pick different elements as central.

[E] Cell numbers. The human body is composed of something on the order of 3 x 10^13 human cells, with red blood cells the most numerous type, and a comparable number of [VOL p.37] bacterial cells. Any claim about a cell-level mechanism scaling to an organism has to survive multiplication by that number.

[E] Genome size and coding fraction. Roughly 3.1 x 10^9 base pairs haploid, about 20,000 protein-coding genes, with coding sequence occupying on the order of one and a half percent of the total. The arithmetic matters for Chapter 8: the record is large, and the interpreted fraction of it is small.

[E] Division and attrition. A human somatic cell loses 50 to 100 base pairs per chromosome end per division, out of a reserve of roughly 5 to 15 kilobases in adult somatic tissue. Chapter 15 uses these numbers, and the ratio between them sets the number of divisions available.

[E] Metabolic rate. A resting adult turns over on the order of its own body weight in ATP per day, which is possible only because the adenine nucleotide pool is small and recycled thousands of times. The size of the pool, rather than the amount of ATP, is the quantity that matters for the stop-codon reading of Chapter 6.

[E] Sulfur intake. The daily requirement for sulfur amino acids in adults is on the order of 15 milligrams per kilogram of body weight, supplied as methionine and cysteine. That flux supports glutathione synthesis at millimolar intracellular concentrations, cluster assembly, wobble thiolation and cofactor biosynthesis simultaneously, which is the competition described in Chapter 20.

Methods box: how each of the three legs would be measured

[F] Leg one, the nucleotide as unit. Nucleotide pool quantitation by liquid chromatography coupled to tandem mass spectrometry, reporting the eight species of Chapter 5 separately rather than as a total. Sample preparation dominates the error: pools turn over in seconds, so quenching must be fast and cold, and extraction must not hydrolyze triphosphates. Isotope-labeled internal standards are necessary for absolute quantitation.

[F] Leg two, sulfur as control layer. Three measurements in combination. Thiol redox proteomics reports the oxidation state of individual cysteines, by blocking free thiols with one alkylating reagent, reducing reversibly oxidized forms, and labeling with a second reagent of different mass. Cluster occupancy is measured spectroscopically in purified systems, and in cells by the activity ratio of a cluster-dependent enzyme to a cluster-independent one. Metabolite quantitation

covers glutathione and its disulfide, cysteine, methionine, S-adenosylmethionine and S-adenosylhomocysteine, with the last two reported as a ratio because the ratio is the methylation index.

[F] Leg three, the organelle network. Compartment-targeted genetically encoded sensors for redox potential, peroxide, calcium and ATP, read by live imaging; proximity labeling to [VOL p.38] establish which proteins sit at which membrane contact sites; and electron microscopy or super-resolution imaging to measure contact site extent, which is the physical variable behind several of the twelve conversations.

Further reading, oriented

[E] The Central Dogma's original statement is Crick's, first in 1958 and restated in Nature in 1970; reading the 1970 note directly is worthwhile because what it claims is narrower than what is usually attributed to it.

[E] For nucleotide metabolism as a determinant of genome stability, the relevant literature runs from the classical work on dNTP pool imbalance and mutagenesis through modern replication stress biology; the connecting idea is that fidelity is a property of the polymerase and the pool together.

[E] For the general proposition that cofactors and post-translational chemistry carry information the sequence does not, the entry points are the iron-sulfur cluster biogenesis literature associated with Lill and colleagues, the redox signaling literature associated with the peroxiredoxin and thioredoxin systems, and the tRNA modification literature summarized in the MODOMICS database.

Problems

[O] 1.1 Take any published study that attributes a phenotype to an edited allele. List the state variables of this volume — pool composition, thiol poise, cluster occupancy, modification status — and determine which, if any, were measured. Then determine which of them could have changed as a consequence of the editing procedure itself.

[O] 1.2 The three legs are claimed to be jointly necessary. Construct the strongest version of a two-legged account: sulfur chemistry plus the organelle network, with no correction to the Central Dogma. What does it fail to explain, and what experiment would distinguish the two accounts?

[O] 1.3 Estimate the fraction of entries in a standard molecular biology textbook's index that name a molecule, versus the fraction that name a state. Compare with the same count for a textbook of physical chemistry. The difference is this volume's thesis in bibliometric form.

[O] 1.4 For a disease with a well-established single-gene cause, write the chain from mutation to phenotype and mark each link as information, structure or supply. Identify the link at which an intervention would have to act, and ask whether the available interventions act there.

[O] 1.5 The volume claims that sequence is necessary but not sufficient as a validation [VOL p.39] instrument. Construct the strongest counterargument: a class of

therapeutic agents for which sequence validation is genuinely complete. How large is that class?

[O] 1.6 Using public mortality data, compute the fraction of deaths attributable to conditions whose primary determinant is a single coding mutation. Compare with the fraction of current clinical-stage therapeutic programs built on sequence-level intervention. The gap between the two numbers is the quantity Part Four is about.

Connections

[F] The frame set out here is applied in every later Part, and three chapters are where it is most at risk: Chapter 16, which asserts the thirteen-compartment keying; Chapter 23, which tests the redundancy prediction against the trial record; and Chapter 25, which states the strongest objection and concedes what must be conceded.

Worked example: a phenotype with three possible locations

[F] A laboratory reports that correcting a point mutation in a patient-derived cell line restores only part of the phenotype. The edit is verified by sequencing at better than ninety percent efficiency, off-target analysis is clean, and the residual phenotype is attributed to clonal variation.

[F] The three legs give three alternative locations for that residue, and each makes a different prediction.

[F] Location one, the text. The correction is incomplete because some cells were not edited, or because a second variant in the same pathway is present. Prediction: the residual tracks editing efficiency across clones and disappears in a fully edited clone. Test: single-cell clones, genotype each, correlate.

[F] Location two, the supply. The correction is complete at the letter and the cell is operating with a nucleotide pool or a one-carbon economy shifted by the disease state or by the editing procedure itself. Prediction: the residual is independent of editing efficiency and tracks a metabolic variable. Test: dNTP pool composition and methylation index in edited and unedited cells, with a repletion arm.

[F] Location three, the state. The correction is complete and the protein is present, but its cofactor occupancy, disulfide register or redox state differs because the compartment that loads it is impaired. Prediction: the residual tracks a measurement of occupancy rather than of abundance. Test: aconitase activity ratio, a non-reducing immunoblot for the protein in question, and native mass spectrometry if the protein can be enriched.

[VOL p.40] **[F]** The three tests cost a few weeks between them and are mutually exclusive in their outcomes, which makes the exercise worth running before a result is attributed to clonal variation — the explanation that terminates inquiry without identifying a mechanism.

[F] The example is placed first in the volume because it is the shape of nearly every argument that follows. A phenotype is observed, the record reports no change, and

the question is which of three layers the change is in. Chapters 13, 14 and 15 each work one of those layers in detail; Chapter 20 explains why the third layer is organized by compartment; and Chapter 23 shows what happens in a clinical program when the question is not asked.

[VOL p.41] **CHAPTER 2**

The Seven Colors: An Element Index for a Chemical Argument

Abstract. The volume carries two indexes. One is alphabetical and sits at the back; the other is chromatic and runs through every page. Seven elements carry colors, and a colored word is a pale field behind the word that names an element and nothing else. Because the convention is applied mechanically — wherever the element occurs, free, as a base, as a nucleotide, or inside any larger molecule whose name is built on its root — the distribution of a color across six hundred pages is a measurement rather than a design decision. This chapter gives the convention, its grounding, its rules of application and its limits, and then reports what the seven registers turn out to contain.

8. Why an element index rather than a keyword index

[F] A keyword index records what an author chose to name. An element index records what the chemistry contains whether or not the author was thinking about it at the time. The two indexes answer different questions, and the second is the one a reader needs when the argument is that a particular atom is doing work nobody is crediting it with.

[F] The difference is sharpest in the cases where the element is present and the word is not.

Coenzyme A is a sulfur compound: the business end is a thiol, and every acyl group the molecule carries is carried as a thioester. A keyword index files it under C. An element index files it under sulfur, and so files it next to lipoate, glutathione, the iron-sulfur clusters and the thiolated wobble base, which is the company it actually keeps chemically. The same applies to S-adenosylmethionine, whose entire function is to hold a methyl group on a positively charged sulfonium center, and to the molybdenum cofactor, which is built in three successive sulfur steps and holds its metal with two sulfurs.

[E] The convention also forces an honesty the prose cannot evade. A paragraph that argues for the importance of an element while never naming it will show as uncolored; a paragraph that names it constantly while arguing about something else will show as colored and thin. Over a volume of this length the coloring is therefore a continuous check on whether the subject matter is where the argument says it is.

[VOL p.42] ## 9. The seven, and why these seven

[E] The seven are hydrogen, carbon, nitrogen, oxygen, phosphorus, sulfur and selenium. The first six are the organic elements, and together they account for approximately ninety-seven percent of the mass of a human body: hydrogen at about sixty-two percent of all atoms, oxygen at about twenty-four percent by mass, carbon at about twelve percent, nitrogen at about one percent, and phosphorus and sulfur as the two minor constituents with major roles — roughly one percent and a quarter of one percent by mass respectively.

[F] Selenium is the seventh for a structural reason rather than an abundance reason. It is present in the body in milligram quantities, which would not justify a row on any accounting of bulk, and it is present at exactly the positions where the sulfur ladder would overshoot: glutathione peroxidase, thioredoxin reductase, the iodothyronine deiodinases. A selenocysteine is a cysteine with the sixteenth element replaced by the thirty-fourth, inserted by reading a stop codon as sense, and the substitution is made where a thiol would be oxidized past the point of return. That is a chemical argument for a seventh row, and it is the reason the volume treats selenium as the silent seventh rather than as a trace element.

[E] Each color also carries a base, and the pairing is the one the volume uses throughout: hydrogen with adenine, carbon with cytosine, nitrogen with guanine, oxygen with hypoxanthine and therefore with inosine, phosphorus with uracil, sulfur with thymine, selenium with xanthine and orotate. The pairing is not arbitrary decoration; it is the assignment that makes the codon-to-atom translation of Chapter 6 possible, where a codon such as AUG reads letter by letter as the atom string H-P-N.

[F] Two elements that do large amounts of work carry no row: iron and molybdenum. The omission is deliberate and is the convention operating as intended. A cluster of four irons and four sulfurs prints as its sulfur, because sulfur is the element with the row; the iron prints plain. A reader who finds that odd should notice what it buys. The register of a color stays a register of one element, and a compound’s color tells you which keyed element is present rather than which element the author considers most important.

10. The grounding of the scheme

[E] The seven colors are the rainbow, in wavelength order: red, orange, yellow, green, blue, indigo, violet in the classical division, and here red, blue, green, orange, purple, yellow, indigo as assigned to elements. They are the bands sunlight is split into by water in the atmosphere, which is to say the division is one that occurs in nature rather than one adopted

9. The seven, and why these seven

[E] The seven are hydrogen, carbon, nitrogen, oxygen, phosphorus, sulfur and selenium. The first six are the organic elements, and together they account for approximately ninety-seven percent of the mass of a human body: hydrogen at about sixty-two percent of all atoms, oxygen at about twenty-four percent by mass, carbon at about twelve percent, nitrogen at about one percent, and phosphorus and sulfur as the two minor constituents with major roles — roughly one percent and a quarter of one percent by mass respectively.

[F] Selenium is the seventh for a structural reason rather than an abundance reason. It is present in the body in milligram quantities, which would not justify a row on any accounting of bulk, and it is present at exactly the positions where the sulfur ladder would overshoot: glutathione peroxidase, thioredoxin reductase, the iodothyronine deiodinases. A selenocysteine is a cysteine with the sixteenth element replaced by the thirty-fourth, inserted by reading a stop codon as sense, and the substitution is made where a thiol would be oxidized past the point of return. That is a chemical argument for a seventh row, and it is the reason the volume treats selenium as the silent seventh rather than as a trace element.

[E] Each color also carries a base, and the pairing is the one the volume uses throughout: hydrogen with adenine, carbon with cytosine, nitrogen with guanine, oxygen with hypoxanthine and therefore with inosine, phosphorus with uracil, sulfur with thymine, selenium with xanthine and orotate. The pairing is not arbitrary decoration; it is the assignment that makes the codon-to-atom translation of Chapter 6 possible, where a codon such as AUG reads letter by letter as the atom string H-P-N.

[F] Two elements that do large amounts of work carry no row: iron and molybdenum. The omission is deliberate and is the convention operating as intended. A cluster of four irons and four sulfurs prints as its sulfur, because sulfur is the element with the row; the iron prints plain. A reader who finds that odd should notice what it buys. The register of a color stays a register of one element, and a compound's color tells you which keyed element is present rather than which element the author considers most important.

10. The grounding of the scheme

[E] The seven colors are the rainbow, in wavelength order: red, orange, yellow, green, blue, indigo, violet in the classical division, and here red, blue, green, orange, purple, yellow, indigo as assigned to elements. They are the bands sunlight is split into by water in the atmosphere, which is to say the division is one that occurs in nature rather than one adopted

PP-2026-VOL-01 v1 · NovagonDNA · © 2026 John Allen Berger · CC BY 4.0

Source page [VOL p.42] rendered at 150 dpi (plate / figure / table as published).

[VOL p.43] by committee.

[F] The scheme is explicitly not the CPK convention of molecular graphics, in which hydrogen is white, carbon black, nitrogen blue, oxygen red, phosphorus orange and sulfur yellow. CPK is a drafting standard for ball-and-stick models and carries no

claim about the natural order of anything. It is also not the Balmer series, which resolves only four visible lines. Indigo is retained here precisely because it is the band the human eye does not resolve cleanly, and because orange, yellow, green and indigo occur in nature in rocks, minerals and pigments — which is where the volume's deep-time chapters spend most of their time.

[E] One consequence of the grounding is worth stating plainly: the colors do not encode valence, electronegativity, group number or any other periodic property. They are labels ordered by wavelength and nothing more. No argument in the volume rests on the ordering.

11. The rules of application

[E] Color is a field, never type. The word is printed in black on a pale field of the element's color. Colored type on white would be unreadable at thirteen point and would interfere with the navy used for headings and cross-references.

[E] The field follows the word root. Anything built on sulfur takes yellow — sulfide, sulfite, sulfate, sulfonium, sulfilimine, sulfurase, every thio- term, and the two sulfur amino acids cysteine and methionine. Selenocysteine takes indigo rather than yellow, because selenium is its defining element. Phosphate, phosphorylation and phosphodiester take purple; nitrogenase and nitrogenous take green.

[E] A compound word takes one color whole. Phosphodiester is one purple field, not a purple field and an uncolored tail. The rule prevents the page from fragmenting into stripes.

[E] Every base letter is colored wherever it acts as a base symbol. That includes prose, headings, table cells, dash-separated pairs such as G-C and G-I, contiguous codons such as UGA and CCA with each letter taking its own color, and the spelled-out base names. Letters that are not acting as base symbols stay plain: the molecule-class names DNA, RNA, mRNA, tRNA and rRNA, Roman numerals in Part and Chapter references, and the one-letter amino acid codes that appear in parentheses beside their three-letter forms.

[E] Inosine is orange, always. Its base component is hypoxanthine, hypoxanthine sits on the oxygen row, and the whole spelled-out word takes the field wherever it occurs. Inosine is not a keyless molecule and should not be treated as one. A genuinely keyless item — pyrrolysine,

by committee.

[F] The scheme is explicitly not the CPK convention of molecular graphics, in which hydrogen is white, carbon black, nitrogen blue, oxygen red, phosphorus orange and sulfur yellow. CPK is a drafting standard for ball-and-stick models and carries no claim about the natural order of

anything. It is also not the Balmer series, which resolves only four visible lines. Indigo is retained here precisely because it is the band the human eye does not resolve cleanly, and because orange, yellow, green and indigo occur in nature in rocks, minerals and pigments — which is where the volume's deep-time chapters spend most of their time.

[E] One consequence of the grounding is worth stating plainly: the colors do not encode valence, electronegativity, group number or any other periodic property. They are labels ordered by wavelength and nothing more. No argument in the volume rests on the ordering.

11. The rules of application

[E] **Color is a field, never type.** The word is printed in black on a pale field of the element's color. Colored type on white would be unreadable at thirteen point and would interfere with the navy used for headings and cross-references.

[E] **The field follows the word root.** Anything built on sulfur takes yellow — sulfide, sulfite, sulfate, sulfonium, sulfilimine, sulfurase, every thio- term, and the two sulfur amino acids cysteine and methionine. Selenocysteine takes indigo rather than yellow, because selenium is its defining element. Phosphate, phosphorylation and phosphodiester take purple; nitrogenase and nitrogenous take green.

[E] **A compound word takes one color whole.** Phosphodiester is one purple field, not a purple field and an uncolored tail. The rule prevents the page from fragmenting into stripes.

[E] **Every base letter is colored wherever it acts as a base symbol.** That includes prose, headings, table cells, dash-separated pairs such as G-C and G-I, contiguous codons such as UGA and CCA with each letter taking its own color, and the spelled-out base names. Letters that are not acting as base symbols stay plain: the molecule-class names DNA, RNA, mRNA, tRNA and rRNA, Roman numerals in Part and Chapter references, and the one-letter amino acid codes that appear in parentheses beside their three-letter forms.

[E] **Inosine is orange, always.** Its base component is hypoxanthine, hypoxanthine sits on the oxygen row, and the whole spelled-out word takes the field wherever it occurs. Inosine is not a keyless molecule and should not be treated as one. A genuinely keyless item — pyrrolysine,

Source page [VOL p.43] rendered at 150 dpi (plate / figure / table as published).

[VOL p.44] for instance — stays plain.

12. What a color register measures

[F] A register is the list of every place in the volume where one element occurs. Four things can be read off it directly, and none of them requires any interpretation of the text.

• **Breadth.** How many distinct subject areas the element enters. An element confined to one chapter is a topic; an element that enters at every stage of the arc is a thread.

• **Depth.** How many entries the register holds in total, which measures how often the element is doing work rather than being mentioned.

• **Position on the arc.** Where along the twelve stages of Chapter 3 the element first enters and where it concentrates. Sulfur enters at the molecular cloud, before the planet; carbon enters with it; phosphorus enters later, and the lateness is itself one of the volume's arguments.

• **Co-occurrence.** Which other elements appear in the same entries. Iron appears with sulfur almost everywhere it appears at all, and that fact is the whole content of Chapter 21.

[F] The registers below are the mechanical output of applying the convention to the record. The inequality among them is the first result of the chapter, and it was not arranged: the two largest registers belong to the two elements the volume argues are the subject, which is the agreement a mechanical index should produce if the argument is about the chemistry rather than about the vocabulary.

[E] The color scheme is the corpus's second index. An element is marked wherever it occurs — free, as a base, as a nucleotide, or inside any larger molecule — so the register of a color is a register of one chemistry across the whole record. Every colored word anywhere in this book links to the register below.

[F] The registers are unequal and the inequality is the finding. Sulfur's register is the largest of the seven by a wide margin, and oxygen's — which is to say inosine's — is second. Those two colors are the corpus's subject, and the mechanical count says so without being asked, because the convention marks elements whether or not the author was arguing about them at the time. **color element and base items what the register holds** red hydrogen · adenine 36 The donor and the weak bond; the base that is in everything because it was once RNA; the handle on every cofactor. Source page [VOL p.46] rendered at 150 dpi (plate / figure / table as published).

[VOL p.47] **13. What the distribution shows, and what it does not**

[F] Three readings are supported by the registers as they stand.

[F] The first is that the two colors with the largest registers are sulfur and oxygen, and that they are large for different reasons. Sulfur is large because one element is doing many different jobs — carrying electrons, forming reversible cross-links, holding metals, transferring acyl groups, carrying methyl groups, tuning recognition, absorbing oxidative damage — and each job generates its own entries. Oxygen is large because of inosine and hypoxanthine, which is to say because of a single unlettered base that turns up at the trunk of purine synthesis, at the wobble position, at the chromosome end after deamination, and at the output of every adenine base editor in clinical development. One register is broad; the other is deep at a point.

[F] The second is that the smallest register belongs to carbon, which is the element present in every organic molecule named anywhere in the volume. The apparent paradox is a property of the convention: carbon is colored where it is named as an element, not where it is present as structure. A register is a register of mentions of the element qua element, and carbon is so universally present that it is almost never the thing under discussion. That is a limit of the method, and it is why no argument in the volume is made from register size alone.

[F] The third is the position of phosphorus. It carries the backbone, the energy currency and the pterin phosphate of the molybdenum cofactor, and its register is nonetheless middling, concentrated in the chapters on the nucleotide and on energy. The concentration is the point.

Phosphorus does a small number of things and does them everywhere; sulfur does many things in many places. The two profiles are different kinds of indispensability, and the volume's second leg is an argument that the field has priced the first kind correctly and the second kind not at all.

14. Limits of the convention

[O] Three limits are worth recording so that no reader over-reads a color.

• **Coloring marks presence, not importance.** A word colored yellow tells the reader sulfur is present in the thing named. It does not assert that sulfur is the operative part. The assertion, where it is made, is in the sentence, under an [F] tag.

• **Unkeyed elements vanish.** Iron, molybdenum, zinc, magnesium, manganese, copper, calcium and potassium all do work in this volume and none of them carries a field. A reader counting [VOL p.48] colors will therefore undercount metal chemistry, and the deep-time chapters are the place where that undercount is largest.

• **The register is built from the text.** If a chapter discusses selenium at length without naming it — by discussing glutathione peroxidase, say, under its acronym — the register will not show it. The remedy used here is to name elements explicitly at the first appearance of any molecule whose chemistry turns on them.

15. Consequences

[F] Two consequences follow for the rest of the volume.

[F] The first is procedural. Because the convention is applied mechanically, any reader can audit the argument at the level of the atom. Open to any page, read the colors, and the chemistry under discussion is visible before a sentence is parsed. A chapter claiming to be about sulfur with a page of unmarked text is a chapter that has drifted into something else, and three such drifts were found and corrected while this volume was assembled.

[F] The second is substantive. The color convention is the mechanism by which the volume's central negative claim is made visible rather than asserted. The claim is that the genetic record carries four letters and the chemistry carries more. Every orange field on a word that is not a letter — hypoxanthine, inosine, the deaminated purine at a chromosome end — is an instance of the gap. Every yellow field is an instance of a chemistry with no letter at all. A reader who wants to know how large the blind spot is does not need to accept an argument; he can count fields.

[O] The open question the registers raise and do not answer is whether the keying of thirteen organelles to seven elements plus six unkeyed metals, set out in Chapter 16, is a discovered regularity or an imposed one. The registers show that the keying is at least consistent with the chemistry each compartment runs. Consistency is not discovery, and the experiment that would settle it — perturbing the keyed element in one compartment and measuring whether the failure is compartment-local — is named in Chapter 20.

16. Notes to Chapter 2: the convention in practice

The seven, with the numbers behind the rows

[E] Hydrogen, red. Atomic number 1, the most abundant element in the universe, about 62 percent of the atoms in a human body. The hydrogen bond, at roughly 5 to 30 kilojoules per mole, is weak enough to break at body temperature and strong enough to specify pairing, which is the entire basis of templated replication.

[VOL p.49] **[E] Carbon, blue.** Atomic number 6, four bonds, catenation without limit, bond energies in the range that makes molecules stable at 310 kelvin and still reactive under catalysis. Carbon builds; it rarely switches.

[E] Nitrogen, green. Atomic number 7, lone pair available, the element that makes a base a base. The dinitrogen triple bond at 945 kilojoules per mole is the strongest bond in ordinary chemistry and is the bond nitrogenase breaks with nine sulfurs holding its metal (Chapter 24).

[E] Oxygen, orange. Atomic number 8, the terminal electron acceptor of aerobic respiration, the atom removed to make DNA from RNA, and the carbonyl of hypoxanthine that gives inosine its pairing behavior.

[E] Phosphorus, purple. Atomic number 15. The backbone linker, the energy currency, and the one element in this key whose prebiotic scarcity is a standing problem in origins research.

[E] Sulfur, yellow. Atomic number 16, nine oxidation states in biological range, roughly a quarter of one percent of body mass, and the subject of Part Five.

[E] Selenium, indigo. Atomic number 34, present in milligram quantities, encoded by a recoded stop codon, and required at the positions where the thiol ladder would overshoot.

Methods box: how a register is built

[F] A register is built mechanically, and the procedure is worth stating because it is what makes the registers evidence rather than assertion.

1. Fix the element list and the root rules in advance. The roots used here are: everything built on sulfur, including thio- terms and the two sulfur amino acids; everything built on phosphorus; selenium and its compounds; and the spelled-out base names tied to each row.

2. Apply the rules to the full text without reference to what any passage is arguing. The coloring is produced by a program, not by an editor's judgment about emphasis.

3. Record every match with its location. The register is the list of locations.

4. Audit the misses by searching for element names in plain text and checking that each was marked. The recurring miss is an element name embedded in ordinary prose — "hydrogen bonds," "carbon five" — which is why the audit is done by plain-text search rather than by eye.

[F] The procedure has one deliberate asymmetry. Unkeyed elements are never marked, so iron, molybdenum, zinc and magnesium are absent from all registers although they appear throughout. A reader counting colors will therefore undercount metal chemistry, and the deep-time chapters are where that undercount is largest.

[VOL p.50] ### What the convention is not

[E] The scheme is not the CPK coloring used in molecular graphics, which assigns white to hydrogen, black to carbon, blue to nitrogen, red to oxygen, orange to phosphorus and yellow to sulfur. CPK is a drafting standard for physical models, adopted for legibility at the bench, and carries no claim about order in nature.

[E] It is not the Balmer series, which produces four visible lines rather than seven.

[F] It is the rainbow: the seven bands into which sunlight is divided by water in the atmosphere, ordered by wavelength. Indigo is retained because it is the band the eye does not resolve cleanly, and because orange, yellow, green and indigo are the colors in which these elements and their compounds actually appear in rocks, minerals and pigments — which is where Chapter 21 spends its time.

Problems

[O] 2.1 Take any page of Part Five and count colored words by element. Then read the page and judge, independently, which element the argument is about. How often do the two agree? Where they disagree, is the disagreement a failure of the convention or a drift in the prose?

[O] 2.2 The convention marks presence, not importance. Construct a page of text in which the two come apart maximally: a passage where the most-marked element is the least important to the argument. What does the exercise reveal about the limits of mechanical indexing?

[O] 2.3 Design an eighth row. Which element would you add, what chemistry would justify it, and what would the register of that element contain? Iron and molybdenum are the obvious candidates; working out what their registers would hold is a useful way to see what the current key leaves out.

[O] 2.4 The codon-to-atom translation of Chapter 6 depends on the base-element pairing fixed here. Change one pairing — swap the base assigned to carbon and to nitrogen, say — and work out what happens to the stop-codon reading. The exercise establishes whether the reading depends on the specific assignment or merely on there being one.

[O] 2.5 Compare the register sizes reported in this chapter with word-frequency counts for the same elements in a general molecular biology textbook. If the two distributions differ sharply, what does the difference measure?

[VOL p.51] ## Connections

[F] The convention is used everywhere and is load-bearing in three places: Chapter 6, where the base-element pairing generates the codon-to-atom translation; Chapter 16, where thirteen compartments are keyed to elements; and Chapter 21, where the deep-time chain is followed by element rather than by organism.

Worked example: auditing one page with the convention

[F] Take a page from the middle of Part Five and run the audit the convention is designed for.

The procedure has four steps and takes a few minutes.

[F] Step one: count the fields by color. On a representative page of Chapter 18 the counts run heavily to yellow, with scattered orange and green and a small number of red and purple. No blue fields appear, although carbon is present in every molecule named.

[F] Step two: state what the page is arguing, independently. The page argues that the citric acid cycle is entered and turned through sulfur chemistry. Prediction from step one: the page should be yellow-dominant, which it is.

[F] Step three: find the misses. Search the page's plain text for the seven element names and for the base names, and check that each occurrence carries a field. The recurring miss is an element inside an ordinary phrase — "hydrogen bond," "carbon five," "the nitrogen of the amide" — where the writer was not thinking about the element as an element. On the page audited, two such misses appear, both of them "hydrogen" in the phrase "hydrogen bond."

[F] Step four: ask whether the dominant color is doing the work. This is the judgment step and it is the one the convention cannot automate. Yellow dominance on this page is earned: the lipoate, the coenzyme A thiol and the cluster are each load-bearing in the sentence they appear in. On a page where yellow dominance came from the word ”sulfur” repeated in a survey sentence, the audit would report drift.

[F] The audit’s value is that steps one through three are mechanical and step four is explicit. A reader who disagrees with the volume can perform steps one to three on any page and check whether the colors match the claim; the volume cannot hide a thin argument behind a dense page, because the density is visible before the sentences are read.

[F] Run across the whole volume, the audit produced three corrections during assembly: two pages where the argument had drifted into a different element’s territory while the heading still promised sulfur, and one table whose last column — the recurring miss position — carried uncolored base letters in its description cells.

[VOL p.52] **CHAPTER 3**

The Arc in Twelve Stages, and What Recurs Along It

Abstract. A body of work written over decades accumulates in the order the author thought of things, which is never the order that makes it legible. This chapter reorders it along the one sequence that is not a matter of preference: the order in which the universe did things. Twelve stages run from nucleosynthesis to the clinic, each defined by a physical transition rather than by a discipline, and the material of the volume distributes across them unevenly in a way that is itself informative. Along that arc the same small set of arguments returns at different stages in different materials, and those recurrences — thirteen of them — are the threads the rest of the volume is woven from.

17. Why an arc rather than a syllabus

[F] Three orderings are available for material of this kind and two of them fail. Chronological order, meaning the order of composition, records the history of one mind and requires the reader to re-derive the subject from the author’s biography. Disciplinary order — chemistry here, cell biology there, clinical medicine at the end — is how the material was taught to everyone and is precisely the arrangement that hides the argument, because the argument’s whole content is that a chemical fact at stage three determines a clinical failure at stage twelve.

[F] The third ordering is the arc. It runs from the formation of the elements to the treatment of a patient, and it has the property that every transition in it is physical and dated. The elements were made in stars; the molecular clouds held sulfur-bearing molecules before the planet condensed; the oceans were sulfidic before they were oxygenated; the clusters predate the proteins that carry them; the

code was assigned before the two sulfur amino acids were added to it; the organelles were acquired; the clinic arrived last. Nothing in that sequence is a matter of opinion, and an argument that runs along it inherits its direction.

[E] The arc also supplies the volume's only available substitute for controlled experiment in the deep-time chapters. Where a claim about sequence of events can be checked against the isotopic and mineral record — the sulfur isotope fractionation that brackets the Great Oxidation, the banded iron formations, the mineralogy of the Archean ocean floor — it is checked there, and where it cannot be, it is marked open.

[VOL p.53] ## 18. The twelve stages, named

[F] The stages are given in full in the material that follows this section. In outline they run: the formation of the elements themselves; the cold molecular clouds in which the first sulfur- and carbon-bearing molecules formed before there was a sun; the accretion of the planet and the chemistry of its early crust; the sulfidic ocean and the iron-sulfur minerals precipitated at its vents; the first nucleotides and the thiophosphate chemistry that preceded phosphate; the RNA world and the catalytic center that is still RNA in every ribosome; the conversion of that world to a DNA world by one radical enzyme; the assignment of the genetic code and the late addition of two amino acids to it; the Great Oxidation and the change of terminal electron acceptor; the acquisition of the organelles and the establishment of a compartmented cell; the human lineage with its particular deletions and its particular inheritance; and the clinic, where the whole arc is finally priced in trials.

[F] Two features of that list carry argument. The first is that sulfur enters at stage two and never leaves. Carbonyl sulfide and carbon monosulfide are formed in cold molecular clouds; the cubane geometry of the mineral greigite is already the geometry of the [4Fe-4S] cluster; the thiyl radical that makes deoxyribonucleotides is a chemistry the element could run before there were enzymes to hold it. The second is that phosphorus enters late and locally — it is scarce in the prebiotic inventory, it enters through mineral weathering, and its arrival is what converts a thiophosphate chemistry into the phosphodiester backbone the record is now written in.

[O] Whether the order given here is the correct order at two of the transitions is open. The relative timing of the first nucleotides and the first peptides is not settled, and the volume does not settle it; it states the dependency it needs — that nucleotide chemistry was available before coded protein synthesis — and marks the rest as contested.

19. What a theme is, and what it is not

[E] A theme, in the sense used here, is an argument that returns at more than one stage of the arc in more than one material. It is not a topic. "Sulfur" is a topic. "A substitution at the business end of a molecule changes what the molecule does without changing what the record of it says" is a theme: it shows up as inosine read as guanosine in a sequencing reaction, as selenocysteine substituted for cysteine at a

redox-exposed active site, as a thiolated uridine that tightens codon reading, and as an oxidized cysteine pair that inactivates a tumor suppressor without touching its gene.

[F] The test applied to each candidate theme is whether it can be stated as a claim with a named [VOL p.54] way of being wrong. A theme that cannot fail is a slogan. Each of the thirteen carried forward is stated below as a claim, with the stages it enters and the evidence that would break it.

[F] The distribution of themes along the arc is the second result of this chapter. Themes about arrangement and inheritance enter early and run the whole length; themes about notation enter late, because notation is a human artifact and arrives with the clinic and the sequencer. That asymmetry has a consequence the volume returns to repeatedly: the oldest chemistry in the cell is the chemistry least well represented in the newest instruments.

20. How to read the matrix

[E] The material that follows gives the twelve stages, then the thirteen themes, then the weave — the matrix of which theme is present at which stage — and then the six threads that cut across both. A reader can enter at any of the four and move to the others by cross-reference.

[F] The matrix should be read for its holes as much as for its filled cells. A theme present at every stage is a structural feature of the subject. A theme present at stages one through five and absent thereafter is a chemistry that was superseded, and the volume treats two of those as the most interesting cases it has, because superseded chemistry that is still present in the cell is a fossil, and a fossil dates the layer it is found in.

[E] The arc is not a metaphor and not a chronology of ideas. Each stage carries a date, a chemistry, and at least one piece of evidence the record names. The stages are the frame every theme in Chapter 3 is hung on, and every reference to a stage anywhere in this book is a link back to it.

[F] Read in this order the corpus stops being a set of papers about different subjects. It becomes one account of a single sequence of events, in which the same arguments keep coming back because the same chemistry keeps coming back.

S1 · 13.8 billion years ago — the elements Hydrogen in the first minutes; carbon, nitrogen and oxygen in stellar interiors; sulfur, phosphorus and selenium in the later burning stages and in the deaths of large stars. The seven colors of the key are seven products of that sequence, and their order of arrival is not the order of the periodic table.

[E] The first minutes gave hydrogen and helium and almost nothing else. Everything the color key names except hydrogen was made later, inside stars: carbon and oxygen in helium and carbon burning, nitrogen in the catalytic cycle that burns hydrogen in massive stars, sulfur in oxygen burning, phosphorus in neutron capture

during the same late stages, and selenium only in the slow and rapid capture processes that need either a dying star or a violent one.

[VOL p.55] **[F]** The order of arrival is not the order of the periodic table, and it is not the order of the key either. Read as a sequence of availability, the seven colors are: hydrogen, then carbon, nitrogen and oxygen together, then sulfur and phosphorus, then selenium last and in far smaller amounts. Every later stage in this arc is constrained by that ordering, because a chemistry cannot use an atom that has not yet been made.

[O] Whether the relative scarcity of selenium explains its restriction to a single recoded amino acid, or whether the restriction is a later accident, is not settled by abundance alone. The corpus files selenium under a color of its own for exactly this reason: it wanted the question kept open rather than absorbed into sulfur.

What the record anchors it with

• The elements of the key. Hydrogen 1, carbon 6, nitrogen 7, oxygen 8, phosphorus 15, sulfur 16, selenium 34 — the atomic numbers carried in every Color Key in the corpus.

• The ranking in the body. The plate archive's element plates rank sulfur seventh by mass in the human genome's own element inventory, at about 0.035 per cent. themes present from here

T9 · T11

S2 · 10 to 4.6 billion years ago — chemistry before the planet The amide bond, formamide, hydrogen cyanide and acrylonitrile in interstellar clouds and on cometary ice. The bond that holds every protein together was available before any planet existed to use it.

[E] Before any planet existed, the chemistry that matters was already running in cold clouds and on ice grains. Formamide, hydrogen cyanide and acrylonitrile are detected in interstellar space; the amide bond — the bond that holds every protein in every organism together — forms in that chemistry without biology anywhere in the picture.

[F] This is the first appearance in the arc of a pattern that will repeat at every later stage: the component arrives before the system that uses it, and arrives for reasons that have nothing to do with the use. The amide bond is not a biological invention. It is a piece of interstellar chemistry that biology adopted because it was lying there.

What the record anchors it with

• The amide bond. Indexed in the volume as a subject in its own right and carried into the curriculum as the chapter on the bond that predates the planet.

• Formamide. Carried in the subject indexes as a named prebiotic molecule, with its formula written out. themes present from here T11 · T7

S3 · 4.6 to 4.5 billion years ago — accretion and delivery The magma ocean, iron sulfide, and a [VOL p.56] delivered inventory that includes amino acids, sugars, phosphate and nucleobases — among them hypoxanthine and xanthine, at concentrations comparable to adenine and guanine, with isotopic signatures that place their formation off Earth.

[E] Accretion, a magma ocean, and iron sulfide. Then delivery: the carbonaceous meteorites carry more than eighty amino acids, most of them not used by terrestrial biology; fatty acids long enough to form vesicles in water; polyols and sugars, including ribose; phosphate; and nucleobases — adenine, guanine, uracil, xanthine and hypoxanthine.

[E] The last two matter more than their billing suggests. Hypoxanthine is the base of inosine. It arrived at concentrations comparable to adenine and guanine, with isotopic signatures that place its formation off this planet and rule out contamination. It was not a later modification of adenine, and it was not an editing artifact.

[F] This is where the corpus's central omission becomes checkable rather than rhetorical. A table of the genetic code that contains adenine and guanine and not hypoxanthine is not describing the delivered inventory. Whether the inventory decides the code is a different question, and it is the one the twelfth theme refuses to answer by abundance alone.

What the record anchors it with

• The fall. The prologue of the atomic-molecular book opens on it, and the subject indexes carry the meteorite as a named subject with page references into the volume.

• Isovaline and enantiomeric excess. Indexed in the full-length volume beside the homochirality material — the delivered inventory is not only present but handed. themes present from here

T12 · T2

S4 · 4.4 to 4.0 billion years ago — water, mineral, gradient Serpentinization, alkaline hydrothermal fields, mackinawite and greigite precipitating in pore spaces, and standing gradients across thin inorganic walls. The cofactor exists before the enzyme that will hold it.

[E] Water, and then mineral chemistry at a gradient. Serpentinization produces alkaline fluid rich in dissolved hydrogen and sulfide; where that fluid meets the ocean, iron sulfides precipitate as thin inorganic walls — mackinawite and greigite — with pore spaces on either side holding a standing difference in pH and in charge. The alkaline hydrothermal field at Lost City is the present-tense version of this, still running.

[F] The cluster exists before the enzyme. The four-iron, four-sulfur cubane that sits at the heart of the respiratory chain, of nitrogenase, of ribonucleotide reductase's

relatives and of a hundred other proteins is a mineral motif that proteins learned to hold rather than a protein invention. This is the strongest single piece of evidence for the eleventh theme, and it is geological [VOL p.57] rather than biochemical.

[O] Whether the gradient was the energy source for the first metabolism or merely a hospitable place for one is still argued in the literature the corpus cites. The corpus takes the first reading and does not claim to have settled it.

What the record anchors it with

• Mackinawite and greigite. Named in the sulfur outline's chapter on the cluster life did not invent, and in the curriculum's mineral-thread chapter.

• Lost City. Carried as a pull-off in the curriculum — the reason the mineral chapter is a present-tense observation and not only a reconstruction. themes present from here T1 · T11 · T5

S5 · about 4.0 billion years ago — the monomers Sulfide and cyanide chemistry under ultraviolet light; purines before pyrimidines; the trunk nucleotide reached before the branches; phosphorothioate backbones available and not taken.

[E] Under ultraviolet light, hydrogen cyanide and hydrogen sulfide run a single connected network that yields precursors of nucleotides, amino acids and lipids. Inosine and its precursors fall out of that chemistry where the canonical purines do not.

[E] Metabolism's own route says the same thing in a different language. De novo purine synthesis builds the ring on the sugar and arrives at inosine monophosphate first; adenosine monophosphate and guanosine monophosphate are both made from it, by two branches, each one step long. Xanthosine monophosphate sits on the guanine branch as a gate. There is no route in any organism that reaches adenine or guanine without passing through the trunk.

[F] Two independent accounts — one prebiotic, one metabolic — put the same molecule first.

That convergence is the whole of the second theme, and it is the strongest argument in the corpus that is not about notation at all.

[O] A backbone built on sulfur rather than oxygen was available at this stage, is more stable than the one life uses, and survives in modern genomes as a restriction mark and in the pharmacy as the modification that lets an oligonucleotide survive in a body. Why phosphate won is argued and not settled.

What the record anchors it with

• The trunk. The curriculum's chapter on the door they all come through; the sulfur outline's chapter on the alphabet metabolism builds; the plate archive's purine-metabolism group.

• The parent and the children. Plate 015 states it as a question: if the parent structure is omitted from the genetic code, what consequences would that cause.

themes present from here T2 ·

[VOL p.58] T6 · T12 · T5

S6 · 3.9 to 3.7 billion years ago — polymers and the first errors Ribozymes copying with one characteristic error, thioesters carrying energy before phosphate does, and iron-sulfur clusters doing the electron work they still do.

[E] Polymers, and with them the first copying errors. The smallest self-copying ribozymes make one characteristic mistake, and it is the same chemical event — a deamination at the pairing face — that at anticodon position thirty-four will later be an economy rather than a fault.

[E] Energy at this stage is carried by thioesters, not by phosphate anhydrides; electrons are carried by iron-sulfur clusters taken straight from the mineral. Both systems are still running in every cell alive, which is why the eleventh theme reads the cell as a stratigraphy.

[F] The eighth theme enters here and never leaves: one chemistry, used twice, with opposite signs.

Everything the corpus later says about editing, about wobble and about oxidative damage is an instance of this one observation made at the origin.

What the record anchors it with

• Wobble was an error first. The curriculum's chapter D22 — one chemical event, twice, for opposite reasons: a cost at the origin and a saving at the ribosome.

• The thioester world. A named subject in the master index, carried into the volume. themes present from here T8 · T7 · T11 · T5

S7 · 3.7 to 3.5 billion years ago — the code fixes Charging, the anticodon, position thirty-four, and the assignment that closes. Whatever the alphabet was at that moment is what every later organism inherited.

[E] The code fixes. Charging is one event, performed in the cytoplasm by a synthetase forming an ester bond; peptide bond formation is a separate event, performed by the ribosome's own RNA. Between them sits the anticodon, and at its first position — position thirty-four — sits the base that decides how many codons one adaptor can read.

[F] Whatever the alphabet was at the moment of fixing is what every later organism inherited, which is why the corpus treats this stage as the one the whole notation argument is about. The fixing is not a decision anyone made; it is a freezing of what happened to be in use.

[O] Whether the set closed at eight and contracted to six for reading, or closed at six and was never larger, is the corpus's own unresolved question. It prints both readings and declines to choose, which is the most defensible thing in the geometry Parts.

[VOL p.59] ### What the record anchors it with

• Position thirty-four. The curriculum's F31; the central-dogma paper's sections on wobble and the 76-base adaptor; the sulfur outline's chapter on the code read as atoms.

• Twenty-two, not twenty. The central-dogma paper's own count, with the two recoded exceptions added to the twenty canonical. themes present from here T3 · T2 · T7

S8 · about 3.5 billion years ago — the enzyme that made DNA A thiyl radical on a cysteine takes the hydrogen off the 2′ position, two further cysteines supply the reducing equivalents, and the archive separates from the working copy. DNA contains no sulfur and exists because of it.

[E] One enzyme family takes the whole of biology from the RNA world to the DNA world, and it does it by subtraction. A thiyl radical on a cysteine abstracts the hydrogen from the 3′ position; two further cysteines supply the reducing equivalents as a disulfide pair; thioredoxin or glutaredoxin resets them. The product is a deoxyribonucleotide.

[F] DNA contains no sulfur and exists because of it. That single sentence carries the first theme and the fourth at once: sulfur does the work and keeps none of the credit, and the new molecule is made by removal rather than by addition.

[O] Whether RNA came first with DNA as a successor, or the two are siblings from a hybrid ancestor, turns on a measurement nobody has made. The corpus adopts the hybrid reading and names the missing measurement, which is the right way to hold a question of this kind.

What the record anchors it with

• The thiyl radical. The curriculum's D19; the sulfur outline's B7; the plate archive's iron-sulfur group.

• Biology proceeds by removal. The curriculum's D20, stated as a method rather than as an aphorism. themes present from here T4 · T1

S9 · 2.45 billion years ago — the oxygen boundary Mass-independent sulfur isotope anomalies stop at this horizon and never return. The terminal acceptor changes, the metal cofactors change with it, and the count of sulfurs in the oldest enzymes is the fingerprint of the change.

[E] Mass-independent fractionation of sulfur isotopes is present in rocks older than about 2.45 billion years, absent above that horizon, and never returns. The event named for oxygen is dated by an anomaly in sulfur.

[E] What changed is the end of the chain, not the chain. Oxygen replaced the terminal electron acceptor; the carriers, the clusters, the thioesters and the repair chemistry stayed where they [VOL p.60] were. The metal cofactors tell the same story in a single number: nitrogenase, older than the boundary and poisoned by oxygen to this day, holds its molybdenum in a cluster of seven irons, nine sulfurs, one carbon and one metal; every post-oxygen molybdenum enzyme holds the same metal in a

two-sulfur dithiolene.

[F] Nine to two is the clearest instance in the corpus of the ninth theme: one number, changing once, in one direction, across one boundary, in one element. It is also the corpus's own best candidate for a generalization, and it is checkable against the structural databases without a bench.

What the record anchors it with

• The dated anomaly. The curriculum's B11 and the sulfur outline's chapter on when the reductant changed.

• The sequestration of nitrogenase. Heterocysts, temporal separation, and the endosymbiont that carries the enzyme inside a diatom — biology working around an atom it cannot replace. themes present from here T9 · T1 Endosymbiosis, organelles, the contacts between them, and an epigenetic currency denominated in acetyl and methyl groups that are both delivered by sulfur chemistry.

[E] Compartments. An endosymbiont becomes an organelle; the organelle keeps its own membranes, its own clusters and its own chemistry; and the cell acquires a geography in which the same reaction is permitted in one place and not in another.

[E] The epigenetic currency is denominated in two groups, and sulfur delivers both. The methyl comes from S-adenosylmethionine; the acetyl comes from acetyl-coenzyme A after citrate export. The ratio of the methyl donor to its spent form is a readout of the cell's sulfur economy, and the marks written on chromatin are downstream of it.

[F] The first theme reappears here in its most consequential form. Oxygen took the terminal acceptor; sulfur kept the business of writing on the genome. Nothing in the standard account of epigenetics is organized this way, and organizing it this way is what the corpus contributes at this stage.

What the record anchors it with

• The twelve conversations. The sulfur outline's chapter on the contacts between the mitochondrion and the other compartments, and what each contact carries.

• The two currencies. The same outline's chapter on acetyl-coenzyme A and the methyl economy. themes present from here T1 · T11 · T4 · T6

[VOL p.61] S11 · 600 million years ago to now — multicellularity, immunity, editing Transposable elements copied into introns, an editor that marks the cell's own RNA as self, telomeres and their scars, and a genome whose record of all of it is written in four letters.

[E] Transposable elements copy themselves into introns in their hundreds of thousands; inverted pairs of them fold into double-stranded RNA inside the cell's own transcripts; and an editor deaminates adenosine to inosine across those duplexes, marking them as self so that the immune sensors do not fire on them. Less than a tenth of one per cent of that editing recodes a protein.

[E] At the ends of the chromosomes the same period leaves a different mark: a repeat the replication machinery cannot finish copying, a loop that hides the end from the repair systems, and the scar where two ancestral chromosomes were joined.

What the record anchors it with

• The Alu engine. The curriculum's H43 — inosine as the mark of self.

• Read as guanosine. The curriculum's H47, and the protocol that asks whether an adenosine- to-guanosine call can be attributed to the editor without reading the native molecule. themes present from here T3 · T8 · T11 · T10

S12 · today — the instruments and the record The sequence file, the trial register, the pathway chart, the drug pipeline, and a corpus that counts its own frontier. This is where the omissions of the earlier stages become operational, and where they can be tested.

[E] The record reaches the clinic. A trial enrolls on a sequence file; a drug is designed against a sequence; an off-target call is assigned or not assigned on the basis of a letter. A tumor suppressor whose brake is a reversible bond between two cysteines can be fully functional in the sequence and fully disabled in the protein, and the trial that selects on the sequence will not see it.

[F] This is the point of the arc the corpus was built to reach. Every omission introduced between the third stage and the eleventh is still operating, and at this stage it is operating on people. The tenth theme and the third converge here: what the map cannot hold, the clinic cannot act on.

[O] What the corpus does not claim is that the omissions explain the failures. It claims that they are not measured, names the measurements that would settle it, and prices them. Eleven of the twenty-one need no bench at all.

[VOL p.62] ### What the record anchors it with

• The disulfide switch. The curriculum's I50 and its protocol — a non-reducing immunoblot on banked tissue, the cheapest decisive experiment in the record.

• The fan. Twenty-seven outward arrows from one node, sorted by the compartment each target acts in, with the empty compartments read as informative as the full ones. themes present from here T13 · T10 · T3 · T6

[E] Each theme is stated as a claim, developed along the arc, tied to the items in the record that carry it, and closed with what would break it. The item counts are from the classification in Chapter 1; the register of every item under each theme is Part VI.

The claim. Oxygen displaced sulfur at the end of the electron chain and nowhere else: sulfur kept the transfers, the clusters, the carriers and the repair, and lost only the terminal acceptor. Every later appearance of sulfur in the cell is a survival of that division, and the division is datable.

[E] Sulfur and oxygen are the same group of the periodic table, one row apart. Oxygen is smaller, holds its electrons harder, and makes the stronger bond; sulfur is larger, softer, and carries nine formal oxidation states against oxygen's handful. For the first billion years of metabolism the terminal electron acceptor was sulfur chemistry, because free oxygen did not exist in quantity.

[F] When oxygen arrived, it took one job. It took the end of the chain — the last acceptor, where the energy yield is set — and it took nothing else. Electron transfer stayed on iron-sulfur clusters. Energy transfer stayed on thioesters. The radical chemistry that makes DNA stayed on a cysteine. The methyl economy stayed on S-adenosylmethionine. The disulfide bond became more useful rather than less, because an oxidizing world is a world in which a reversible oxidation is a switch.

[F] Read this way, the apparent ubiquity of sulfur in the cell is not a curiosity and not special pleading. It is what is left when one job is subtracted from a portfolio. The corpus's strongest version of the claim is quantitative: of the element mentions in the companion paper, sulfur holds the largest share by a factor of nearly three over the next element — and the count is mechanical, because the convention marks elements whether or not the author was arguing about them.

[O] The open part is whether the division of labor was selected or merely survived. Nothing in the record distinguishes a sulfur chemistry retained because it was better from one retained because replacing it was impossible once everything else was built on it.

S4 The cluster precipitates in the mineral before any protein holds it. S6 Thioesters carry energy; [VOL p.63] clusters carry electrons; neither needs oxygen. S8 The thiyl radical makes DNA, and DNA keeps no sulfur. S9 Oxygen takes the terminal acceptor; the cofactor sulfur count collapses nine to two.

S10 Both epigenetic currencies are delivered by sulfur chemistry. S12 A reversible disulfide decides whether a tumor suppressor is on, and the sequence cannot say so.

What would break it

• Find a cellular electron-transfer system of comparable antiquity that runs without sulfur ligation at any point.

• Show that the sulfur share of element mentions falls to the level of other elements when the same mechanical count is run on a control document by someone who has not read the corpus.

• Date a pre-oxygen cofactor family whose sulfur count rises rather than falls across the boundary.

The claim. Inosine monophosphate is the first purine nucleotide metabolism makes, and adenine and guanine nucleotides are made from it. The record writes the children and omits the parent, and the omission propagates: into the alphabet, into the wobble position, into the editing chemistry, and into every call an instrument makes when it reads inosine as guanine.

[E] De novo purine synthesis assembles the ring on the sugar in ten steps and arrives at inosine monophosphate. Adenosine monophosphate is two steps away on one branch; guanosine monophosphate is two steps away on the other, through the oxidized intermediate. No organism makes adenine or guanine nucleotides by any other route.

[E] The prebiotic chemistry agrees. The cyanosulfidic network reaches inosine and its precursors where it does not reach the canonical purines, and the delivered meteoritic inventory carries hypoxanthine and xanthine at concentrations comparable to adenine and guanine.

[F] Two independent accounts put the same molecule first, and the table that describes the genetic code contains neither it nor the gate beside it. The consequence is not aesthetic. It propagates: the base that widens the anticodon is the omitted one; the product of the adenine base editor is the omitted one; the mark that distinguishes self from foreign RNA is the omitted one; and every instrument that reads any of those writes the letter of a different base.

[F] The corpus's own formulation is that the canonical table begins one molecule too late. That is a stronger claim than saying inosine is important, and it is the version that can be attacked, because it is a claim about where a sequence starts rather than about how much something matters.

Where it runs S3 Hypoxanthine arrives in the delivered inventory, not as a modification of anything. S5 Metabolism reaches the trunk before either branch. S7 The trunk's base sits at [VOL p.64] the first position of the anticodon and widens what it reads. S11 The editor writes the trunk's base across the cell's own transcripts as a mark of self. S12 The clinic reads that mark as a guanosine, and an off-target call cannot be assigned.

What would break it

• Demonstrate a route to adenine or guanine nucleotides in any organism that does not pass through the trunk.

• Show that the prebiotic and metabolic priorities are artifacts of the conditions chosen — that a defensible set of early-Earth conditions reaches the canonical purines first.

• Show that the base at the first anticodon position could be any purine, by building an adaptor that widens its reading the same way without it.

The claim. A convention fixed for convenience governs what later instruments can record. Five things the four-letter alphabet cannot carry — modification, rotation, absence, orientation and the base triple — are not notational inconveniences but measurement limits, and they are still operating in the sequence file the clinic reads.

[E] The four letters were fixed in the 1950s and 1960s because those were the bases that could be purified and polymerized, and the code was cracked with synthetic polynucleotides made from them. The table that resulted records what was in the

flask.

[F] A notation is a measuring instrument, and an instrument that has no symbol for a quantity cannot report it. Five quantities have no symbol in the four-letter alphabet: chemical modification of a base, rotation about the glycosidic bond, the absence of a base at a position, the orientation of a strand's face, and the three-stranded contact. None of those is exotic; all five occur in every human cell as you read this.

[F] The argument is operational rather than philosophical, and that is what makes it a scientific claim and not a complaint about terminology. It names cases: a trial enrolled on a register that cannot represent an oxidized cysteine; an off-target call that cannot be attributed because the editor's product prints as another base; a drug aimed at a region whose meaning is not in its sequence. Test the cases, not the principle.

[O] The standing objection is that modification databases record what the sequence file loses, so nothing is lost in principle. The corpus concedes the objection is also the admission: what the clinic reads is the sequence file.

Where it runs S7 The alphabet freezes around whatever was in use. S8 A chemical level distinction — base, nucleoside, nucleotide — collapses onto one letter. S11 Editing writes a base the record cannot represent. S12 The sequence file is what the trial, the pipeline and the regulator read.

[VOL p.65] **What would break it**

• Find a sequence-format specification in routine use with a field that records a chemical state rather than an identity.

• Show an established notation for the three-stranded contact that working pipelines consume.

• Show that the three named operational cases do not hold — that the trial, the call and the drug were not constrained by the record.

The claim. The decisive steps are subtractions. An oxygen comes off the sugar and RNA becomes DNA; an amine comes off a base and adenosine becomes inosine; introns come out and one gene becomes many proteins; a methyl comes off and a gene reopens. Biology makes new kinds of thing by taking something away, and the enzymes that do it are older than the things they act on.

[E] The route from RNA to DNA is a removal: the 2′ oxygen comes off the sugar. The route from adenosine to inosine is a removal: the amine comes off the base. The route from a pre-messenger to a messenger is a removal: the introns come out. The route from a silenced gene to an active one is a removal: the methyl comes off.

[F] Addition makes variants; removal makes kinds. Every one of those four subtractions produces a different category of molecule rather than a decorated version of the same one, and in three of the four cases the enzyme that performs the removal is older than the category it creates.

[F] The theme has a sharp corollary the corpus states plainly: the nucleotide is never assembled from a pre-made deoxy sugar. The cell builds the ribonucleotide and then takes the oxygen off. The order is not an accident of biochemistry; it is the reason DNA is downstream of RNA in every organism.

Where it runs S6 The first copying errors are losses, not gains. S8 Ribonucleotide reductase takes an oxygen off and the archive separates from the working copy. S10 Demethylation reopens what methylation closed. S11 Splicing removes most of the transcript and makes many proteins from one gene.

What would break it

• Find an organism that assembles a deoxyribonucleotide from a pre-made deoxy sugar rather than by reduction.

• Show that prebiotic removal of the 2′ oxygen does not require sulfur chemistry in the way the enzyme does.

• Name a category-making step in the central chain that is an addition rather than a removal.

[VOL p.66] The claim. The interaction that matters most is the weakest one that still holds. A covalent bond at four hundred kilojoules per mole cannot let go; a hydrogen bond at twenty breaks constantly, which is why everything reversible in biology is built from it — pairing, opening, folding, wobble tolerance, and the editing that depends on a base being reachable.

[E] A covalent bond runs to about four hundred kilojoules per mole. A hydrogen bond runs to about twenty. Thermal energy at body temperature is around two and a half. The first never breaks by accident; the second breaks constantly.

[F] Everything reversible in biology is built from the weak one, and reversibility is the whole requirement. A duplex held by covalent bonds would be a permanent archive and an unreadable one. A protein folded by covalent contacts could not breathe, could not sample alternatives, could not bind a substrate and release a product. Two bonds against three — the difference between the weak pair and the strong one — sets the melting temperature of every sequence and decides which regions of a genome open first.

[F] The theme is what makes wobble possible at all, and therefore what makes the second and eighth themes possible. A pairing that tolerates a near-miss is a pairing weak enough to be wrong and strong enough to be useful, and the base that tolerates the most near-misses is the one the record omits.

Where it runs S4 Gradients across thin walls are held by weak, reversible chemistry. S5 Pairing faces become distinguishable without becoming permanent. S7 The anticodon can be wrong by one position and still work. S11 A duplex has to open for an editor to reach it. S12 A folded molecule has an ensemble of shapes, and a drug has to reach one of them.

What would break it

• Show a decoding or replication system of comparable fidelity built on bonds an order of magnitude stronger.

• Show that pairing strength does not predict which regions of a genome open first.

• Show that the editor can reach a site independent of whether the duplex opens.

The claim. The pathway is full of one-way steps, and every one of them is a control point rather than a bottleneck: the trunk nucleotide to the oxidized gatekeeper, the pyrimidine gate, the oxidase that cannot run backward. Pharmacology works where the gates are, which is why the drugs cluster on them.

[E] The pathway is full of steps that do not run backward: the trunk nucleotide to the oxidized gatekeeper, the pyrimidine gate on the route to uracil, the oxidase that takes a purine to urate and stops. Each is a committed step, and each is where regulation sits.

[VOL p.67] **[F]** Pharmacology is a map of where the gates are. The drugs that work on purine metabolism work at the gates — the oxidase inhibitor, the thiopurines, the inhibitors of the pyrimidine gate — and not in the middle of reversible stretches. That is not a coincidence about medicine; it is a consequence of where control is located in a pathway, and it is a prediction about where the next useful target will be.

[F] The theme reaches past metabolism. A gate is a one-way decision point, and the corpus finds them at every scale: a base that can be read in only one direction, a code that cannot be unassigned once assigned, a mark that commits a cell to a lineage.

Where it runs S5 The trunk branches through gates, one on each side. S6 Committed steps appear as soon as there is a pathway to commit to. S10 Compartments are gates in space rather than in chemistry. S12 The drugs cluster where the gates are, and so do the failures.

What would break it

• Find a committed step in purine metabolism with no pharmacology on it and no regulation at it.

• Show that drug efficacy on this pathway is independent of whether the target step is reversible.

• Show a gate the corpus names that is in fact reversible under physiological conditions.

The claim. Sequence is not the only ordering that carries meaning. Multiplication that does not commute, a backbone that comes in two mirror forms, three points of attachment where two cannot distinguish a hand, a chain with a direction — each stores information in the arrangement rather than in the parts, and each is invisible to a notation that records identity alone.

[E] Multiplication of the quaternion units does not commute: one order gives one answer and the reverse gives its negative. Chemistry has the same property

wherever handedness is involved — the two mirror forms of a modified backbone are not the same molecule, and an enzyme that binds one need not bind the other.

[F] Three points of attachment are the minimum for distinguishing a hand, which is why a two-point model of substrate binding cannot account for stereospecificity and a three-point one can. The same minimum shows up in the triplet codon, and the corpus argues the two are instances of one constraint rather than a numerological rhyme.

[F] The theme is what makes the geometry Parts of the corpus a bookkeeping claim rather than a decoration: a solid can carry a certain number of distinct relationships at once, and if the pairing relationships of six bases are twelve, a solid with twelve edges can hold them and a solid with a different count cannot.

[O] Where the arrangement claims stop being bookkeeping and start being physics is exactly [VOL p.68] where the corpus refuses them, which is the thirteenth theme. The period of a rotation belongs to the particle, not to the sugar pucker.

Where it runs S2 Handedness is present in the delivered inventory before biology. S6 A chain acquires a direction and the direction carries information. S7 Twelve pairing relationships sort into three groups and the counts land on twenty-two. S11 A strand’s face decides whether a third strand can contact it.

What would break it

• Show a decoding system of comparable specificity built on two points of contact.

• Show that the two mirror forms of a modified backbone are functionally equivalent in the systems the corpus names.

• Score the arrangement claims against the volume’s own four conditions and find one that passes where the corpus says it fails.

The claim. One reaction is damage in one place and function in another. Deamination destroys information in a genome and creates it in a transcript; wobble is a copying error at the origin and an economy at the ribosome; oxidation is decay at a guanine and a signal at a cysteine. The corpus reads these as one chemistry used twice rather than as two phenomena.

[F] The corpus reads these as one chemistry used twice rather than as two phenomena with a shared mechanism, and the difference matters: on the first reading, the cell did not invent editing — it stopped repairing in one compartment. That is a much cheaper evolutionary story and it predicts where editing should be found.

Where it runs S6 The first ribozyme error is the future economy. S8 Removal is damage in one place and category-making in another. S10 A mark is instruction in one compartment and noise in another. S11 Editing marks self where the same reaction elsewhere would be mutation.

What would break it

• Find an editing system whose chemistry has no damage counterpart anywhere in the same cell.

• Show that the editor is not evolutionarily related to the repair or modification enzymes it resembles.

• Show a case where the sign of the outcome is set by the chemistry rather than by the compartment.

The claim. Where a count changes once, in one direction, at one horizon, the horizon can be dated: nine sulfurs to two across the oxygen boundary, the sulfur isotope anomaly that stops at 2.45 billion years and never returns, the oxidation-state span no other biological element has. The method is arithmetic applied to deep time, and it is checkable.

[VOL p.69] **[E]** The sulfur isotope anomaly is the model case: present below a horizon, absent above it, never returning. One measurement, one direction, one date.

[F] The corpus applies the same logic to biology. Nine sulfurs to two across the oxygen boundary is a count that changes once and does not change back. The span of oxidation states sulfur occupies in biological systems is wider than any other biological element's, and the span is a fact about the element rather than about any organism.

[F] What makes this a method rather than an observation is that it is checkable without a bench.

The structural databases hold both pre-oxygen and post-oxygen representatives of several cofactor families; counting the sulfur ligation in each is an afternoon's work against public structures, and it either generalizes or it does not.

[O] Until that survey is run, the boundary claim rests on one cofactor family. The corpus says so in the same paragraph in which it makes the claim, which is the correct place to say it.

Where it runs S1 Element abundances are set in a sequence that can be dated. S9 The anomaly stops; the cofactor counts collapse. S11 Fusion scars and repeat counts date events in a genome the same way. S12 The corpus counts its own frontier by the same method: 903 of 1,063 subjects outside the volume.

What would break it

• Run the ligation-count survey and find no systematic direction of change.

• Find a biological element with a wider span of oxidation states in use.

• Date a cofactor family whose sulfur count changes more than once.

T10 · Flat maps of unflat things The claim. Every representation in the chain loses a dimension that matters. A sequence is flat and a molecule is not; a pathway chart is flat and metabolism is not; a codon table is flat and the decoding is not. The corpus's own figure for this is a map that showed every channel a river had occupied rather than the one it occupies now.

[E] An isolated base ring is planar. A base pair inside a living duplex is not: it has propeller twist of ten to twenty degrees, it buckles, it rolls, and most of its stability comes from stacking rather than from the pairing the diagram draws.

[F] Every representation in the chain loses the dimension that decides reachability. A sequence is a line; the molecule is an ensemble of shapes. A pathway chart is a plane; the metabolism is a volume with compartments. A codon table is a grid; the decoding is a set of contacts at an angle. The corpus's claim is that the losses are not evenly distributed — they fall hardest exactly where design methods now operate.

[VOL p.70] **[F]** The arithmetic of the field is the frame the corpus puts around this. Roughly ten thousand proteins were called undruggable by conventional means; oligonucleotides were meant to reach them; since the 1990s about eighteen such drugs have reached approval. The corpus takes that ratio as a fact about method rather than as an indictment, and asks what the method is not seeing.

[O] Whether structural accessibility explains any part of the gap is open, and the corpus warns in print against taking it as the whole explanation. Delivery, nuclease susceptibility and toxicity are real and are not being displaced.

Where it runs S3 The delivered inventory is three-dimensional and the manifest is a list. S7 The codon table is flat and the contacts are not. S11 The record of editing is a letter and the event is a chemistry. S12 A design pipeline selects sites on a flat map of an unflat molecule.

What would break it

• Show that approved and failed antisense sites do not differ in ensemble accessibility.

• Show a commercial pipeline that already models accessibility in the way the corpus says is missing.

• Show that the flat representation loses nothing a working method needs.

The claim. Structures persist because nothing had a reason to remove them. A cofactor carries a nucleotide handle from an RNA world; an iron-sulfur cluster carries the chemistry of a mineral surface; a transposable element carries a copying accident into immunity; a telomere carries the scar of a joining. The cell is a stratigraphy and can be read as one.

[E] Cofactors carry nucleotide handles that do nothing in their chemistry. The best account of why is that they were once made of RNA, and nothing had a reason to remove the handle when protein enzymes took over the catalysis.

[F] The same argument runs on minerals, on organelles, on transposable elements and on telomeres. An iron-sulfur cluster is a mineral surface that a protein learned to hold. A mitochondrion is a bacterium that stayed. An Alu element is a copying accident that became a substrate for the editor. A telomere is the record of an end-replication problem that was solved rather than removed.

[F] The cell is therefore readable as a stratigraphy, and the corpus reads it that way: each layer is dated by the chemistry it preserves rather than by its position. This is the theme that lets the arc be run in reverse — from a modern cell back to the conditions that are still visible in it.

Where it runs S2 The amide bond arrives before anything that needs it. S4 The cofactor exists before the enzyme that holds it. S6 The energy and electron systems of the origin are still running.

[VOL p.71] S10 An endosymbiont becomes an organelle and keeps its chemistry. S11 A copying accident becomes an immune mark.

What would break it

- Show a cofactor whose nucleotide handle is required by its chemistry.
- Show that the cluster motifs in modern proteins are not mineral-like in structure.
- Show that the editor's substrates are not dominated by the repeat family the corpus names.

The claim. What was available does not establish what was used. Abundance in a meteorite, stability in a backbone, and presence in a pathway are each arguments for availability and none of them is an argument for membership in the code. The distinction cuts both ways, and it is the one the corpus insists on against its own case as well as for it.

[E] The meteoritic inventory contains more than eighty amino acids and biology uses twenty. It contains hypoxanthine and xanthine in quantity and the canonical code uses neither. Abundance is not membership.

[F] The corpus applies the rule against itself, which is the only way the rule is worth anything.

The same argument that says a delivered base is not thereby a letter also says that a stable backbone available at the origin is not thereby the backbone that was chosen, and that a nucleotide that metabolism makes first is not thereby a letter of the code. The second theme survives this test because it does not rest on abundance; it rests on the route.

[F] The distinction also sets the terms of the corpus's own strongest unresolved question: whether the eight nucleotides of metabolism are an alphabet or an inventory of manufacture. The reading that survives both ways is two alphabets for two jobs — one for what is built, one for what is read.

Where it runs S3 Delivery establishes availability and nothing else. S5 Both backbones are available and one is taken. S7 The set that closes is not the set that was present. S12 An expanded code is engineered today, which shows the constraint was never material scarcity.

What would break it

• Show that code membership tracks prebiotic abundance across the five canonical bases.

• Show that the alternative backbone fails on a chemical ground rather than on a historical one.

• Show that the eight of manufacture and the set that is read are the same set.

The claim. The corpus declines shapes it wanted. There is no sixty-four-cell; the sugars fail the four conditions a spin claim must satisfy; three things do not fit inside the construction and the volume calls that the best result in the Part; one element is kept out of the color scheme entirely.

[VOL p.72] A body of work is testable in proportion to what it refuses, and the refusals are where this one is strongest.

[E] The corpus declines shapes it wanted. There is no sixty-four-cell that carries the counts it needed to carry. The sugars fail all four conditions a half-integer spin claim has to satisfy, and the volume prints the failure. Three things do not fit inside the modeling construction, and the volume calls that the best result in the Part. One element is kept out of the color scheme entirely because it does not belong there.

[F] A body of work is testable in proportion to what it refuses. Each refusal above converts a claim that could have been made into a boundary, and a boundary is what makes the remaining claims falsifiable. The corpus’s dispute register — fourteen contested positions, each with two readings and a statement of where the corpus stands, including the places where it declines to choose — is the same discipline applied to the live questions.

[F] The theme is also the reason this volume can be written at all. A corpus that refused nothing would have no shape to find: every item would support every theme and the classification in Part VII would be meaningless.

[O] The hardest refusal is still outstanding, and the corpus names it: the chain itself is a plausible ordering rather than a documented one. The corpus’s own verdict on its central narrative is the weaker of the two available readings, printed in its own register.

Where it runs S7 The counts that close the set are stated and the ones that do not are refused.

S9 A single-cofactor result is labeled as resting on one cofactor. S11 The editing claim is split into two functions rather than collapsed into one. S12 The register of disputes and the register of protocols are printed rather than summarized.

What would break it

• Find a claim in the corpus that is held without a stated condition under which it would be wrong.

• Show that a refused shape in fact satisfies the conditions the volume set for it.

• Show that the dispute register omits a live dispute the corpus's own material raises.

[E] The matrix below is the book's central picture. Rows are the thirteen themes; columns are the twelve stages of the arc. A letter E marks the stage at which a theme enters and becomes available; an X marks a stage in which it is doing visible work; a stop marks a stage it is absent from. Every row heading links to its theme, and every column heading links to its stage.

[VOL p.73]

The matrix: thirteen themes against twelve stages

[F] Three patterns are visible in it before any argument is made about them. The themes about arrangement and about inheritance enter earliest and reach furthest, because arrangement is available as soon as there are molecules and inheritance begins the moment anything persists. The themes about chemistry — the substitution, the gate, the double sign, the removal — cluster in the middle stages, between the first polymers and the oxygen boundary, which is where the chemistry of the cell was actually decided. The themes about the record enter last: notation at the stage the code fixes, flat maps at the stage the genome is read, refusal at the present stage, where a claim first has to be defended rather than made.

[F] The late entries are the ones that matter for how the corpus should be read. A reader who meets the notation argument first takes it for a complaint about terminology. A reader who meets it at the stage where the alphabet froze — after eight stages in which the chemistry was settling what there was to name — reads it as what it is: a claim that a measuring instrument was fixed before anyone knew what it would be asked to measure.

[O] The matrix is an assignment, not a measurement. A different reader would move cells in the middle stages, where the chemistry is dense and the attributions are arguable. The cells that are not arguable are the entries, and those are the ones the argument rests on.

The themes against the six threads

T6	·	X	·	·	X	·
T7	X	·	X	·	·	X

T8	·	X	·	X	·	X
T9	X	X	·	·	X	·
T10	·	·	X	·	X	X
T11	·	·	·	X	X	·
T12	·	X	·	·	·	X

[VOL p.74] **theme atomic chemical molecular cellular biological geneti** T13 X · X · · X

[F] No theme rides all six threads and none rides only one. The genetic thread carries the most themes, which is what one would expect of a corpus whose subject is a record; the cellular thread carries the fewest, which is a gap rather than a result — the corpus is strong on chemistry and on notation and comparatively thin on what happens inside a particular compartment at a particular moment.

[O] That thinness is the clearest place where the record could be extended without any new argument at all: the material exists in the plate archive's organelle plates and in the sulfur outline's chapter on the twelve conversations, and it has not yet been written into the volume.

How a theme enters and leaves a chapter A theme does not run continuously once it enters. It is picked up where the material needs it and put down where it does not, and the pattern of pickups is what gives a chapter its shape. Three worked cases, each traced through the chapter-length works already in the record:

• The substitution, through the sulfur outline. It enters at the chapter on the mineral and the cluster, is set down through the glycolysis and citric-acid chapters where the subject is thioester chemistry rather than the acceptor, is picked up hard at the oxygen boundary chapter, and returns in the cofactor Part where the count collapses. Four appearances, three absences, in thirty-four chapters.

• The parent, through the curriculum. It enters in the alphabet Part, is absent through the whole geometry Part, returns in the recognition Part at the wobble position, runs the entire editor Part, and closes the clinical Part at the off-target call. The absence in the geometry Part is the informative one: the geometry is about arrangement and does not need the trunk.

• The refusal, through both. It appears only where a claim is being declined — the shapes that do not fit, the conditions a spin claim fails, the element kept out of the scheme, the dispute register. It is absent from every chapter that is purely expository, which is why it reads as a method rather than as a subject.

[E] The six threads are the ones this work has always been organized by: atomic, chemical, molecular, cellular, biological, genetic. They are not six subjects. They are six ways of following the same arc, and a claim that holds on one and fails on another is telling you where its limit is.

[VOL p.75] **[F]** Each thread below carries its own reading line — a short sequence of chapters and sections already in the record that can be read end to end without the

rest of the corpus. A reader who wants the chemistry and not the notation argument can take the chemical line alone and will not be missing a step.

The atomic thread The elements themselves: which were available, in what order, at what cost, and what each one can do that no other can. · themes riding it: T1 · T5 · T7 · <a href="#t-T9">T9 · T13

[E] The atomic thread is the one the corpus starts from, and it is the reason the color key exists at all. Seven elements, each with a position in the order of stellar production, a set of oxidation states, a size and a hardness, and a set of things it can do that no substitute can.

[F] Followed on its own, this thread answers a question the other five cannot: why these seven and not others. Hydrogen because it is the universal donor and the weak bond. Carbon because it catenates. Nitrogen because it holds a lone pair and makes a base a base. Oxygen because it is the hardest acceptor available. Phosphorus because a triply-charged linker resists hydrolysis and stays put. Sulfur because it spans nine oxidation states and will take a radical and hand it back. Selenium because it is sulfur with a lower barrier, which is useful exactly where speed matters more than stability.

The reading line source where to read why it sits here AMB Chapter One — Red: hydrogen and adenine the weak bond, introduced as a design principle rather than as a property **SCN A1 · Why Sulfur Was Available the six properties no other available atom combines** SCN A3 · The Eighteen Functional Groups every shape one element takes, with the two that have no biological role PLATE Element availability plates 084 and 110 volt-equivalent against oxidation state at pH 7; sulfur spans the full width CURR B7 · The Element Itself nine formal oxidation states, stated once, before any biology uses them AMB Chapter Six — Indigo: selenium and xanthine the band the eye does not resolve, and the element kept separate from sulfur on purpose CURR B6 · Where the Seven Came From the order of stellar production, which is not the order of the key

[VOL p.76] **[E]** The chemical thread is about bonds and reactions: what forms, what breaks, what is reversible, and at what cost. It is the thread on which the corpus is strongest, because every claim on it can be checked against a number.

the shapes they take.	· themes riding it: <a href="#t-T2">T2 · T4 · T5 · T7 · <a href="#t-T10">T10</a> · T13	

[E] The molecular thread is the objects: nucleotides, cofactors, backbones, adaptors, and the shapes they hold. It is where the corpus's central omission lives, because a nucleotide is the unit the record refuses to count.

[F] The thread's own argument is that the unit has been mis-set. A letter names a base; the thing that exists is a nucleotide; and three chemical levels — base, nucleoside, nucleotide — have been collapsed onto one symbol. Everything else on this thread follows from reinstating the distinction.

The cellular thread The compartments and the traffic between them: where each chemistry is allowed to run. · themes riding it: <a href="#t-T1">T1 · T4 · T8 · T11

[E] The cellular thread is geography: which chemistry is permitted where, what crosses between compartments, and what a membrane is for. It is the thinnest thread in the record and the one with the most room to grow.

[F] Its strongest material is the organelle sort — twenty-seven outputs of one node filed by the compartment each acts in, with three compartments receiving none. A sort of that kind turns a list of targets into a statement about where a signal is allowed to go.

The biological thread The organism and its history: inheritance, immunity, disease and the clinic.

[VOL p.78]

· themes riding it: <a href="#t-T6">T6 · T9 · T10 · T11

[E] The biological thread is organisms and their history: inheritance, immunity, disease, and

the clinic where all of it is priced.
It is the thread on which the corpus makes its most
consequential claims and its most attackable ones.

[F] Its logic is that history is still running. An immune system that distinguishes self from foreign by a chemical mark is using a Precambrian reaction for a Cambrian problem; a tumor that is genotypically normal and phenotypically switched is a disease of chemistry rather than of sequence; and a trial that enrolls on sequence will not see it.

The genetic thread The record and its instruments: the alphabet, the code, the sequence file, and what they can and cannot hold. · themes riding it: T2 · T3 · T4 · T7 .

T8 · T10 · T12 · T13

[E] The genetic thread is the record and its instruments: the alphabet, the code, the adaptor, the sequence file, and the pipelines that consume it. It carries more themes than any other thread, and it is where the corpus's case stands or falls.

[F] Its sequence is short enough to state in one line: the alphabet was fixed before the chemistry was known; the chemistry exceeded the alphabet; the excess is now invisible to every instrument that reads the record; and the invisibility has operational consequences that can be measured without a bench.

21. The four themes that carry the rest of the volume

[F] Of the thirteen, four do the structural work and are worth isolating here because every later

chapter is an instance of one of them.
•
The substitution at the business end. A molecule’s identity in the record is its sequence; its
behavior is set by the chemical state of a few atoms at the position where it acts. Change that
state and the behavior changes while the record does not. Instances: inosine for guanosine

at a wobble position and in a sequencing readout (Chapters 7 and 8); selenium for sulfur at a peroxidase active site (Chapter 17); an oxidized cysteine pair at PTEN (Chapter 22); a

thiolated uridine at anticodon position 34 (Chapter 7).
•
The supply line, not the text. What limits a biological process is usually the delivery of a
part rather than the instruction to use it. Instances: de novo nucleotide synthesis and its three
one-way gatekeepers (Chapter 5); cysteine desulfurase supplying both clusters and wobble

thiolation (Chapter 20); the cofactor built in three sulfur steps (Chapter 24).

•	**The unrepresentable quantity.** Some quantities that govern cell fate have no place in a sequence record at all, not because the record is too shallow but because it is the wrong kind of object. Instances: the length of the shortest telomere among ninety-two ends (Chapter 15); cofactor occupancy and disulfide register in a folded protein (Chapter 13); the methylation state of a promoter in a cell whose sequence is unchanged (Chapter 14).
•	**Redundancy decides the outcome.** Whether removing a node matters depends on how many other routes the output has, and the number of routes is set by architecture rather than by affinity. Instances: the Akt output fan and the Phase 3 record against it (Chapters 22 and 23);

[VOL p.80] the two arms of the molybdenum cofactor and why one kills (Chapter 24); the mitochondrion’s exclusive possession of cluster assembly (Chapter 20).

22. What the weave establishes and what it leaves open

[F] The weave establishes distribution. Eleven of the thirteen themes appear in more than one source and at more than one stage, which makes them properties of the subject matter rather than habits of one document. Two appear in a single source and are carried forward on their content rather than their distribution, and they are marked as such where they appear.

[O] The weave does not establish causation between stages. That a theme present at the molecular cloud is also present at the clinic is a statement about recurrence; it is not an assertion that the early instance produced the late one. Where the volume does claim a causal chain across stages — the mineral to the cofactor in Chapter 21, the desulfurase to the reading frame in Chapter 20 — the claim is made in its own chapter with its own evidence, and the weave is at most a pointer toward where to look.

[O] One structural question is left open deliberately. The arc has twelve stages because twelve physical transitions could be named and dated; nothing requires that number, and a reader who split the Great Oxidation into its onset and its completion, or merged the two prebiotic stages, would get eleven or thirteen without damaging any argument. The stage count is scaffolding. The transitions are the content.

23. Consequences

[F] Reordering the material along the arc produces one immediate practical result and one scientific one.

[F] The practical result is that the volume can be read in two directions. Forward, it is a history: elements, minerals, nucleotides, code, organelles, lineage, clinic. Backward, it is a diagnosis: a clinical failure, traced to an architectural property, traced to a chemistry, traced to an atom that entered the account before the planet existed. Part Four reads backward and Part Five reads forward, and they meet at Chapter 21.

[F] The scientific result is a prediction about where the field's remaining surprises are. If the oldest chemistry is the least well represented in the newest instruments, then the unexplained residue in modern datasets should be enriched for exactly the chemistry that predates the code: thiol redox state, cluster occupancy, modified bases, and the metabolite pools that feed them. That is a claim about the structure of future error rather than about any single experiment, and it is the reason the volume spends its last four chapters on what would show it to be wrong.

[VOL p.81] ## 24. Notes to Chapter 3: dating the arc

The stages, with their dates and their evidence

[E] Nucleosynthesis. Hydrogen and helium from the first minutes of the universe; carbon, nitrogen and oxygen from stellar burning; sulfur principally from oxygen burning in massive stars and from thermonuclear supernovae; selenium largely from neutron capture processes. The evidence is spectroscopic and isotopic, and the orders of magnitude are secure even where individual yields are debated.

[E] Molecular clouds, before the solar system. Carbonyl sulfide, carbon monosulfide, hydrogen sulfide and a growing list of sulfur-bearing molecules are detected by radio astronomy in cold dense clouds. The relevance here is that sulfur chemistry in molecules predates the planet by a long interval, which is the content of the claim that the ladder's two halves are joined in the cloud.

[E] Accretion and the early crust, about 4.5 billion years ago. Dated by meteoritic and lunar samples. The early Earth's mantle and crust set the inventory of iron, sulfur and phosphorus available to any prebiotic chemistry.

[E] The sulfidic ocean and the iron sulfides. Archean oceans were anoxic and, in many settings, rich in dissolved iron or sulfide depending on region and period. Mackinawite and greigite precipitate under those conditions, and greigite contains the Fe4S4 cubane unit that appears in ferredoxins.

[E] First nucleotides and thiophosphate chemistry. Prebiotically plausible routes to nucleotides have been demonstrated in the laboratory under conditions involving sulfur species; thiophosphate has been shown to act as a phosphorylating agent. Dates are not available; the claim is about chemical availability, not chronology.

[E] The RNA world and the ribosome's RNA core. The peptidyl transferase center is RNA, which is structural fact rather than inference, and it bounds the sequence of events: catalysis before coded protein synthesis.

[E] The DNA transition. Ribonucleotide reductase, in three classes distributed by oxygen regime, is the only de novo route. Its class distribution is consistent with an origin before atmospheric oxygenation.

[E] Code assignment and the late amino acids. Consensus orderings derived from prebiotic abundance, biosynthetic cost and codon patterns place cysteine and methionine late. This is the objection of Chapter 25.

[VOL p.82] **[E] The Great Oxidation, about 2.4 billion years ago.** Dated by multiple proxies; the disappearance of mass-independent sulfur isotope fractionation is among the sharpest, and it is itself a sulfur signal. Banded iron formations record the oxidation of dissolved ferrous iron.

[E] Organelle acquisition. The mitochondrion derives from a bacterial endosymbiont; the plastid from a cyanobacterial one. Both are supported by genome content, by membrane chemistry and by the retained bacterial features of their translation machinery, including formylmethionine initiation.

[E] The human lineage. Specific deletions, including the loss of functional uricase, and specific inheritances, including the chromosome 2 fusion, date to the primate and hominid lineages and are read directly from comparative genomes.

[E] The clinic. The last stage, in which the whole arc is priced in randomized trials, and the only one in which the data are generated deliberately.

Methods box: how a stage is dated, and what the date means

[F] Three kinds of dating appear in this volume and they are not equally strong.

Isotopic and radiometric dating gives absolute ages with quantified uncertainty and is the basis for the planetary stages. When this volume says 2.4 billion years, it is reporting such a date.

Phylogenetic inference gives relative order and, with calibration, approximate dates. It is model-dependent, and the dependency matters most for deep divergences. Claims about the order of enzyme classes rest on this and are marked accordingly.

Chemical plausibility gives no date at all. A demonstration that a reaction proceeds under plausible early-Earth conditions establishes availability, not occurrence. The volume uses this class of evidence for the prebiotic links and marks them open.

Problems

[O] 3.1 Choose a theme from Chapter 3 and construct the strongest case that it is an artifact of how the material was written rather than a property of the subject. What evidence would distinguish the two?

[O] 3.2 The arc has twelve stages because twelve transitions could be dated. Reconstruct it with eight stages and with sixteen. Does any argument in the volume change?

[O] 3.3 For each of the four themes isolated at the end of the chapter, find an instance from a field this volume does not cover — immunology, plant biology, microbial ecology. A theme that recurs outside the volume's own material is stronger evidence than one that recurs inside it.

[O] 3.4 The volume claims the oldest chemistry is least well represented in the newest [VOL p.83] instruments. Test it: take three measurement technologies introduced in the last decade and ask, for each, which chemistry they report and when that chemistry entered the arc.

[O] 3.5 Build the matrix yourself for a subset of the material — three themes, four stages — and compare with the one given. Disagreements about cell contents are more informative than agreement, because they locate the places where the classification rule is doing work.

[O] 3.6 The reverse reading of the arc is a diagnosis: a clinical failure traced back to an atom. Perform it for a drug withdrawal or trial failure of your choice, and determine at which stage of the arc the relevant chemistry entered.

Connections

[F] The arc is used as the ordering principle of Part Five and as the backbone of Chapter 21, which walks seven of the twelve stages in sequence. The theme matrix is referenced wherever a pattern recurs, and the four isolated themes are named again in Appendix C alongside their falsifiers.

Worked example: running the arc backward on one clinical failure

[F] Take a drug program that failed in Phase 3 for lack of overall survival benefit, and run the arc backward from the clinic to the atom. The exercise is the volume's reverse reading, and it can be done for any program with a public record.

[F] Stage twelve, the clinic. The agent inhibited its target potently, engaged it in tumor tissue as measured by a pharmacodynamic marker, improved progression-free survival modestly, and did not extend life. The standard explanations are resistance mutations, insufficient exposure and patient selection.

[F] Stage eleven, the lineage. Ask whether the target's output distribution is a property of human cell biology rather than of the tumor. If the node's outputs are executed in five compartments, inhibition removes one input to each of five processes rather than removing any of them.

[F] Stage ten, the compartments. Ask which of the five compartments has an alternative input to the same output. Each alternative is a compensation route, and the number of them is the redundancy number of Chapter 23.

[F] Stage nine, the chemistry. Ask whether the target's activity is set by anything other than its sequence and its ligand: a redox-sensitive cysteine, a cofactor, a metabolite sensor. If so, the trial's enrollment criterion was measuring one input to a quantity with several.

[F] Stages one through eight, the history. Ask why the architecture is built that way. A node whose output is distributed across compartments acquired that distribution over the arc, as [VOL p.84] compartments were acquired and as signaling was layered onto an existing metabolism. The distribution is not a design; it is a history, which is why it is uneven rather than systematic.

[F] The backward reading produces a specific, checkable claim at each stage, and it ends with a question that can be asked before the next trial is designed: how many compartments execute this node's output, and how many of them have another input? The answer is available from the published literature in a week, and it would have been available before each of the programs discussed in Chapter 23 began.

[VOL p.85] Review of Part I

What Part One established

[F] Three chapters, three results, and one piece of apparatus.

[F] The argument has three legs and they fail together. The unit of genetic information is the nucleotide rather than the letter; the supply line that manufactures nucleotides runs on chemistry the record does not represent; and both operate inside an architecture of thirteen compartments with one exclusive supplier. A reader who accepts the first and rejects the second is left with a terminological preference; a reader who accepts the second and rejects the third is left with a catalog of interesting facts. The joints are where the argument is attackable, and the chain of links in the front matter states them one by one.

[F] An element index is a measurement. Because the color convention is applied mechanically, the distribution of a color across the volume reports what chemistry is under discussion independently of what any sentence claims. The two largest

registers belong to the two elements the volume argues are its subject, and nothing was arranged to produce that result.

[F] The arc is the ordering that makes the material legible. Twelve dated transitions, from nucleosynthesis to the clinic, with the same small set of arguments returning at several of them. Four of those recurrences carry the rest of the volume: the substitution at the business end, the supply line rather than the text, the unrepresentable quantity, and redundancy deciding the outcome.

What Part One did not establish

[O] It did not establish that any of the three legs is true. Chapters 1 through 3 state the claim, the apparatus and the ordering; the evidence is in Parts Two through Six, and a reader who wants to judge the volume rather than follow it should spend their skepticism there.

[O] It did not establish that the thirteen-compartment keying is a discovered regularity. Two of the thirteen assignments have independent confirmation from disease genes; eleven do not, and the experiment that would settle it is stated at the end of Chapter 20.

[O] It did not establish that the recurrences are features of the subject rather than habits of one author's vocabulary. The classification in Chapter 3 shows distribution across sources, which is the best available evidence short of finding the same recurrences in literatures this volume does not cover. Problem 3.3 asks the reader to do exactly that.

[VOL p.86] ### The apparatus, restated

[E] Paragraph tags: [E] established, [F] argued here, [O] open. Reading only the [F] paragraphs of a chapter gives the claim beyond the record.

[E] Color: seven elements, pale field behind the word, applied by root so that everything built on sulfur takes yellow and selenocysteine takes indigo. Unkeyed elements print plain, so a cluster prints as its sulfur.

[E] Numbering: sections run continuously across all twenty-five chapters, so §117 is unambiguous and, in the digital file, clickable.

Questions a reader should be able to answer

[O] R1.1 State the three legs in one sentence each, and name the chapter that supports each.

[O] R1.2 Why does the volume claim that an element index measures something a keyword index cannot? Give an example where the two file the same molecule differently.

[O] R1.3 The arc has twelve stages. Name the transition at each and say which are dated abso-lutely, which relatively, and which not at all.

[O] R1.4 Which of the four recurring arguments is at work when a tumor with wild-type sequence behaves as though it carried a loss-of-function mutation?

[O] R1.5 What would have to be observed for the compartment keying to be abandoned?

Where to go next

[F] A reader following the chemistry should continue to Part Two, which takes the nucleotide apart and shows what the supply line is made of. A reader who wants the argument priced immediately should jump to Part Four, which is where it is most exposed, and return here when a cross-reference needs explaining. A reader interested in notation as such — what a record can and cannot hold, independently of biology — should read Chapters 4, 5, 6 and 8 and then Appendix O, which gives the history of how four letters became the field's notation.

[THEMES p.6] **code theme threads it rides enters items** T13 The discipline of refusal atomic · molecular · genetic S12 111

[F] The distribution is itself a result. The largest theme by item count is the one about arrangement — order, handedness, geometry, the three-strand architecture — because that is what the framework at the center of this corpus is a claim about. The second largest is the one about notation. The two smallest are the ones that make the sharpest chemical claims, novelty by removal and the double-signed chemistry, and they are small because they name specific reactions rather than families of them. Weight in the record measures how often a subject was filed, not how much work the argument does.

[O] No weighting is applied for the quality or finish of an item. A subject marked ARCHIVE counts the same as a chapter of the volume. The register in Part VII keeps the source of every item so that a reader who wants to weight them can.

Part II — The arc, in twelve stages

[E] The arc is not a metaphor and not a chronology of ideas. Each stage carries a date, a chemistry, and at least one piece of evidence the record names. The stages are the frame every theme in Part III is hung on, and every reference to a stage anywhere in this book is a link back to it.

[F] Read in this order the corpus stops being a set of papers about different subjects. It becomes one account of a single sequence of events, in which the same arguments keep coming back because the same chemistry keeps coming back.

S1 · 13.8 billion years ago — the elements

Hydrogen in the first minutes; carbon, nitrogen and oxygen in stellar interiors; sulfur, phosphorus and selenium in the later burning stages and in the deaths of large stars. The seven colors of the key are seven products of that sequence, and their order of arrival is not the order of the periodic table.

[E] The first minutes gave hydrogen and helium and almost nothing else. Everything the color key names except hydrogen was made later, inside stars: carbon and

oxygen in helium and carbon burning, nitrogen in the catalytic cycle that burns hydrogen in massive stars, sulfur in oxygen burning, phosphorus in neutron capture during the same late stages, and selenium only in the slow and rapid capture processes that need either a dying star or a violent one.

[F] The order of arrival is not the order of the periodic table, and it is not the order of the key either. Read as a sequence of availability, the seven colors are: hydrogen, then carbon, [THEMES p.7] nitrogen and oxygen together, then sulfur and phosphorus, then selenium last and in far smaller amounts. Every later stage in this arc is constrained by that ordering, because a chemistry cannot use an atom that has not yet been made.

[O] Whether the relative scarcity of selenium explains its restriction to a single recoded amino acid, or whether the restriction is a later accident, is not settled by abundance alone. The corpus files selenium under a color of its own for exactly this reason: it wanted the question kept open rather than absorbed into sulfur.

What the record anchors it with

• **The elements of the key.** Hydrogen 1, carbon 6, nitrogen 7, oxygen 8, phosphorus 15, sulfur 16, selenium 34 — the atomic numbers carried in every Color Key in the corpus.

• **The ranking in the body.** The plate archive's element plates rank sulfur seventh by mass in the human genome's own element inventory, at about 0.035 per cent. **themes present from here** T9 · T11

S2 · 10 to 4.6 billion years ago — chemistry before the planet

The amide bond, formamide, hydrogen cyanide and acrylonitrile in interstellar clouds and on cometary ice. The bond that holds every protein together was available before any planet existed to use it.

[E] Before any planet existed, the chemistry that matters was already running in cold clouds and on ice grains. Formamide, hydrogen cyanide and acrylonitrile are detected in interstellar space; the amide bond — the bond that holds every protein in every organism together — forms in that chemistry without biology anywhere in the picture.

[F] This is the first appearance in the arc of a pattern that will repeat at every later stage: the component arrives before the system that uses it, and arrives for reasons that have nothing to do with the use. The amide bond is not a biological invention. It is a piece of interstellar chemistry that biology adopted because it was lying there.

What the record anchors it with

• **The amide bond.** Indexed in the volume as a subject in its own right and carried into the curriculum as the chapter on the bond that predates the planet.

• **Formamide.** Carried in the subject indexes as a named prebiotic molecule, with its formula written out. **themes present from here** T11 · T7

[THEMES p.8] ## S3 · 4.6 to 4.5 billion years ago — accretion and delivery

The magma ocean, iron sulfide, and a delivered inventory that includes amino acids, sugars, phosphate and nucleobases — among them hypoxanthine and xanthine, at concentrations comparable to adenine and guanine, with isotopic signatures that place their formation off Earth.

[E] Accretion, a magma ocean, and iron sulfide. Then delivery: the carbonaceous meteorites carry more than eighty amino acids, most of them not used by terrestrial biology; fatty acids long enough to form vesicles in water; polyols and sugars, including ribose; phosphate; and nucleobases — adenine, guanine, uracil, xanthine and hypoxanthine.

[E] The last two matter more than their billing suggests. Hypoxanthine is the base of inosine.

It arrived at concentrations comparable to adenine and guanine, with isotopic signatures that place its formation off this planet and rule out contamination. It was not a later modification of adenine, and it was not an editing artifact.

[F] This is where the corpus's central omission becomes checkable rather than rhetorical. A table of the genetic code that contains adenine and guanine and not hypoxanthine is not describing the delivered inventory. Whether the inventory decides the code is a different question, and it is the one the twelfth theme refuses to answer by abundance alone.

What the record anchors it with

• **The fall.** The prologue of the atomic-molecular book opens on it, and the subject indexes carry the meteorite as a named subject with page references into the volume.

• **Isovaline and enantiomeric excess.** Indexed in the full-length volume beside the homochirality material — the delivered inventory is not only present but handed.
themes present from here T12 · T2

S4 · 4.4 to 4.0 billion years ago — water, mineral, gradient

Serpentinization, alkaline hydrothermal fields, mackinawite and greigite precipitating in pore spaces, and standing gradients across thin inorganic walls. The cofactor exists before the enzyme that will hold it.

[E] Water, and then mineral chemistry at a gradient. Serpentinization produces alkaline fluid rich in dissolved hydrogen and sulfide; where that fluid meets the ocean, iron sulfides precipitate as thin inorganic walls — mackinawite and greigite — with pore spaces on either side holding a standing difference in pH and in charge. The alkaline hydrothermal field at Lost City is the present-tense version of this, still running.

[F] The cluster exists before the enzyme. The four-iron, four-sulfur cubane that sits at the heart of the respiratory chain, of nitrogenase, of ribonucleotide reductase's

relatives and [THEMES p.9] of a hundred other proteins is a mineral motif that proteins learned to hold rather than a protein invention. This is the strongest single piece of evidence for the eleventh theme, and it is geological rather than biochemical.

[O] Whether the gradient was the energy source for the first metabolism or merely a hospitable place for one is still argued in the literature the corpus cites. The corpus takes the first reading and does not claim to have settled it.

What the record anchors it with

• **Mackinawite and greigite.** Named in the sulfur outline's chapter on the cluster life did not invent, and in the curriculum's mineral-thread chapter.

• **Lost City.** Carried as a pull-off in the curriculum — the reason the mineral chapter is a present-tense observation and not only a reconstruction. **themes present from here** T1 · T11 · T5

S5 · about 4.0 billion years ago — the monomers

Sulfide and cyanide chemistry under ultraviolet light; purines before pyrimidines; the trunk nucleotide reached before the branches; phosphorothioate backbones available and not taken.

[E] Under ultraviolet light, hydrogen cyanide and hydrogen sulfide run a single connected network that yields precursors of nucleotides, amino acids and lipids. Inosine and its precursors fall out of that chemistry where the canonical purines do not.

[E] Metabolism's own route says the same thing in a different language. De novo purine synthesis builds the ring on the sugar and arrives at inosine monophosphate first; adenosine monophosphate and guanosine monophosphate are both made from it, by two branches, each one step long. Xanthosine monophosphate sits on the guanine branch as a gate. There is no route in any organism that reaches adenine or guanine without passing through the trunk.

[F] Two independent accounts — one prebiotic, one metabolic — put the same molecule first. That convergence is the whole of the second theme, and it is the strongest argument in the corpus that is not about notation at all.

[O] A backbone built on sulfur rather than oxygen was available at this stage, is more stable than the one life uses, and survives in modern genomes as a restriction mark and in the pharmacy as the modification that lets an oligonucleotide survive in a body. Why phosphate won is argued and not settled.

[THEMES p.10] ### What the record anchors it with

• **The trunk.** The curriculum's chapter on the door they all come through; the sulfur outline's chapter on the alphabet metabolism builds; the plate archive's purine-metabolism group.

• **The parent and the children.** Plate 015 states it as a question: if the parent structure is omitted from the genetic code, what consequences would that cause.

themes present from here T2 · T6 · T12 · T5

S6 · 3.9 to 3.7 billion years ago — polymers and the first errors

Ribozymes copying with one characteristic error, thioesters carrying energy before phosphate does, and iron-sulfur clusters doing the electron work they still do.

[E] Polymers, and with them the first copying errors. The smallest self-copying ribozymes make one characteristic mistake, and it is the same chemical event — a deamination at the pairing face — that at anticodon position thirty-four will later be an economy rather than a fault.

[E] Energy at this stage is carried by thioesters, not by phosphate anhydrides; electrons are carried by iron-sulfur clusters taken straight from the mineral. Both systems are still running in every cell alive, which is why the eleventh theme reads the cell as a stratigraphy.

[F] The eighth theme enters here and never leaves: one chemistry, used twice, with opposite signs. Everything the corpus later says about editing, about wobble and about oxidative damage is an instance of this one observation made at the origin.

What the record anchors it with

• **Wobble was an error first.** The curriculum's chapter D22 — one chemical event, twice, for opposite reasons: a cost at the origin and a saving at the ribosome.

• **The thioester world.** A named subject in the master index, carried into the volume. **themes present from here** T8 · T7 · T11 · T5

S7 · 3.7 to 3.5 billion years ago — the code fixes

Charging, the anticodon, position thirty-four, and the assignment that closes. Whatever the alphabet was at that moment is what every later organism inherited.

[THEMES p.11] **[E]** The code fixes. Charging is one event, performed in the cytoplasm by a synthetase forming an ester bond; peptide bond formation is a separate event, performed by the ribosome's own RNA. Between them sits the anticodon, and at its first position — position thirty-four — sits the base that decides how many codons one adaptor can read.

[F] Whatever the alphabet was at the moment of fixing is what every later organism inherited, which is why the corpus treats this stage as the one the whole notation argument is about. The fixing is not a decision anyone made; it is a freezing of what happened to be in use.

[O] Whether the set closed at eight and contracted to six for reading, or closed at six and was never larger, is the corpus's own unresolved question. It prints both readings and declines to choose, which is the most defensible thing in the geometry Parts.

What the record anchors it with

• **Position thirty-four.** The curriculum's F31; the central-dogma paper's sections on wobble and the 76-base adaptor; the sulfur outline's chapter on the code read as atoms.

• **Twenty-two, not twenty.** The central-dogma paper's own count, with the two recoded exceptions added to the twenty canonical. **themes present from here** T3 · T2 · T7

S8 · about 3.5 billion years ago — the enzyme that made DNA

A thiyl radical on a cysteine takes the hydrogen off the 2′ position, two further cysteines supply the reducing equivalents, and the archive separates from the working copy. DNA contains no sulfur and exists because of it.

[E] One enzyme family takes the whole of biology from the RNA world to the DNA world, and it does it by subtraction. A thiyl radical on a cysteine abstracts the hydrogen from the 3′ position; two further cysteines supply the reducing equivalents as a disulfide pair; thioredoxin or glutaredoxin resets them. The product is a deoxyribonucleotide.

[F] DNA contains no sulfur and exists because of it. That single sentence carries the first theme and the fourth at once: sulfur does the work and keeps none of the credit, and the new molecule is made by removal rather than by addition.

[O] Whether RNA came first with DNA as a successor, or the two are siblings from a hybrid ancestor, turns on a measurement nobody has made. The corpus adopts the hybrid reading and names the missing measurement, which is the right way to hold a question of this kind.

[THEMES p.12] **What the record anchors it with**

• **The thiyl radical.** The curriculum's D19; the sulfur outline's B7; the plate archive's iron-sulfur group.

• **Biology proceeds by removal.** The curriculum's D20, stated as a method rather than as an aphorism. **themes present from here** T4 · T1

S9 · 2.45 billion years ago — the oxygen boundary

Mass-independent sulfur isotope anomalies stop at this horizon and never return. The terminal acceptor changes, the metal cofactors change with it, and the count of sulfurs in the oldest enzymes is the fingerprint of the change.

[E] Mass-independent fractionation of sulfur isotopes is present in rocks older than about

2.45 billion years, absent above that horizon, and never returns. The event named for oxygen is dated by an anomaly in sulfur.

[E] What changed is the end of the chain, not the chain. Oxygen replaced the terminal electron acceptor; the carriers, the clusters, the thioesters and the repair chemistry stayed where they were. The metal cofactors tell the same story in a single

number: nitrogenase, older than the boundary and poisoned by oxygen to this day, holds its molybdenum in a cluster of seven irons, nine sulfurs, one carbon and one metal; every post-oxygen molybdenum enzyme holds the same metal in a two-sulfur dithiolene.

[F] Nine to two is the clearest instance in the corpus of the ninth theme: one number, changing once, in one direction, across one boundary, in one element. It is also the corpus's own best candidate for a generalization, and it is checkable against the structural databases without a bench.

What the record anchors it with

• **The dated anomaly.** The curriculum's B11 and the sulfur outline's chapter on when the reductant changed.

• **The sequestration of nitrogenase.** Heterocysts, temporal separation, and the endosymbiont that carries the enzyme inside a diatom — biology working around an atom it cannot replace. **themes present from here** T9 · T1

S10 · 2.0 to 0.6 billion years ago — compartments

[THEMES p.13] Endosymbiosis, organelles, the contacts between them, and an epigenetic currency denominated in acetyl and methyl groups that are both delivered by sulfur chemistry.

[E] Compartments. An endosymbiont becomes an organelle; the organelle keeps its own membranes, its own clusters and its own chemistry; and the cell acquires a geography in which the same reaction is permitted in one place and not in another.

[E] The epigenetic currency is denominated in two groups, and sulfur delivers both. The methyl comes from S-adenosylmethionine; the acetyl comes from acetyl-coenzyme A after citrate export. The ratio of the methyl donor to its spent form is a readout of the cell's sulfur economy, and the marks written on chromatin are downstream of it.

[F] The first theme reappears here in its most consequential form. Oxygen took the terminal acceptor; sulfur kept the business of writing on the genome. Nothing in the standard account of epigenetics is organized this way, and organizing it this way is what the corpus contributes at this stage.

What the record anchors it with

• **The twelve conversations.** The sulfur outline's chapter on the contacts between the mitochondrion and the other compartments, and what each contact carries.

• **The two currencies.** The same outline's chapter on acetyl-coenzyme A and the methyl economy. **themes present from here** T1 · T11 · T4 · T6

S11 · 600 million years ago to now — multicellularity, immunity, editing

Transposable elements copied into introns, an editor that marks the cell's own RNA as self, telomeres and their scars, and a genome whose record of all of it is written in four letters.

[E] Transposable elements copy themselves into introns in their hundreds of thousands; inverted pairs of them fold into double-stranded RNA inside the cell's own transcripts; and an editor deaminates adenosine to inosine across those duplexes, marking them as self so that the immune sensors do not fire on them. Less than a tenth of one per cent of that editing recodes a protein.

[E] At the ends of the chromosomes the same period leaves a different mark: a repeat the replication machinery cannot finish copying, a loop that hides the end from the repair systems, and the scar where two ancestral chromosomes were joined.

[F] The whole of the third theme becomes operational here. An inosine in a transcript is read by every sequencing instrument as a guanosine, so the mark of self is written into the [THEMES p.14] record as a different base. The editing is not hidden by nature; it is hidden by the notation.

What the record anchors it with

• **The Alu engine.** The curriculum's H43 — inosine as the mark of self.

• **Read as guanosine.** The curriculum's H47, and the protocol that asks whether an adenosine-to-guanosine call can be attributed to the editor without reading the native molecule. **themes present from here** T3 · T8 · T11 · T10

S12 · today — the instruments and the record

The sequence file, the trial register, the pathway chart, the drug pipeline, and a corpus that counts its own frontier. This is where the omissions of the earlier stages become operational, and where they can be tested.

[E] The record reaches the clinic. A trial enrolls on a sequence file; a drug is designed against a sequence; an off-target call is assigned or not assigned on the basis of a letter. A tumor suppressor whose brake is a reversible bond between two cysteines can be fully functional in the sequence and fully disabled in the protein, and the trial that selects on the sequence will not see it.

[F] This is the point of the arc the corpus was built to reach. Every omission introduced between the third stage and the eleventh is still operating, and at this stage it is operating on people. The tenth theme and the third converge here: what the map cannot hold, the clinic cannot act on.

[O] What the corpus does not claim is that the omissions explain the failures. It claims that they are not measured, names the measurements that would settle it, and prices them. Eleven of the twenty-one need no bench at all.

What the record anchors it with

• **The disulfide switch.** The curriculum's I50 and its protocol — a non-reducing immunoblot on banked tissue, the cheapest decisive experiment in the record.

• **The fan.** Twenty-seven outward arrows from one node, sorted by the compartment each target acts in, with the empty compartments read as informative as the full ones. **themes present from here** T13 · T10 · T3 · T6

4. The nucleotide and the alphabet (with new Plate N-1, the nucleotide octahedron)

[VOL p.87] **Part II**

The Nucleotide and the Alphabet

[VOL p.88] Five chapters on the unit of genetic information and the notation used to record it.

The order is deliberate. Chapter 4 moves the first term of the Central Dogma one place to the left, from the polymer to the nucleotide, and shows what that costs the standard account and what it buys. Chapter 5 follows the supply line backward into de novo synthesis and finds eight nucleotide species where the code lists four, with the unlettered one sitting at the trunk of the purine branch rather than at its periphery. Chapter 6 takes the element assignment of the color key seriously enough to run it through the codon table, which turns every codon into a string of atoms and puts a testable reading on the three stop codons. Chapter 7 goes to the one position in the anticodon where both of the volume's elements act at once, inosine widening recognition and a thiolated uridine narrowing it. Chapter 8 closes the Part by stating the consequence that the rest of the volume prices: a four-letter record can represent a substitution and nothing else, so any chemical change that preserves the letter, and any change that has no letter at all, is unrepresentable in the record the field validates against.

The Part is about notation as much as chemistry. A notation is not neutral. It decides which errors can be seen, which experiments look necessary, and which failures will be read as noise.

[VOL p.89] **CHAPTER 4**

Correcting the Central Dogma

Abstract. The Central Dogma is stated as DNA to RNA to protein and has been taught in that form for more than seven decades. Stated that way it begins with a polymer that already exists and describes only what is done with it afterward. This chapter extends the chain one term to the left — nucleotides to DNA to RNA to proteins — and works out what the extra term costs and what it buys. It costs the clean separation of genetics from metabolism. It buys a supply line with a rate, a cost, a set of gatekeepers and a characteristic mode of failure, and it converts a class of clinical observations that are currently filed as genomic instability into observations about manufacturing.

25. What the original formulation was, and was not, about

[E] Crick's formulation in 1958, restated in 1970, was a statement about the impossibility of information transfer out of protein. Its content was negative and precise: once information has passed into protein it cannot get out again into nucleic acid. It was never a claim about the material origin of nucleic acids, and Crick did not present it as one.

[F] What happened subsequently is a familiar kind of drift. A negative statement about information flow was absorbed into teaching as a positive diagram of how a cell works, and the diagram starts with DNA because DNA is where the lecture starts. Three generations of molecular biologists have been trained on an arrow that begins at a molecule whose manufacture is treated as someone else's chapter — intermediary metabolism, usually, taught in a different course by a different department.

[F] The consequence is not an error in the dogma. It is an omission in the frame. A cell that has run out of deoxythymidine triphosphate does not have an information problem, and nothing in the standard diagram tells you where to look when it stalls.

26. What the nucleotide is

[E] A nucleotide is a molecular triad. A nitrogenous base carries the pairing rule and therefore the digital code. A pentose sugar, ribose or deoxyribose, forms the structural bridge and fixes the geometry. A phosphate group anchors the unit, carries the charge, and supplies the thermodynamic drive for polymerization. The three are not components that happen to be [VOL p.90] joined. They are one unit, and the unit — not the base — is what a polymerase accepts.

[E] Each of the three carries information that the letter does not. The sugar carries it as pucker and as a single 2′ substituent: ribose carries a 2′ hydroxyl, deoxyribose does not, and that one oxygen is the difference between a molecule that is catalytically reactive and chemically fragile and a molecule that is inert enough to archive. The phosphate carries it as charge density: the backbone's regular negative charge produces the electrostatic field that governs histone binding, nucleosome positioning, and the energetic cost of strand separation. The base carries it as hydrogen-bonding geometry — two bonds for A with T, three for G with C — and the arithmetic of that difference sets the thermal stability of every duplex in the cell.

[F] Information in a cell is therefore not merely sequential. It is spatial, electrostatic and energetic at the same time, and a sequence read as text omits the geometry that makes the text legible to the machinery that reads it. This is the sense in which the letter is a lossy compression of the nucleotide.

27. What the extra term buys

[F] Four things become visible once the chain begins at the nucleotide, and none of them is visible when it begins at DNA.

• **A rate.** Nucleotide pools are finite and are consumed at the replication fork. The rate of supply is set by de novo synthesis and salvage, and when supply falls behind demand the fork slows, stalls and collapses. Replication stress of this kind is one of the best-documented routes to chromosomal rearrangement in the literature, and it is a supply failure rather than an information failure.

• **A composition.** Pools are not only finite, they are balanced or unbalanced. An imbalanced dNTP pool raises the misincorporation rate of a polymerase whose fidelity is unchanged, which means a mutation can be caused by metabolism in a cell whose replication machinery is faultless. The experimental literature on this is forty years old and is almost never included in discussions of mutational signatures.

• **A gatekeeper.** De novo purine synthesis converges on a single branch point, and both branches are one-way. A pathway with a branch point has a place where regulation can be applied, and a place where inherited failure concentrates. Chapter 5 takes that structure apart.

• **A chemistry.** Making a deoxyribonucleotide from a ribonucleotide requires removing an oxygen from an unactivated carbon, which is difficult chemistry and is performed by a transient radical on a cysteine. That reaction, and not any step of the standard diagram, is the point at which the RNA world becomes a DNA world. It is covered in Chapter 19.

[VOL p.91] 28. Why editing the base alone is incomplete

[E] Current gene and epigenetic editing tools act on the base. A nuclease cuts the backbone and leaves the cell's repair machinery to rejoin it. A base editor chemically converts one base into another in place: an adenine base editor deaminates adenosine to inosine, which is read as guanosine; a cytosine base editor deaminates cytidine to uridine, which is read as thymidine. A prime editor writes a short sequence from an RNA template through a reverse transcriptase.

[F] All three change the letter. None of them changes the sugar or the phosphate, and none of them restores a metabolic state. If a disease phenotype depends on the thermodynamic stability, the spatial geometry or the energetic flux of the nucleotide unit, correcting the letter leaves the structural and functional environment of the sugar-phosphate backbone exactly as it was. The attempt is to repair a foundation by painting one brick.

[F] The point is sharpest at a single position. A cytosine base editor deaminates cytosine to uracil in order to simulate thymine. A real thymine is made by thymidylate synthase, which attacks C6 of the pyrimidine ring with a conserved active-site cysteine to activate it and then transfers a methyl group drawn from a one-carbon pool coupled to the methionine cycle. The editor produces the letter without the sulfur chemistry that normally produces it. Whether that difference is detectable downstream is an empirical question that the field has not asked, because the assay it uses to verify the edit reports the letter and stops.

[O] The experiment is straightforward and is named here so that it can be run: compare, in isogenic cells, a locus whose thymine arrived through thymidylate synthase with the same locus whose thymine arrived through cytosine base editing, and measure one-carbon flux, dUTP misincorporation and uracil excision load. If the two are indistinguishable at every level, the objection in this section fails and should be withdrawn.

29. Correcting the Central Dogma

[F] The Watson–Crick Central Dogma states the flow of information as DNA to RNA to protein.

For more than seven decades it has been taught as a unidirectional digital script, with the cell cast as a passive biological computer executing text. The formulation takes the polymer as given and describes only what is done with it afterward.

[F] The correction is to extend the chain one term to the left: nucleotides to DNA to RNA to proteins. Nucleotides are the direct precursors of the nucleic acids, and without the base, the sugar and the phosphate no nucleic acid is made at all. That addition is not cosmetic.

[VOL p.92] It changes what the chain is a chain of. The original sequence describes the movement of information between molecules that already exist; the corrected sequence describes the manufacture of those molecules from parts, and manufacture has a supply line, a rate, a cost and a point of failure.

[F] Once the nucleotide is admitted as the first term, the question of where nucleotides come from ceases to be a matter for a separate chapter on intermediary metabolism and becomes the first question in genetics.

30. The nucleotide as a triad

[E] A nucleotide is a molecular triad. A nitrogenous base carries the digital code. A pentose sugar, ribose or deoxyribose, forms the structural bridge. A phosphate group anchors the unit and acts as the thermodynamic engine. The three are not separable components that happen to be joined; they are one unit, and the unit is the material and thermodynamic source of the information.

[E] The sugar–phosphate backbone dictates the physical geometry, the electrical charge, the thermodynamic stability and the spatial orientation of the double helix. The phosphate groups carry a consistent negative charge, creating an intense electrostatic field that governs how DNA folds, how it interacts with histones, and how it opens for transcription. The ribose or deoxyribose provides the exact angular constraints that allow the bases to stack and pair.

[F] Information in the cell is not merely sequential. It is spatial and energetic. A sequence read as text omits the geometry that makes the text legible to the machinery that reads it.

31. Why base editing is incomplete

[E] Current gene and epigenetic editing tools act on the base. CRISPR-Cas9 acts as a blunt mechanical scissor, cutting the backbone and forcing the cell's error-prone repair machinery to rejoin the sequence. Base editors use deaminases to chemically alter a single nitrogenous base — converting a cytosine to a uracil, for example, in order to simulate a thymine.

[F] These tools use the base and not the base, sugar and phosphate as the genetic and metabolic information source, and therefore correct neither the structure nor the function completely. If a mutation or disease state alters the thermodynamic stability, the spatial geometry or the metabolic energy flux of the nucleotide unit, changing the base letter leaves the structural and functional environment of the sugar–phosphate backbone uncorrected. The attempt is to repair a structural foundation by painting over a single brick.

[F] The point is sharpest at a single position. A cytosine base editor deaminates cytosine to [VOL p.93] uracil in order to simulate a thymine. A real thymine is made by thymidylate synthase, through a conserved active-site cysteine that attacks C6 of the pyrimidine ring to activate it, using a methyl group drawn from a one-carbon pool coupled to the methionine cycle. The editor produces the letter without the sulfur chemistry that normally produces it.

[F] True genetic and epigenetic correction cannot be achieved by manipulating the base in a vacuum. It requires delivering and managing the complete nucleotide unit — base, sugar and phosphate — as a unified, energetic source of structural data, and it requires that the scaffolding not remain warped by metabolic disease.

32. The corrected chain, stated as a diagram

[F] The chain the rest of the volume uses runs: elements, to nucleotides, to DNA, to RNA, to proteins, with two returns. The first return is from proteins to nucleotides, because the enzymes of de novo synthesis are themselves proteins and the pathway is therefore autocatalytic at the level of the cell. The second is from proteins to the elements, because cofactor assembly — iron-sulfur clusters, the molybdenum cofactor, heme — consumes inorganic atoms and delivers them into protein in a form no sequence records.

[F] Three properties of this diagram are worth stating because they do not hold of the standard one.

• **It has a source term.** Atoms enter the account. In the standard diagram nothing enters; information merely moves.

• **It has failure modes that are not mutations.** Pool depletion, pool imbalance, cofactor misloading and redox state are all failures of the chain that leave the sequence unchanged.

• **It is the version that matches the clinic.** The two disease classes that kill at scale are vascular and oncologic, and both are diseases of flux, aging and supply rather than diseases of a mistyped letter. Chapter 12 gives that record in full.

33. Objections, stated at full strength

[F] First objection: this is a terminological preference with no empirical content. A critic may grant that nucleotides precede DNA and deny that anything follows from saying so. The answer is Chapter 5. If the supply line manufactures eight nucleotide species where the code names four, and one of the unnamed ones sits at the trunk rather than at the periphery, then the extension of the chain is not terminological: it changes what counts as the alphabet.

[F] Second objection: nucleotide metabolism is already studied and already targeted. It is, and the drugs are old and successful — methotrexate, 5-fluorouracil, 6-mercaptopurine, [VOL p.94] hydroxyurea, mycophenolate. That is a point in favor of the correction rather than against it. Each of those agents acts on the supply line and none of them acts on the text, and none is usually taught as a genetic intervention even though every one of them changes what the genome does.

[F] Third objection: the geometry argument proves too much. If a letter is a lossy compression, why does sequence predict so much? Because for the questions the field has asked, the compression is lossless enough: coding sequence does determine primary structure, and primary structure does determine backbone geometry to a good approximation. The claim here is narrower and is made in Chapter 13: what the compression loses is the cofactor layer, and the cofactor layer is where the residual error of the folding problem now sits.

34. Consequences and tests

[F] Four consequences follow for a working program.

• **Measure the pool.** Any experiment attributing a phenotype to an edit should report dNTP pool composition in the edited and unedited cells. The measurement is routine mass spectrometry and is almost never reported.

• **Treat replication stress as a supply readout.** Fork stalling, origin firing changes and micronucleus frequency are downstream of pool state. Where they appear after an intervention, the supply line is the first place to look rather than the last.

• **Separate the letter from the molecule in reporting.** A paper that reports an A-to-G change should state whether the molecule now present is guanosine or inosine, because those are different molecules with the same readout, and Chapters 7 and 8 show that the difference has consequences at the wobble position, at the chromosome end and in the immune system.

• **Price the metabolic cost of an edit.** Editing a locus in a cell whose one-carbon pool is depleted is not the same intervention as editing it in a replete cell, and the difference is measurable with existing reagents.

[O] The open question this chapter leaves is quantitative. If the nucleotide rather than the letter is the unit, how much of the variance currently attributed to sequence is in fact attributable to supply? Nobody has measured it, because no study has been

designed with supply as the independent variable and sequence held constant. The design is not difficult: isogenic lines, controlled nucleotide availability, identical sequence, phenotype measured. Until it is run, the size of the effect argued for in this volume is unknown even if its direction is not.

35. Notes to Chapter 4: the nucleotide, measured

[VOL p.95] **Quantities worth carrying**

[E] Pool sizes. Intracellular dNTP concentrations in mammalian cells sit in the low micromolar range and vary across the cell cycle by severalfold, rising at S phase. The pools are small relative to the demand of a replication fork, which is why supply is rate-relevant rather than merely permissive.

[E] Pool asymmetry. The four dNTPs are not equimolar; dGTP is typically the least abundant.

Asymmetry matters because polymerase misinsertion rates depend on the ratio of correct to incorrect nucleotide available at the site, so an imbalance raises error rates without any change in the enzyme.

[E] Fork speed. Mammalian replication forks progress at roughly 1 to 2 kilobases per minute under normal conditions, and slow measurably under nucleotide limitation. Fork slowing is an early, sensitive readout of supply stress.

[E] Cost of synthesis. De novo purine synthesis costs approximately six high-energy phosphate equivalents per nucleotide; salvage costs about one. The eightfold difference is why salvage pathways exist and why their failure, as in Lesch-Nyhan syndrome, has consequences out of proportion to the enzyme's apparent redundancy.

[E] Backbone charge. Each phosphodiester carries one negative charge at physiological pH, giving a linear charge density that determines counter-ion condensation, persistence length and the energetics of histone binding. This is the quantity the letter does not record.

[E] The 2′ difference. RNA is hydrolyzed orders of magnitude faster than DNA at neutral pH because the 2′ hydroxyl attacks the adjacent phosphate. One oxygen is the difference between a transient molecule and an archival one.

Methods box: measuring the supply line

[F] dNTP quantitation. The established approaches are a polymerase-based extension assay, in which a template-primer pair reports the concentration of a single dNTP, and liquid chromatography with tandem mass spectrometry, which reports all four plus ribonucleotides in one run. The mass spectrometric route requires rapid quenching in cold methanol or acid, isotope-labeled standards, and care to avoid degradation during extraction.

[F] Flux rather than pool. Pool size is a state variable and can be stable while flux changes. Stable-isotope tracing — feeding labeled glucose, glutamine, glycine,

formate or serine and following label into nucleotides — reports the flux through de novo synthesis and distin[VOL p.96]guishes it from salvage. Formate and serine tracers are the ones that report the one-carbon contribution.

[F] Replication stress readouts. DNA fiber analysis reports fork speed and origin firing directly; phosphorylated checkpoint markers report the response; micronucleus frequency reports the downstream consequence. Fiber analysis is the only one that gives a rate rather than a signal.

[F] Thymidylate-specific measurements. Because the thymidine nucleotide is made either by thymidylate synthase or by salvage of thymidine, the two can be separated by labeling, and the uracil content of DNA — the signature of dUTP misincorporation under folate or thymidylate limitation — can be quantified by excision assays or by mass spectrometry.

Further reading, oriented

[E] The classical literature on nucleotide pool imbalance and mutagenesis runs from the mid-twentieth century and is worth reading in the original, because it stated the dependency plainly before sequencing made the letter the object of study.

[E] For the polymerase side, the fidelity literature quantifies how misinsertion rates depend on nucleotide concentration ratios, which is the mechanistic link between a metabolic variable and a mutational one.

[E] For the clinical side, the antimetabolite literature — methotrexate, 5-fluorouracil, 6-mercaptopurine, hydroxyurea, mycophenolate — is a sixty-year demonstration that inter-vening in the supply line changes what the genome does, assembled before the vocabulary of this volume existed.

Problems

[O] 4.1 Write the corrected chain — elements, nucleotides, DNA, RNA, proteins, with returns — and mark for each arrow whether it is an information transfer, a material transfer or both.

The exercise shows where the original dogma’s claim about information applies and where it is silent.

[O] 4.2 For a cytosine base editor, enumerate everything about the edited position that differs from a position whose thymine was made by thymidylate synthase. Then say which of those differences could be detected by sequencing.

[O] 4.3 Estimate the number of nucleotides required for one round of replication in a human cell and compare with the measured pool size. The ratio gives the number of times the pool must turn over during S phase, which is the quantitative statement of why supply matters.

[O] 4.4 Take a published mutational signature analysis and ask which of the signatures could be [VOL p.97] produced by a supply-side cause — pool imbalance, folate limitation, dUTP misincorporation — rather than by a damage source. How would the

two be distinguished?

[O] 4.5 The chapter claims that correcting a letter does not restore a metabolic state. Design the control experiment that would show whether the distinction matters for a specific disease allele.

[O] 4.6 Consider a cell in which de novo synthesis is blocked and salvage is intact. Which of the eight species of Chapter 5 can still be made, and from what? The answer explains why salvage inhibitors and de novo inhibitors have different toxicity profiles.

Connections

[F] This chapter's correction is the premise of Chapter 5, which takes the supply line apart, and of Chapter 8, which draws the notational consequence. Its clinical form appears in Chapter 12, where the diseases that kill turn out to be diseases of flux, and in Chapter 24, where a cofactor built from a nucleotide gates two metabolic exits.

Worked example: two thymines with different histories

[F] Consider one position in one genome, carrying a thymine, in two cells.

[F] Cell one. The thymine arrived by normal replication. Its deoxythymidine triphosphate was made by thymidylate synthase, which attacked C6 of the pyrimidine ring with a conserved active-site cysteine, received a methyl group from methylenetetrahydrofolate, and released dihydrofolate — which the cell then reduced back at the cost of NADPH. The nucleotide carried its own sugar and phosphate into the polymer.

[F] Cell two. The thymine arrived by cytosine base editing. A deaminase converted the cytosine in place to uracil; replication then read the uracil as thymine and installed a thymine on the opposite strand's template. No thymidylate synthase was involved, no methyl group was drawn from the folate pool, and no new sugar or phosphate entered at that position.

[F] What the sequence record says. T, in both cells, with identical quality scores.

[F] What differs, and whether it is measurable. Four things differ and three are measurable with existing methods.

• The uracil intermediate existed transiently in cell two and is a substrate for uracil-DNA glycosylase, whose excision initiates base excision repair at that position. Measurable: the frequency of repair intermediates, by cleavage assays.

• The folate and one-carbon economy was drawn on in cell one and not in cell two. Measurable: one-carbon flux by isotope tracing.

[VOL p.98] • Cell two's editing event may have occurred on one strand only, leaving a mismatch until replication. Measurable: strand-specific analysis at the locus.

• The local chromatin and repair history differ, since cell two experienced a repair event at that position. Partly measurable, by assays of repair-associated marks.

[F] The point. Nothing here says that base editing is unsafe or that the two thymines behave differently in the long run. The point is that the question has not been asked, because the instrument that verifies the edit reports a letter that is identical in both cells, and the differences are in a layer the instrument does not address. The experiment named at the end of Chapter 4 is the one that would settle it, and it is a week's work in an isogenic system.

[VOL p.99] **CHAPTER 5**

Eight Nucleotides and Three One-Way Gatekeepers

Abstract. The genetic code names four nucleotides. De novo synthesis builds eight, and three of the eight are one-way gates through which every nucleic acid in the cell must pass. The trunk of the purine branch is inosine monophosphate, which has no letter; the gate on the guanine branch is xanthosine monophosphate, which has no letter; the gate on the whole pyrimidine arm is orotidine monophosphate, which has no letter. This chapter walks the pathway, states the three gates and their irreversibility, places the drugs that already act on them, and sets out what a four-letter notation loses by recording only end products.

36. The purine pathway, step by step

[E] De novo purine synthesis builds the ring on the sugar rather than attaching a finished base to it. The committed step is the conversion of 5-phosphoribosyl-1-pyrophosphate to 5-phosphoribosylamine by phosphoribosyl pyrophosphate amidotransferase, which takes the amide nitrogen from glutamine. Ten enzymatic steps follow, carried in human cells on three multifunctional proteins and two single-function ones, and the atoms of the finished purine ring arrive from five sources: glycine contributes two carbons and one nitrogen whole; glutamine contributes two nitrogens; aspartate contributes one; carbon dioxide contributes one carbon; and two further carbons arrive as formyl groups from 10-formyltetrahydrofolate.

[E] The product of the tenth step is inosine monophosphate. The cost is approximately six high-energy phosphate equivalents per purine. Nothing in the pathway produces adenine or guanine directly; both are made from the inosine nucleotide afterward.

[F] That last sentence is the chapter's first result and the reason the pathway is drawn here in full.

The two bases the code names are not synthesized. They are derived, one step each, from a base the code does not name.

37. The trunk and its two branches

[E] From inosine monophosphate the pathway forks, and the two arms are energetically cross-linked in a way that is not an accident.

• **To adenine.** Adenylosuccinate synthetase condenses the inosine nucleotide with aspartate [VOL p.100] using GTP as the energy source, and adenylosuccinate lyase then eliminates fumarate to leave adenosine monophosphate. The adenine arm is paid for in guanine currency.

• **To guanine.** IMP dehydrogenase oxidizes the inosine nucleotide at C2 with NAD+ to give xanthosine monophosphate, and GMP synthase then aminates it using glutamine and ATP to give guanosine monophosphate. The guanine arm is paid for in adenine currency.

[F] The reciprocal arrangement is a balancing device built into the chemistry. If adenine nucleotides fall, the synthesis of guanine nucleotides slows because it is ATP-dependent; if guanine nucleotides fall, the synthesis of adenine nucleotides slows because it is GTP-dependent. The pool is held near a ratio without any transcriptional regulation at all, and the device is possible only because both arms leave from a common trunk.

[E] IMP dehydrogenase is the rate-limiting step of guanine nucleotide synthesis, is strongly upregulated in proliferating cells, and is the target of mycophenolic acid, used clinically as an immunosuppressant, and of ribavirin. Adenylosuccinate lyase deficiency is an inherited disease with severe neurological presentation. Both of those clinical facts are facts about the unlettered trunk and its gates.

38. The pyrimidine arm

[E] Pyrimidine synthesis runs in the opposite order: the ring is built first and attached to the sugar afterward. Carbamoyl phosphate synthetase II, aspartate transcarbamoylase and dihydrooro-tase — all three carried on the single multifunctional CAD protein in human cells — build dihydroorotate from glutamine, bicarbonate and aspartate. Dihydroorotate dehydrogenase then oxidizes it to orotate.

[E] That enzyme is worth pausing on. It is the only enzyme of pyrimidine synthesis that is not cytosolic: it sits on the outer face of the inner mitochondrial membrane and passes its electrons to ubiquinone, which places pyrimidine supply in direct physical contact with the respiratory chain. A cell with a failing electron transport chain has a pyrimidine problem for reasons that have nothing to do with its genome, and the clinical exploitation of that link — dihydroorotate dehydrogenase inhibitors in autoimmune disease and in acute myeloid leukemia — is already established practice.

[E] Orotate is then joined to the sugar by orotate phosphoribosyltransferase to give orotidine monophosphate, which is decarboxylated to uridine monophosphate by orotidine monophosphate decarboxylase. Both activities sit on one bifunctional protein, UMP synthase. Everything else in the pyrimidine series is made from uridine monophosphate: UDP, UTP, CTP by amination at the [VOL p.101] triphosphate level, dUMP by reduction and dephosphorylation, and thymidine monophosphate by methylation of dUMP.

[E] The decarboxylation step is among the most proficient reactions known in biology. The uncatalyzed reaction has a half-life measured in tens of millions of years; the enzyme performs it in milliseconds, a rate enhancement of roughly seventeen orders of magnitude, achieved with no metal and no cofactor.

39. The three gates, and what one-way means

[F] Three of the eight nucleotide species are gates rather than products, and in each case the gate is one-way.

• **Inosine monophosphate gates everything purine.** De novo synthesis converges on it, and both branches leave from it. There is no route to adenine or guanine nucleotides that bypasses it except salvage of a preformed base.

• **Xanthosine monophosphate gates guanine.** The oxidation by IMP dehydrogenase is irreversible under cellular conditions, and the amination by GMP synthase follows it in that order and no other.

• **Orotidine monophosphate gates every pyrimidine.** The decarboxylation is effectively irreversible, and uridine monophosphate is the precursor of all the rest.

[F] Remove any one of the three and the cell makes no nucleic acid at all. That is the structural sense in which the alphabet is eight and not four: three of the eight are obligatory, and the three obligatory ones are precisely the three with no letter.

[E] The inherited failures confirm the structure. Hereditary orotic aciduria is UMP synthase deficiency; it presents with megaloblastic anemia and developmental delay, it is diagnosed by the accumulation of the unlettered intermediate in urine, and it is treated by supplying uridine to bypass the gate. Lesch-Nyhan syndrome is a failure of the salvage enzyme HGPRT, which recovers hypoxanthine and guanine, and it presents with hyperuricemia and severe neurological disease because the unsalvaged purines are driven down the degradation arm instead.

40. Salvage, degradation, and the molybdenum exit

[E] Salvage recovers free bases at about one ATP equivalent rather than six: HGPRT for hypoxanthine and guanine, APRT for adenine, both requiring phosphoribosyl pyrophosphate. Degradation runs the purines the other way — nucleotide to nucleoside to free base — through inosine to hypoxanthine, then to xanthine, then to urate, with xanthine [VOL p.102] oxidoreductase carrying out both of the last two oxidations.

[F] That exit enzyme carries a molybdenum cofactor whose metal is held by a dithiolene, which is to say by two sulfur atoms, and whose terminal sulfur ligand is installed by a dedicated sulfurase. The same cofactor family carries sulfite oxidase, which performs the terminal step of sulfur amino acid catabolism. One cofactor, two gates, the same element holding the metal in both: the purine exit and the sulfur exit are built on the same chemistry, and Chapter 24 takes that coincidence apart in detail, including the three inherited deficiencies that grade by which atom is

stranded.

[F] The arrangement also explains an otherwise odd clinical fact. Allopurinol, the standard treatment for gout, is a hypoxanthine analog that inhibits the exit enzyme, and the consequence of inhibiting it is accumulation of the two unlettered purines — hypoxanthine and xanthine — rather than of the lettered ones. A drug taken by millions of people every day works by raising the concentration of two bases that the genetic alphabet does not contain.

41. The eight nucleotides, and the three one-way gatekeepers

[F] The alphabet that de novo synthesis actually builds has eight members, not four. On the purine side: IMP, XMP, GMP and AMP. On the pyrimidine side: OMP, UMP, CMP and TMP. These are nature's own, with no synthetic base anywhere in the set, which distinguishes the count from expanded-alphabet work that adds unnatural pairs.

[F] Three of the eight are gatekeepers, and the gate is one-way. IMP is the trunk: de novo purine synthesis converges on inosine monophosphate, and only then branches to AMP and to GMP. XMP gates G: IMP dehydrogenase takes IMP to xanthosine monophosphate, and GMP synthase takes XMP to GMP, in that order and no other. OMP gates U: orotidine monophosphate is decarboxylated to UMP, and every other pyrimidine follows from UMP. Remove any one of the three and there are no nucleic acids at all.

[F] Those three are necessary but not sufficient, and understating them is the error the four-letter alphabet institutionalizes. A notation that records only the four end products records the branches and loses the trunk. It is the same omission as the one §290 found in a clinical trial and §306 found in an off-target call: the thing that determined the outcome is not in the record, because the record was designed to name identities rather than to trace pathways.

[E] The three routes that handle those eight are distinct and each is a mutation surface. De novo synthesis builds the ring from amino acids, carbon dioxide and folate, at six ATP per purine, converging on IMP. Salvage recovers free bases at one ATP, through HGPRT for hypoxanthine and guanine and APRT for adenine, and both require a steady supply [VOL p.103] of phosphoribosyl pyrophosphate. Degradation runs the purines down through inosine to hypoxanthine, then xanthine, then urate, with xanthine oxidoreductase carrying a molybdenum cofactor whose metal is held by a dithiolene — two sulfur atoms — and whose terminal

sulfido ligand decides whether the valve opens at all.

[F] The same cofactor family that completes sulfur's own oxidation also gates the purine exit.

Sulfite oxidase and xanthine dehydrogenase both carry it, and in both the metal is held by sulfur and the sulfur that builds the holder is delivered as a thiocarboxylate. Two gates, one metal, the same element holding it in both — and one of those gates,

when it fails, turns the unfinished atom into an excitotoxin that kills infants within days.

42. The eight, in one table

[F] The table sets the eight species against what the code records, what the enzyme that makes them is, and what inherited or pharmacological failure of that step produces. Three rows have no letter, and those three are the gates.

species	letter	made by	gate	failure of this step
inosine	none	purine pathway, ten steps	trunk of all	ADSL deficiency downstream;
monophosphate		from PRPP	purines	6-mercaptopurine acts here
xanthosine monophosphate	none	IMP dehydrogenase	gate to guanine	mycophenolate, ribavirin; IMPDH1 mutation in retinitis pigmentosa
adenosine monophosphate	A	adenylosuccinate synthetase and lyase, GTP-driven	branch product	ADSL deficiency, succinylpurinemia
guanosine monophosphate	G	GMP synthase, ATP-driven	branch product	depletion under IMPDH blockade
orotidine monophosphate	none	orotate phosphoribosyltransferase	gate to all pyrimidines	hereditary orotic aciduria
uridine monophosphate	U	OMP decarboxylase	parent pyrimidine	rescued by dietary uridine

[VOL p.104]

species	letter	made by	gate	failure of this step
cytidine triphosphate	C	CTP synthase, from UTP	branch product	CTPS1 deficiency, immunodeficiency
thymidine monophosphate	T	thymidylate synthase, from dUMP	branch product	5-fluorouracil; folate deficiency

Table. The eight nucleotide species of de novo synthesis. Three carry no letter in the genetic code, and those three are

the obligatory gates.

43. What the four-letter notation loses

[F] A notation that records only the four end products records the branches and loses the trunk. The loss is not aesthetic. Four specific things become unstateable.

•
The identity of the limiting step. A cell short of guanine nucleotides and a cell short of adenine nucleotides are in different states with different consequences, and both appear in a sequence record as an unchanged genome.

•	**The direction of a perturbation.** Inhibiting the gate to guanine raises the concentration of the trunk nucleotide; inhibiting the trunk lowers everything. The record cannot distinguish these because neither species has a symbol.
•	**The route by which a base arrived.** A thymine made by thymidylate synthase and a thymine

produced by deaminating a cytosine are the same letter arriving by different chemistry at different metabolic cost, and Chapter 8 shows that the difference has consequences the assay cannot see.

•
The existence of the unlettered pools themselves. Hypoxanthine and xanthine circulate at
measurable concentrations in human plasma, rise in ischemia, and are the substrate of the
enzyme whose inhibition is standard gout therapy. None of them has a place in the alphabet
that the field treats as the complete description of genetic material.

44. Predictions and tests

[F] Four predictions follow, each checkable with existing reagents.	

•	**Prediction one.** Under partial IMP dehydrogenase inhibition, the unlettered trunk pool should rise before the guanine pool falls, and the time lag between the two should set the therapeutic window of mycophenolate better than plasma drug concentration does. Measurable by targeted mass spectrometry in peripheral blood mononuclear cells.

[VOL p.105] • **Prediction two.** Adenine base editing should be more efficient in cells with a high ratio of trunk to branch purines, because the product of the edit is the trunk base itself and product inhibition of the deaminase should scale with the free inosine pool. Testable with isogenic lines under mycophenolate.

• **Prediction three.** Dihydroorotate dehydrogenase inhibition should phenocopy a partial respiratory chain defect in the specific respect of pyrimidine supply, and supplying uridine should rescue the pyrimidine phenotype without rescuing the respiratory one. This experiment has been done in fragments across several literatures; it has not been done as a single controlled comparison.

• **Prediction four.** In any tissue where the exit enzyme is pharmacologically inhibited, the ratio of unlettered to lettered purines should shift measurably and persistently, and the shift should be detectable in a routine metabolomics panel. If it is not, the model of the exit as a one-way gate is wrong.

45. Consequences

[F] The structural conclusion is that the genetic alphabet, as the field uses it, is a list of products rather than an account of a pathway, and that the three species it omits are the ones through which everything must pass. The practical conclusion is that intervention at a gate is categorically different from intervention at a branch: a gate has no bypass, which is why the drugs that act at gates — mycophenolate, leflunomide, allopurinol — are old, effective and used at scale, and why inherited failures at gates present in infancy rather than in middle age.

[O] The open question is whether the trunk nucleotide does anything beyond passing material through. It is the base that appears at wobble position 34 after deamination, the base an adenine editor writes, the base that marks transcripts as self rather than foreign, and the base that accumulates at a deaminated chromosome end. A molecule that is simultaneously the obligatory metabolic trunk and the principal product of RNA editing may be doing one job or two. Chapters 7 and 8 take that question as far as the evidence currently allows.

46. Notes to Chapter 5: the gates, measured

Quantities worth carrying

[E] Branch point flux. The partition of inosine monophosphate between the adenine and guanine arms is set by the relative activity of adenylosuccinate synthetase and IMP dehydrogenase, each of which uses the opposite branch’s triphosphate as cosubstrate. Under normal conditions the pools of adenine and guanine nucleotides differ by several fold, with adenine [VOL p.106] nucleotides the larger.

[E] IMP dehydrogenase isoforms. Two isoforms exist in humans. One is broadly expressed; the other is strongly induced in proliferating cells and is the principal target of mycophenolate's antiproliferative effect, which is why the drug is an immunosuppressant rather than a general poison.

[E] The decarboxylation rate enhancement. The uncatalyzed decarboxylation of orotidine monophosphate has a half-life on the order of tens of millions of years at neutral pH; the enzyme performs it in milliseconds, a rate enhancement near 10^17, with no metal and no cofactor. It is among the largest rate enhancements measured for any enzyme.

[E] Plasma concentrations of the unlettered purines. Hypoxanthine and xanthine circulate at low micromolar concentrations in healthy plasma and rise substantially in ischemia, strenu-ous exercise and tumor lysis. They are routinely measurable and are not part of any genetic workup.

[E] Urate. Human plasma urate sits in the range of 3 to 7 milligrams per deciliter, far higher than in species with functional uricase, and close to its solubility limit, which is why small changes precipitate disease.

Methods box: watching a gate

[F] Isotope tracing through the branch point. Feed labeled glycine, formate or glutamine and follow label into inosine, adenine and guanine nucleotides separately. The ratio of label arrival at the two branches reports the partition, which no measurement of pool size alone can give.

[F] Enzyme activity in situ. IMP dehydrogenase activity can be assayed in permeabilized cells or in extracts by following NADH production. Clinically, mycophenolate exposure is sometimes monitored by its pharmacokinetics; monitoring the enzyme's inhibition directly is feasible and rarely done.

[F] Detecting the gates' failures. Hereditary orotic aciduria is diagnosed by orotic acid in urine; molybdenum cofactor deficiency by sulfite and S-sulfocysteine; xanthinuria by the substitution of xanthine and hypoxanthine for urate. In each case the diagnostic is the accumulation of an unlettered intermediate, which is a useful reminder that clinical chemistry has been reporting these species routinely for decades while genetics has had no symbol for them.

[F] Targeted metabolomics panels. A single liquid chromatography-mass spectrometry method can report all eight species of this chapter plus the salvage intermediates. The method is standard; what is not standard is including it in studies whose endpoint is a sequence.

[VOL p.107] ### Further reading, oriented

[E] The biosynthetic pathways are textbook and are best read in a primary biochemistry text for the stoichiometry, then in the clinical genetics literature for the inherited failures, which is where the structure of the pathway becomes visible as a set of graded phenotypes.

[E] For the enzymology of the decarboxylation step, the Radzicka and Wolfenden analysis of uncatalyzed reaction rates is the entry point and is worth reading for its method as much as its result.

[E] For the therapeutic side, the literature on dihydroorotate dehydrogenase inhibition in autoimmune disease and in leukemia connects pyrimidine supply to the respiratory chain through a single enzyme and is the clearest current example of supply-line pharmacology.

Problems

[O] 5.1 Draw the pathway and mark every step that is irreversible under cellular conditions.

Compare your list with the three gates named in the chapter. If you find a fourth, what does it gate?

[O] 5.2 The reciprocal energetics of the two purine arms is presented as a balancing device.

Model it: write the two rate expressions with the opposite triphosphate as cosubstrate, and show under what conditions the arrangement stabilizes the ratio and under what conditions it does not.

[O] 5.3 Given that dihydroorotate dehydrogenase is coupled to ubiquinone, predict the effect of complex III inhibition on pyrimidine supply, and design the experiment that separates that effect from the general energetic consequence.

[O] 5.4 Allopurinol raises hypoxanthine and xanthine concentrations. Predict the consequences for salvage flux through HGPRT and for the inosine pool, and say what would be measured to test it.

[O] 5.5 Construct the strongest argument that the alphabet should remain four letters — that the three gates, being intermediates, do not belong in a notation of genetic information. Then say what that argument costs when applied to inosine, which is both an intermediate and an edited product in RNA and DNA.

[O] 5.6 Estimate the ATP cost of replicating a human genome by de novo synthesis alone, and compare with the measured ATP turnover of a dividing cell. What fraction of the cell's energy budget is nucleotide supply?

[VOL p.108] ### Connections

[F] The trunk base of this chapter is the subject of Chapters 7, 8 and 14, where it reappears as the product of editing and as the base that reads as another letter. The exit enzyme reappears in Chapter 24, where its cofactor is built in three sulfur steps and its inherited failures grade by which atom is stranded.

Worked example: what mycophenolate does, read as a gate

[F] Mycophenolate is given to transplant recipients to suppress lymphocyte proliferation. Read through the gate structure of this chapter, its mechanism and its therapeutic window become one statement rather than two.

[F] The target. IMP dehydrogenase, which converts the unlettered trunk nucleotide into the unlettered xanthine nucleotide. It is the rate-limiting step of guanine nucleotide synthesis and the first gate on the guanine arm.

[F] Why it is selective. Proliferating lymphocytes depend heavily on de novo purine synthesis and have limited salvage capacity relative to other cell types, which do recover preformed bases through HGPRT. A gate inhibitor therefore hits the cells that must build from scratch and spares the cells that can recycle. The selectivity is a property of the pathway's architecture, not of the drug's binding.

[F] What rises and what falls. Blocking the gate lowers guanine nucleotides and raises the trunk nucleotide upstream. Because the adenine arm leaves from the same trunk and is driven by GTP, the adenine arm slows too, by a second-order effect through the reciprocal energetics.

[F] What the record would show. Nothing. The genome of a treated lymphocyte is unchanged.

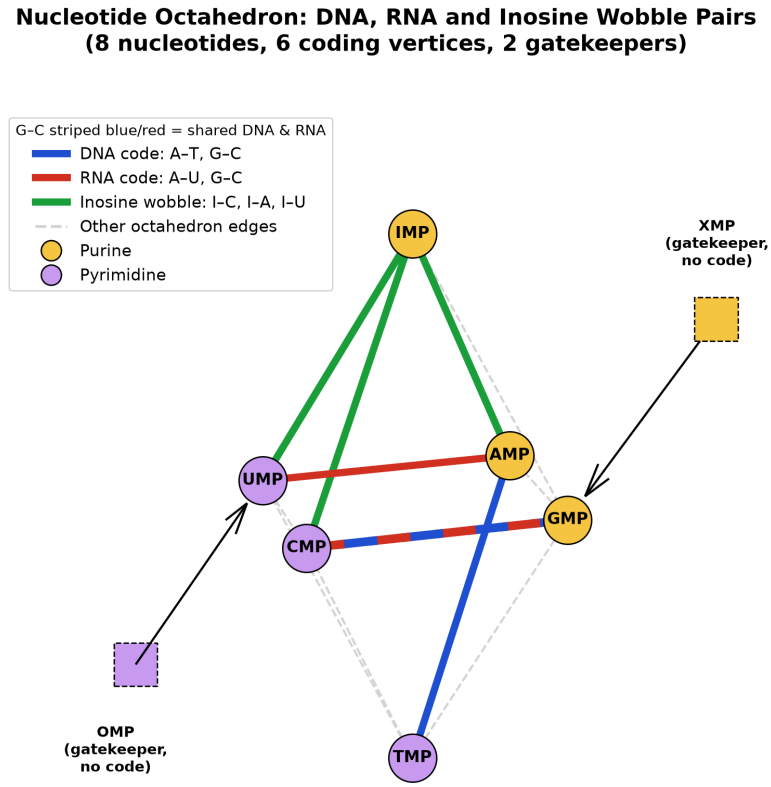
The effect is entirely in the pools, which no sequence assay reports.

[F] What follows for monitoring. Clinical monitoring of this drug uses plasma concentration.

The quantity that determines effect is the degree of gate inhibition, which is reported better by the ratio of the trunk nucleotide to guanine nucleotides in the target cells. That measurement is a targeted mass spectrometry panel on peripheral blood mononuclear cells, and it is the chapter's first prediction stated as a clinical proposal rather than an experiment.

[F] What would falsify the reading. If the trunk nucleotide does not rise under partial inhibition — if, say, it is consumed by degradation as fast as it accumulates — then the gate model needs amending, and the degradation arm becomes the quantity to watch. That alternative is itself testable in the same panel, by measuring hypoxanthine and xanthine alongside.

Plate N-1 · The nucleotide octahedron [H] — new material, J. A. Berger, October 2026



Opposite (non-edge) vertex pairs: IMP–TMP and GMP–UMP (forbidden by model); AMP–CMP is the remaining third axis.
Gatekeepers XMP→GMP and OMP→UMP sit off the octahedron (metabolic only, no coding role).

NovagonDNA · J. A. Berger · CC BY 4.0

Plate N-1 [H] (new, JAB). Eight nucleotides take part in de novo purine and pyrimidine synthesis: purines IMP, XMP, GMP, AMP and pyrimidines UMP, OMP, CMP, TMP. XMP and OMP are one-way gatekeepers (XMP → GMP, OMP → UMP) and carry no code, so they sit off the solid. The remaining six are the coding vertices of an octahedron. Opposite vertices — IMP–TMP, GMP–UMP and AMP–CMP — share no edge, so no pairing joins them. Colored edges are the pairings: DNA A–T (blue); RNA A–U (red); G–C, used by both codes (striped blue/red); inosine wobble I–A, I–C and I–U (green). The six remaining edges (dashed gray) carry no pairing. DNA code = AMP, TMP, GMP, CMP; RNA code = AMP, UMP, GMP, CMP; wobble = IMP, CMP, AMP, UMP. This is a proposed geometric model, tagged [H]; it is not drawn from the source papers. Compare Chapter 5, “Eight Nucleotides and Three One-Way Gatekeepers”, immediately above.

[VOL p.109] **CHAPTER 6**

Codons Read as Atoms

Abstract. Each base in the color key names an element, and an element has an atomic symbol. Applying that correspondence letter by letter turns every codon into a three-atom string: adenine reads as hydrogen, cytosine as carbon, guanine as nitrogen, uracil as phosphorus, thymine as sulfur, inosine as oxygen. This chapter gives the translation for all twenty-two coded amino acids and the three stop codons, states what the translation does and does not assert, and isolates two results. The first is that sulfur never appears in a codon's atom string at all, although two amino acids are built on it. The second is that the three stop codons translate into strings whose hydrogen counts and hydrogen positions correspond, in order, to the three adenine-nucleotide states.

47. What the translation is

[E] The correspondence is fixed by the color key and is not adjustable. Adenine sits on the hydrogen row, cytosine on carbon, guanine on nitrogen, uracil on phosphorus, thymine on sulfur, and hypoxanthine — and therefore inosine — on oxygen. Because each row names exactly one element, each base names exactly one atomic symbol, and a codon of three bases names a string of three atoms in order.

[F] Methionine's start codon AUG reads HPN: hydrogen, phosphorus, nitrogen. Proline's CCC reads CCC. Tryptophan's UGG reads PNN. The reading is mechanical and reversible; nothing is chosen.

[F] What the translation asserts is this and no more: the four-letter notation is already an elemental notation in disguise, because each letter was assigned to an element on chemical grounds before any codon was examined. What it does not assert is that the atom named is the atom doing work in that codon's amino acid. Those are different claims, and the second one is false in the two most important cases, which is the first result of the chapter.

48. The full translation

[F] Table 1 gives all twenty-two coded amino acids with every codon that specifies them, the atom string for each codon, and the note that matters chemically. Single-letter amino-acid codes in parentheses are amino-acid abbreviations, not base symbols, and carry no color.

CHAPTER 6

Codons Read as Atoms

Abstract. Each base in the color key names an element, and an element has an atomic symbol. Applying that correspondence letter by letter turns every codon into a three-atom string: adenine reads as hydrogen, cytosine as carbon, guanine as nitrogen, uracil as phosphorus, thymine as sulfur, inosine as oxygen. This chapter gives the translation for all twenty-two coded amino acids and the three stop codons, states what the translation does and does not assert, and isolates two results. The first is that sulfur never appears in a codon's atom string at all, although two amino acids are built on it. The second is that the three stop codons translate into strings whose hydrogen counts and hydrogen positions correspond, in order, to the three adenine-nucleotide states.

47. What the translation is

[E] The correspondence is fixed by the color key and is not adjustable. Adenine sits on the hydrogen row, cytosine on carbon, guanine on nitrogen, uracil on phosphorus, thymine on sulfur, and hypoxanthine — and therefore inosine — on oxygen. Because each row names exactly one element, each base names exactly one atomic symbol, and a codon of three bases names a string of three atoms in order.

[F] Methionine's start codon AUG reads HPN: hydrogen, phosphorus, nitrogen. Proline's CCC reads CCC. Tryptophan's UGG reads PNN. The reading is mechanical and reversible; nothing is chosen.

[F] What the translation asserts is this and no more: the four-letter notation is already an elemental notation in disguise, because each letter was assigned to an element on chemical grounds before any codon was examined. What it does not assert is that the atom named is the atom doing work in that codon's amino acid. Those are different claims, and the second one is false in the two most important cases, which is the first result of the chapter.

48. The full translation

[F] Table 1 gives all twenty-two coded amino acids with every codon that specifies them, the atom string for each codon, and the note that matters chemically. Single-letter amino-acid codes in parentheses are amino-acid abbreviations, not base symbols, and carry no color.

Table. The twenty-two coded amino acids and the three stop codons, each codon translated letter by letter into its atomic symbols.

49. The first result: sulfur is absent from the notation and present in the chemistry

[F] No codon anywhere in the table contains a sulfur atom. The symbol cannot appear, because sulfur belongs to thymine and thymine is a DNA base: messenger RNA carries uracil, and the codon table is read in RNA. The elemental notation of the coded message is therefore built from hydrogen, carbon, nitrogen and phosphorus only.

[E] Two amino acids are nevertheless built on sulfur, and both are load-bearing. Methionine is the start codon's product and the precursor of S-adenosylmethionine, which carries the methyl group for every methylation mark in the cell, including the one written on the messenger's own 5′ cap before anything is read from it. Cysteine's thiol becomes the transient thiyl radical of ribonucleotide reductase, which converts ribonucleotides into the deoxyribonucleotides the genome is built from, and the same thiolate ligates iron in every iron-sulfur cluster.

[F] So the code opens on a sulfur amino acid whose sulfur is invisible in the notation that spells it. The sulfur sits in the side chain, where the codon has nothing to say about it, and the side

Table. The twenty-two coded amino acids and the three stop codons, each codon translated letter by letter into its atomic symbols.

49. The first result: sulfur is absent from the notation and present in the chemistry

[F] No codon anywhere in the table contains a sulfur atom. The symbol cannot appear, because sulfur belongs to thymine and thymine is a DNA base: messenger RNA carries uracil, and the codon table is read in RNA. The elemental notation of the coded message is therefore built from hydrogen, carbon, nitrogen and phosphorus only.

[E] Two amino acids are nevertheless built on sulfur, and both are load-bearing. Methionine is the start codon's product and the precursor of S-adenosylmethionine, which carries the methyl group for every methylation mark in the cell, including the one written on the messenger's own 5′ cap before anything is read from it. Cysteine's thiol becomes the transient thiyl radical of ribonucleotide reductase, which converts ribonucleotides into the deoxyribonucleotides the genome is built from, and the same thiolate ligates iron in every iron-sulfur cluster.

[F] So the code opens on a sulfur amino acid whose sulfur is invisible in the notation that spells it. The sulfur sits in the side chain, where the codon has nothing to say about it, and the side

Source page [VOL p.111] rendered at 150 dpi (plate / figure / table as published).

[VOL p.112] chain is where the work happens. That is the volume's recurring finding arriving at the first codon of every transcript: the record names identities and the chemistry does the work, and the two do not coincide.

[F] The bookend on the other side is the purine trunk. De novo purine synthesis converges on inosine monophosphate, the orange base, and branches from there to adenine and guanine nucleotides. Start is sulfur chemistry, carried in a side chain the codon cannot show; stop, as the next section argues, is hydrogen and oxygen chemistry; and the trunk between them is a base with no letter at all.

50. The translation: codons read as atoms

Source page [VOL p.113] rendered at 150 dpi (plate / figure / table as published).

[VOL p.114] **Table 8.** The twenty-two coded amino acids and three stop codons, with each codon translated letter by letter into its atomic symbols. Single-letter amino-acid codes in parentheses are not base symbols and are not colored.

[F] Two entries carry more than the rest. Methionine, the start codon, and cysteine are the two sulfur-bearing amino acids, and in neither does the sulfur appear in the codon's own atom translation. It is in the side chain, and it does the work. Methionine becomes S-adenosylmethionine and methylates the messenger's own cap before anything is read from it. Cysteine's thiol becomes the thiyl radical of §275 and converts ribonucleotides into the deoxyribonucleotides the genome is built from. The code opens on a sulfur amino acid whose sulfur is invisible in the notation that spells it, which is the paper's recurring finding arriving once more, now at the first codon of every transcript.

[F] The bookend is the purine trunk. De novo purine synthesis converges on inosine monophosphate and branches to AMP and GMP; AMP is the nucleotide the stop-codon reading below depends on. Start is sulfur chemistry; stop is hydrogen and oxygen chemistry; and the trunk between them is the orange base.

[F] The three stop codons, read as atoms. UAA reads PHH, UAG reads PHN, and UGA reads PNH. Counting hydrogens and their positions gives a pattern that lines up with the three adenine-nucleotide states. PHH carries two hydrogens, at positions two and three, which reads as AMP with its two hydrogen bonds. PHN carries one hydrogen, in the middle position, which reads as ADP. PNH carries one hydrogen, in the third and final position, which reads as ATP — and the terminal position is where a signal to stop would have to sit.

[E] The groundwork this rests on is established and is worth separating from the reading itself.

The three stop codons are not equivalent in biology. UAA is the strictest: it is the most used stop across genomes, it is the least leaky, and it has never been reassigned to an amino acid in any organism. UAG and UGA are the leaky ones, and both have been recoded — UGA to selenocysteine in every domain of life, UAG to pyrrolysine in the methanogenic archaea. Readthrough rates differ in the same order. And the adenine nucleotides differ in exactly the way the reading requires: AMP, ADP and ATP are distinguished by the number of phosphoanhydride bonds and by the hydrogen-bonding states that accompany them.

[O] The hypothesis, stated as such: that the atom translation of a stop codon is not a coincidence of the color scheme but a reading of the signal the ribosome and ATP synthesis share — that the position of the hydrogen in the three-atom string corresponds to the adenine-nucleotide state, and that UGA at PNH, with its hydrogen terminal, is the one that says stop to ATP synthesis as well as to translation. If that is right it would be the first quantum signal from

Table 8. The twenty-two coded amino acids and three stop codons, with each codon translated letter by letter into its atomic symbols. Single-letter amino-acid codes in parentheses are not base symbols and are not colored.

[F] Two entries carry more than the rest. Methionine, the start codon, and cysteine are the two sulfur-bearing amino acids, and in neither does the sulfur appear in the codon's own atom translation. It is in the side chain, and it does the work. Methionine becomes S-adenosylmethionine and methylates the messenger's own cap before anything is read from it. Cysteine's thiol becomes the thiyl radical of §275 and converts ribonucleotides into the deoxyribonucleotides the genome is built from. The code opens on a sulfur amino

acid whose sulfur is invisible in the notation that spells it, which is the paper's recurring finding arriving once more, now at the first codon of every transcript.

[F] The bookend is the purine trunk. De novo purine synthesis converges on inosine monophosphate and branches to AMP and GMP; AMP is the nucleotide the stop-codon reading below depends on. Start is sulfur chemistry; stop is hydrogen and oxygen chemistry; and the trunk between them is the orange base.

[F] The three stop codons, read as atoms. UAA reads PHH, UAG reads PHN, and UGA reads PNH. Counting hydrogens and their positions gives a pattern that lines up with the three adenine-nucleotide states. PHH carries two hydrogens, at positions two and three, which reads as AMP with its two hydrogen bonds. PHN carries one hydrogen, in the middle position, which reads as ADP. PNH carries one hydrogen, in the third and final position, which reads as ATP — and the terminal position is where a signal to stop would have to sit.

[E] The groundwork this rests on is established and is worth separating from the reading itself. The three stop codons are not equivalent in biology. UAA is the strictest: it is the most used stop across genomes, it is the least leaky, and it has never been reassigned to an amino acid in any organism. UAG and UGA are the leaky ones, and both have been recoded — UGA to selenocysteine in every domain of life, UAG to pyrrolysine in the methanogenic archaea. Readthrough rates differ in the same order. And the adenine nucleotides differ in exactly the way the reading requires: AMP, ADP and ATP are distinguished by the number of phosphoanhydride bonds and by the hydrogen-bonding states that accompany them.

[O] The hypothesis, stated as such: that the atom translation of a stop codon is not a coincidence of the color scheme but a reading of the signal the ribosome and ATP synthesis share — that the position of the hydrogen in the three-atom string corresponds to the adenine-nucleotide state, and that UGA at PNH, with its hydrogen terminal, is the one that says stop to ATP synthesis as well as to translation. If that is right it would be the first quantum signal from

[VOL p.115] proton tunneling to be read off the genetic code, and it belongs with the proton-tunneling material rather than beside it.

[O] It lines up with known biology in a way that is not forced. The strictest stop, UAA, is the one whose atom string carries two hydrogens and reads as the

lowest-energy adenine nucleotide — the state furthest from a cell that can still do work. The two leaky, recodable stops carry one hydrogen each, and differ only in its position. The order of strictness and the order of the reading are the same order, and neither was derived from the other.

[O] The falsifiable predictions are three. First, readthrough rate at each stop should track the cell's adenylate energy charge, and should do so in the order UAA least, UGA most. Second, recoding to selenocysteine at UGA should be sensitive to the ATP/ADP ratio independently of selenium supply. Third, no organism should be found that has reassigned UAA to an amino acid; a single counterexample would break the reading, because UAA is the one the model requires to be unavailable for recoding.

51. The three stop codons, read as atoms

[F] The three stop codons translate as follows. UAA reads PHH. UAG reads PHN. UGA reads PNH. All three begin with phosphorus, which is uracil in the first position, and the three differ only in what follows.

[F] Counting hydrogens and noting their positions gives a pattern. PHH carries two hydrogens, at positions two and three. PHN carries one hydrogen, in the middle position. PNH carries one hydrogen, in the third and final position. Two hydrogens, one hydrogen in the middle, one hydrogen at the end: three distinct states, in a system whose central energy currency also has exactly three states.

52. The groundwork this rests on

[E] Four established facts are needed before the reading can be stated, and they are separated here from the reading itself so that a reader can accept the groundwork and reject the hypothesis.

• **The three stops are not equivalent.** UAA is the most used stop codon across genomes, the least leaky, and has never been reassigned to an amino acid in any organism examined. UAG and UGA are both leakier and both have been recoded: UGA to selenocysteine in all three domains of life, UAG to pyrrolysine in methanogenic archaea. Measured readthrough rates follow the same order.

• **Readthrough is context-dependent and physiological.** Stop-codon readthrough is not purely

proton tunneling to be read off the genetic code, and it belongs with the proton-tunneling material rather than beside it.

[O] It lines up with known biology in a way that is not forced. The strictest stop, UAA, is the one whose atom string carries two hydrogens and reads as the lowest-energy adenine nucleotide — the state furthest from a cell that can still do work. Source page [VOL p.115] rendered at 150 dpi (plate / figure / table as published).

[VOL p.116] an error process. It is regulated, it varies with the nucleotide immediately 3′ of the stop, and it is used productively — selenoprotein synthesis is the clearest case, where a stop is read as sense through a dedicated element in the untranslated region.

• **The adenine nucleotides are three distinct states.** AMP, ADP and ATP differ by the number of phosphoanhydride bonds and therefore by the free energy available on hydrolysis. The ratio among them — the adenylate energy charge — is one of the most tightly regulated quantities in the cell, and it is sensed directly by AMP-activated protein kinase.

• **Translation is one of the cell's largest consumers of that currency.** Each elongation cycle costs the equivalent of four high-energy phosphate bonds, and termination is the step at which that consumption stops.

53. The hypothesis, stated as such

[O] The hypothesis is that the atom translation of a stop codon is not an artifact of the color scheme but a reading of a signal that the ribosome and ATP synthesis share: that the position of the hydrogen in the three-atom string corresponds to the adenine-nucleotide state, and that UGA at PNH, with its hydrogen terminal, is the one that signals stop to ATP synthesis as well as to translation. On that reading, PHH with two hydrogens corresponds to AMP, the state furthest from a cell that can still do work; PHN with one hydrogen in the middle position corresponds to ADP; and PNH with one hydrogen in the terminal position corresponds to ATP, with the terminal position being where a signal to stop would have to sit.

[O] If that is right it would be the first signal of proton position read directly off the genetic code, and it belongs with the proton-tunneling material rather than beside it. Proton transfer in enzymes is not classical: hydrogen tunneling contributes measurably to catalysis in several well-studied systems, and the proton gradient across the inner mitochondrial membrane is the physical quantity that ATP synthase converts into chemistry. A code whose termination signals encode proton count and proton position would be a code that carries, in its least examined codons, information about the energetic state of the compartment doing the work.

54. Why the alignment is not forced

[O] The ordering was not arranged. The strictest stop, UAA, is the one whose string carries two hydrogens and reads as the lowest-energy adenine nucleotide. The two leaky, recodable stops carry one hydrogen each and differ only in its position. The order of strictness established in the literature and the order produced by the reading are the same order, and neither was derived from the other: the color assignments were fixed on chemical grounds, the strictness [VOL p.117] ordering comes from comparative genomics, and the two were compared only after both were fixed.

[O] Three predictions follow, each of which can break the reading.

• **Prediction one.** Readthrough rate at each stop should track the cell's adenylate energy charge, and should do so in the order UAA least sensitive, UGA most. The experiment is a dual-luciferase readthrough reporter run across a titration of energy charge — oligomycin, 2-deoxyglucose, or a controlled glucose ramp — with charge measured directly rather than inferred.

• **Prediction two.** Recoding to selenocysteine at UGA should be sensitive to the ATP/ADP ratio independently of selenium supply. Selenoprotein synthesis is usually studied as a function of selenium availability; holding selenium constant and varying energy charge is the test, and it has not been done.

• **Prediction three.** No organism should be found that has reassigned UAA to an amino acid. A single clear counterexample breaks the reading, because UAA is the stop the model requires to be unavailable for recoding. This prediction is already exposed to the entire comparative genomic record, which is what makes it worth stating.

[F] The hypothesis is given here at its full strength and marked open throughout. It is not load-bearing for any other chapter: remove it and the translation table, the sulfur result and the purine bookend all stand unchanged. It is included because a reading that generates three falsifiable predictions, one of which is already exposed to an existing dataset, is worth more in print than in a drawer.

55. Consequences

[F] Two consequences hold regardless of what happens to the stop-codon reading.

[F] The first is that the codon table can be written in elements rather than in letters, and that doing so makes two absences visible at once: sulfur, which does not appear in any codon string although two amino acids depend on it, and inosine, whose atom is oxygen and which appears in no codon at all although it is the trunk of purine synthesis and the product of the most abundant editing reaction in human cells.

[F] The second is methodological. A notation that can be rewritten in another alphabet without loss is a notation whose content is the mapping and not the symbols. The genetic code is usually taught as if the letters were primitive. They are not: they are names for molecules, the molecules are made of atoms, and the atoms are what reacts.

[VOL p.118] ## 56. Notes to Chapter 6: the translation, checked

Quantities worth carrying

[E] Codon counts. Sixty-four codons: sixty-one sense and three stop. Twenty standard amino acids plus selenocysteine and, in some archaea, pyrrolysine. Degeneracy is concentrated at the third position, which is the position the wobble chemistry of Chapter 7 operates on.

[E] Stop codon usage. Across genomes, UAA is the most frequently used stop in many organisms, with usage varying by GC content and by gene expression level. The ordering of leakiness — UAA least, UGA most — is consistent across the experimental literature.

[E] Readthrough rates. Basal stop-codon readthrough is typically well below one percent but varies by orders of magnitude with the stop codon, the following nucleotide and the sequence context. Program d readthrough events, including

selenoprotein synthesis, are far more efficient because they use dedicated signals.

[E] Energy charge. The adenylate energy charge, defined as the ratio of ATP plus half ADP to the total adenine nucleotide pool, is held near 0.85 to 0.95 in healthy cells and falls under ischemia. It is the quantity the stop-codon hypothesis of this chapter proposes as an input to termination.

[E] Cost of translation. Elongation consumes the equivalent of four high-energy phosphate bonds per residue: two for charging the transfer RNA and two for the elongation cycle. Translation is therefore among the largest single consumers of the currency whose state the hypothesis concerns.

Methods box: testing a reading

[F] Dual-reporter readthrough assay. Two reporter proteins separated by an in-frame stop codon; the ratio of downstream to upstream signal gives readthrough efficiency. Control constructs with a sense codon in place of the stop normalize for expression. This is the assay for prediction one.

[F] Clamping energy charge. Energy charge can be lowered with oligomycin, with 2deoxyglucose, or by controlled glucose limitation, and raised by substrate repletion. The essential discipline is to measure the charge directly by nucleotide quantitation rather than to infer it from the treatment.

[F] Selenoprotein readout. Selenocysteine incorporation at a UGA codon can be measured with a reporter carrying a selenocysteine insertion sequence element in its untranslated region. The test of prediction two requires holding selenium supply constant — verified [VOL p.119] by measuring selenoprotein P or glutathione peroxidase activity — while varying energy charge.

[F] Comparative genomics for prediction three. Searching for an organism that has reassigned UAA requires systematic analysis of codon usage and of stop codon context across sequenced genomes, of the kind already performed for ciliate and mitochondrial reassignments. The prediction is exposed to the entire existing record.

What the translation does and does not assume

[F] The translation assumes only the base-element pairing of the color key. It does not assume that the element named is the element doing chemical work in the amino acid, and the two sulfur amino acids are the standing counterexample: their sulfur is in the side chain and absent from the codon string.

[F] It does not assume that the atom string has any physical reality in the ribosome. The strings are a rewriting of the notation, and the only claim that goes beyond rewriting is the stop-codon hypothesis, which is marked open throughout and is independent of the rest of the volume.

Problems

[O] 6.1 Write out the atom strings for all sixty-four codons, including the eighteen not listed in Table 1 because they are synonymous. Then ask: is any atom string

unique to one amino acid? What would it mean if one were?

[O] 6.2 Count the hydrogen atoms in the atom strings of the start codon and of each stop codon. The hypothesis of this chapter uses stop-codon hydrogen counts; does the start codon's count fit any comparable pattern, and is the question well posed?

[O] 6.3 Construct the strongest objection to the stop-codon reading: that any three-element mapping applied to three codons will produce some pattern. Quantify it — how many mappings of six elements to six bases produce an equally good match to the strictness ordering?

[O] 6.4 Selenocysteine is read from UGA and pyrrolysine from UAG. Both are recoded stops; neither is UAA. Is this evidence for the hypothesis, or is it the observation the hypothesis was built from? Distinguish carefully.

[O] 6.5 Design an experiment that would detect an effect of adenylate energy charge on termination that is not mediated by the obvious route — that is, not by changes in release factor abundance or by global translation slowdown.

[O] 6.6 The two sulfur amino acids have no sulfur in their codon strings. List every other amino acid whose functionally decisive atom is absent from its own codon string. What does the [VOL p.120] resulting list suggest about what a codon encodes?

Connections

[F] The translation is used in Chapter 16, where the element keying of compartments is set out, and in Chapter 21, where the code's opening on a sulfur amino acid is one link of the chain. The stop-codon hypothesis stands alone and is listed among the falsifiers of Appendix C with its own breaking condition.

Worked example: translating one gene's opening codons

[F] Take the first five codons of a transcript and run the translation, to see what the exercise does and does not show.

[F] The start codon is AUG, which reads HPN: hydrogen, phosphorus, nitrogen. The amino acid is methionine, whose side chain contains a sulfur atom that appears nowhere in the string.

[F] Suppose the next four codons are GCC, AAG, UCU and UGC. They read NCC, HHN, PCP and PNC respectively, and they specify alanine, lysine, serine and cysteine. Again the final residue's decisive atom — the thiol sulfur of cysteine — is absent from its own codon's string.

[F] Two observations follow immediately and a third requires care.

• **Observation one.** The atom strings use only four symbols, because messenger RNA uses only four bases and the fifth and sixth assignments, sulfur and oxygen, belong to thymine and inosine. A coded message is written in hydrogen, carbon, nitrogen and phosphorus.

• **Observation two.** Of the two residues in this short peptide whose chemistry is likely to matter catalytically — the initiating methionine and the cysteine — neither

has its functional atom represented. The code names the residue, not the chemistry.

• **Observation three, stated carefully.** The translation is a rewriting, not a discovery. It shows that the four-letter notation is an elemental notation in disguise, since the letters were assigned to elements on chemical grounds. It does not show that the ribosome, the transfer RNA or the messenger does anything with the atoms named.

[F] The one place the volume goes beyond rewriting is the stop codons, where the pattern in hydrogen count and position is compared with the three adenine-nucleotide states. That comparison is marked open, carries three predictions, and is deliberately isolated so that a reader who rejects it loses nothing else.

[F] A reader who wants to test the translation’s informativeness should run it over a gene of their

resulting list suggest about what a codon encodes?

Connections

[F] The translation is used in Chapter 16, where the element keying of compartments is set out, and in Chapter 21, where the code's opening on a sulfur amino acid is one link of the chain. The stop-codon hypothesis stands alone and is listed among the falsifiers of Appendix C with its own breaking condition.

Worked example: translating one gene's opening codons

[F] Take the first five codons of a transcript and run the translation, to see what the exercise does and does not show.

[F] The start codon is AUG, which reads HPN: hydrogen, phosphorus, nitrogen. The amino acid is methionine, whose side chain contains a sulfur atom that appears nowhere in the string.

[F] Suppose the next four codons are GCC, AAG, UCU and UGC. They read NCC, HHN, PCP and PNC respectively, and they specify alanine, lysine, serine and cysteine. Again the final residue's decisive atom — the thiol sulfur of cysteine — is absent from its own codon's string.

[F] Two observations follow immediately and a third requires care.

- **Observation one.** The atom strings use only four symbols, because messenger RNA uses only four bases and the fifth and sixth assignments, sulfur and oxygen, belong to thymine and inosine. A coded message is written in hydrogen, carbon, nitrogen and phosphorus.
- **Observation two.** Of the two residues in this short peptide whose chemistry is likely to matter catalytically — the initiating methionine and the cysteine — neither has its functional atom represented. The code names the residue, not the chemistry.
- **Observation three, stated carefully.** The translation is a rewriting, not a discovery. It shows that the four-letter notation is an elemental notation in disguise, since the letters were assigned to elements on chemical grounds. It does not show that the ribosome, the transfer RNA or the messenger does anything with the atoms named.

[F] The one place the volume goes beyond rewriting is the stop codons, where the pattern in hydrogen count and position is compared with the three adenine-nucleotide states. That comparison is marked open, carries three predictions, and is deliberately isolated so that a reader who rejects it loses nothing else.

[F] A reader who wants to test the translation's informativeness should run it over a gene of their

[VOL p.121] own choosing and ask whether any atom string tracks anything — hydrophobicity, secondary structure propensity, codon usage. If none does, the translation is a notation and nothing more, which is exactly what the chapter claims for all of it except the three stop codons.

[VOL p.122] **CHAPTER 7**

Wobble Position Thirty-Four

Abstract. One position in one molecule carries both of this volume's elements doing opposite work. Position 34 of the anticodon is the wobble position, the first base of the anticodon and the one that pairs with the third base of the codon. In a substantial fraction of human transfer RNAs that position carries inosine, produced by deamination of an encoded adenosine, which widens recognition so that one transfer RNA reads three codons. In another set it carries a thiolated uridine, produced by a sulfur transfer from a cysteine desulfurase, which narrows recognition and stabilizes the codon-anticodon duplex so the reading frame holds. One position, two chemical corrections, in opposite directions, neither of them written in any sequence record.

57. Why position 34 exists at all

[E] The genetic code is degenerate: sixty-one sense codons specify twenty amino acids, so most amino acids have several codons, and the redundancy sits almost entirely in the third codon position. A cell could in principle encode a separate transfer RNA for every codon. No cell does. Human cells carry on the order of forty to fifty distinct anticodon species to read sixty-one codons, and the gap is closed by letting one anticodon read more than one codon.

[E] Crick's 1966 wobble hypothesis described how. Pairing at the third codon position is geometrically looser than at the first two, and a base at anticodon position 34 can therefore make non-Watson-Crick pairs. The hypothesis explicitly included inosine, which Crick proposed could pair with uridine, cytidine and adenosine — three codons from one anticodon.

[F] Two consequences of that arrangement are worth making explicit before the chemistry. First, the decoding capacity of a cell is not set by its genome's complement of transfer RNA genes alone; it is set by the genes plus the post-transcriptional chemistry applied to position

34. Second, that chemistry is therefore a regulatory layer sitting between the genome and the proteome, and it is one that no sequencing of the genome, and no standard sequencing of the transcriptome, will report.

[VOL p.123] 58. The widening correction: adenosine to inosine

[E] Inosine at position 34 is not transcribed. It is made in place by deamination of an encoded adenosine, catalyzed in eukaryotes by the heterodimeric enzyme ADAT2/ADAT3, which acts on a set of transfer RNAs that in humans numbers in the high single digits to low teens depending on the species counted. Removing the exocyclic amine of adenine leaves hypoxanthine, whose nucleoside is inosine; the base retains the purine skeleton and loses the hydrogen-bond donor that made it adenine.

[E] The pairing consequence is the one Crick predicted. Inosine at 34 reads codons ending in U, C and A. A single transfer RNA species therefore covers an entire three-codon set, and the cell's decoding table is compressed accordingly.

[F] Three facts about this reaction matter to the rest of the volume. It is essential: loss of the deaminase is lethal in every organism in which it has been tested, and hypomorphic alleles in humans produce intellectual disability. It is invisible: inosine is read as guanosine by reverse transcriptase, so a sequencing readout of a transfer RNA carrying inosine at 34 reports a G at that position, and the edit is erased in the record. And it is the same reaction, with the same product, that an adenine base editor performs on DNA — a point Chapter 14 develops, because the catalytic core of the first adenine base editors was an evolved bacterial enzyme whose native substrate is precisely position 34.

59. The narrowing correction: thiolation at the second carbon of uridine

[E] Where the wobble base is uridine, a different correction applies. In human cells the mitochondrial and cytosolic modification systems both install a sulfur atom at the second carbon of the uracil ring, producing 2-thiouridine, usually in combination with a modification of the fifth position. The sulfur comes from cysteine by way of a cysteine desulfurase, NFS1, which abstracts it as a persulfide and hands it down a relay of sulfur carrier proteins to the thiouridylase that installs it.

[E] The chemical effect of replacing the 2-oxygen with sulfur is well characterized. Sulfur is larger and less electronegative than oxygen; it is a poorer hydrogen-bond acceptor; and in a pyrimidine ring it strongly biases the sugar pucker toward the C3′-endo conformation. The practical result is a nucleoside that pairs more rigidly and more selectively: 2-thiouridine at 34 pairs well with A and poorly with G, which restricts a wobble that would otherwise be loose, and it raises the thermal stability of the codon-anticodon duplex.

58. The widening correction: adenosine to inosine

[E] Inosine at position 34 is not transcribed. It is made in place by deamination of an encoded adenosine, catalyzed in eukaryotes by the heterodimeric enzyme ADAT2/ADAT3, which acts on a set of transfer RNAs that in humans numbers in the high single digits to low teens depending on the species counted. Removing the exocyclic amine of adenine leaves hypoxanthine, whose nucleoside is inosine; the base retains the purine skeleton and loses the hydrogen-bond donor that made it adenine.

[E] The pairing consequence is the one Crick predicted. Inosine at 34 reads codons ending in U, C and A. A single transfer RNA species therefore covers an entire three-codon set, and the cell's decoding table is compressed accordingly.

[F] Three facts about this reaction matter to the rest of the volume. It is essential: loss of the deaminase is lethal in every organism in which it has been tested, and hypomorphic alleles in humans produce intellectual disability. It is invisible: inosine is read as guanosine by reverse transcriptase, so a sequencing readout of a transfer RNA carrying inosine at 34 reports a G at that position, and the edit is erased in the record. And it is the same reaction, with the same product, that an adenine base editor performs on DNA — a point Chapter 14 develops, because the catalytic core of the first adenine base editors was an evolved bacterial enzyme whose native substrate is precisely position 34.

59. The narrowing correction: thiolation at the second carbon of uridine

[E] Where the wobble base is uridine, a different correction applies. In human cells the mitochondrial and cytosolic modification systems both install a sulfur atom at the second carbon of the uracil ring, producing 2-thiouridine, usually in combination with a modification of the fifth position. The sulfur comes from cysteine by way of a cysteine desulfurase, NFS1, which abstracts it as a persulfide and hands it down a relay of sulfur carrier proteins to the thiouridylase that installs it.

[E] The chemical effect of replacing the 2-oxygen with sulfur is well characterized. Sulfur is larger and less electronegative than oxygen; it is a poorer hydrogen-bond acceptor; and in a pyrimidine ring it strongly biases the sugar pucker toward the C3′-endo conformation. The practical result is a nucleoside that pairs more rigidly and more selectively: 2-thiouridine at 34 pairs well with A and poorly with G, which restricts a wobble that would otherwise be loose, and it raises the thermal stability of the codon-anticodon duplex.

PP-2026-VOL-01 v1 · NovagonDNA · © 2026 John Allen Berger · CC BY 4.0

Source page [VOL p.123] rendered at 150 dpi (plate / figure / table as published).

[VOL p.124] **[E]** Loss of the modification has a precise phenotype. In yeast and in human cells, failure of the mitochondrial thiolation pathway produces ribosomal frameshifting and impaired respiration; in humans, mutations in the mitochondrial thiouridylase MTU1 cause acute infantile liver failure, and the same sulfur relay

supports both this modification and iron-sulfur cluster

assembly. One desulfurase feeds both.

60. Two opposite corrections, one position

[F] Set side by side, the two modifications are chemically opposite operations performed on the

same position for the same purpose.		
property	**inosine at 34**	**2-thiouridine at 34**
made from	encoded adenosine, by deamination	encoded uridine, by sulfur transfer
atom changed	nitrogen removed, oxygen exposed	oxygen replaced by sulfur
effect on pairing	widens: reads U, C and A	narrows: pairs A, discriminates against G
effect on duplex	lowers specificity, raises coverage	raises stability and specificity
supply line	deaminase, no cofactor consumed	cysteine desulfurase, sulfur relay
appears in a sequence	guanosine	uridine
record as		
failure phenotype	lethality; intellectual disability in hypomorphs	frameshifting, respiratory failure, infantile liver failure

Table. The two chemical corrections at anticodon position 34, compared.

[F] The last row but one is the point this volume keeps returning to. One modification is misread as a different base, the other is read as its unmodified parent. In both cases the record reports something that is not what is in the molecule, and in both cases what is in the molecule is what determines whether the ribosome reads the frame correctly.

[F] The sulfur modification also ties the reading frame to respiration through a shared supply.

NFS1 is the single cysteine desulfurase of the human mitochondrion. Its persulfide output feeds iron-sulfur cluster assembly, which supplies the respiratory chain and several DNA repair enzymes, and it feeds wobble thiolation, which supplies the reading frame. A cell short of cysteine, or carrying a defect in the relay, loses both at once. Chapter 20 follows that supply line in detail; Chapter 15 follows one of its consequences to the chromosome end.

[VOL p.125] 61. Wobble position thirty-four: inosine, and the sulfur beside it

[E] Position thirty-four of a transfer RNA anticodon is where the code stops being a lookup table.

Deamination of A at that position by the ADAT2/ADAT3 pair gives I, and inosine is the only base that pairs with three others — A, C and U. The three nucleic-acid alphabets are not one alphabet: DNA reads ATGC, RNA reads UACG, and the wobble row reads AUIC — with no guanine in it. Hydrogen-bonding counts across the set are A=3, G=2, C=3, U=2, I=1 and T=1, totaling twelve.

[E] Position thirty-four is also where sulfur sits. The 2-thiouridine modifications — the s2U family, and in eukaryotes the (m)cm5(s2)U forms specifically — are written at exactly that position, and they hold the reading frame. The eight wobble-34 modifications peculiar to Eukarya are galQ, manQ, m5C, f5Cm, (m)cm5(s2)U, (m)chm5U, ncm5U(m) and Ψ, and the literature on them is thin enough that the position is open frontier rather than settled ground.

[F] The same anticodon position carries both the inosine that widens recognition and the sulfur that tightens it. One deamination broadens a tRNA to read three codons; one thiolation narrows and stabilizes the pairing so the frame does not slip. Operation six of the seven — tuning recognition — is therefore not a general property distributed over the molecule. It is localized to a single nucleotide, and that nucleotide is the one the four-letter alphabet is least able to represent.

[E] The enzyme that writes the thiolation closes the chain back to its start. In the mitochondrial pathway MTU1/TRMU installs 2-thiouridine at position thirty-four, and the sulfur it installs is delivered by the cysteine desulfurase NFS1 as a persulfide — the same enzyme, the same persulfide relay, that supplies the iron-sulfur clusters of §273. Failure of TRMU causes acute infantile liver failure; failure of MTO1 causes cardiomyopathy with lactic acidosis.

[F] One cysteine desulfurase supplies both the oldest cofactor in biology and the modification that holds the ribosome’s reading frame. The mineral relic and the reading frame draw on the same sulfur donor. That is the single tightest link in this chain,

62. Alu, ADAR, and inosine as the mark of self

[E] Alu elements are jumping genes — short interspersed retrotransposons, roughly three hundred bases, present in over a million copies and making up more than a tenth of the human genome. When two Alu copies land in one transcript facing each other, the transcript folds into a double-stranded structure indistinguishable from viral RNA, and MDA5 exists to detect exactly that. The cell’s answer is not to remove the Alu. It is to edit the duplex: each inosine [VOL p.126] ADAR places weakens the pairing until the hairpin is untidy enough that the sensor no longer reads it as an invader.

[E] The genetics show this is the actual function rather than an incidental one. An ADAR1 knockout mouse is embryonic lethal, and the lethality is rescued by loss of MAVS or of MDA5 — the animal does not die because editing is missing, it dies because its own RNA is read as foreign. The human failure of the same marking is Aicardi-Goutieres syndrome type 6, a permanent antiviral response mounted against

the self.

[F] The cell does not distinguish self from non-self RNA by sequence. It distinguishes by a chemical mark that a sequence file does not record. And the mark is inosine, the same base that is the trunk of purine synthesis in §41, the same base that is prebiotically easier than guanine in §274, the same base that widens the anticodon in §61, and the same base an adenine editor writes in §306 while the record says G. Four distinct roles, one base, and in every one of them the notation loses it.

[F] This also places a constraint on the jumping genes themselves that the usual account misses.

A retrotransposon that inserts itself a million times is normally described as a parasite the genome tolerates. On this reading the genome did not merely tolerate the Alu expansion; it could only tolerate it because it already had an inosine-writing enzyme to mark the resulting duplexes as self. The editor is a precondition for the expansion, not a response to it.

63. What follows from two corrections at one position

[F] Four conclusions follow, in increasing order of how much they cost the field.

• **Decoding capacity is chemical, not genetic.** Two cells with identical transfer RNA gene complements can have different decoding tables if their modification enzymes differ in activity. Codon usage analysis performed on a genome assumes a fixed mapping from gene to anticodon function. The assumption is wrong at position 34, and it is wrong in a direction that depends on sulfur supply and on deaminase activity.

• **Two different errors look identical in the record.** A transfer RNA that failed to be deaminated reads as an A at position 34 and a transfer RNA that was successfully deaminated reads as a G. The failure state and the normal state are both representable, but as different letters, so a study comparing two conditions by sequence will record a letter change where there is no genetic change at all.

• **The reading frame has a metabolic dependency.** Frameshifting is normally treated as a property of the message — slippery sequences, pseudoknots, program d events. At position 34 it is also a property of sulfur supply, because the modification that stabilizes the codon-[VOL p.127]anticodon duplex is built from cysteine sulfur. A cell under cysteine restriction is a cell with a less accurate ribosome.

• **The two elements of this volume meet here.** Oxygen, as the carbonyl of hypoxanthine, and sulfur, as the thiocarbonyl of 2-thiouridine, occupy the same position in the same molecule and move recognition in opposite directions. If the volume had to be reduced to a single position in a single molecule, this would be the position.

64. Objections

[F] The modifications are known, cataloged and studied; nothing here is new. Correct and important. Every statement in this chapter marked [E] is established. What is argued is the consequence: that an essential, non-genetic, metabolically supplied chemical layer sits between the genome and the proteome, that it is invisible to the instruments used to validate genetic medicines, and that its failure modes are already in the clinic under other names.

[F] Transfer RNA modification is peripheral to disease. It is not. Mutations in the enzymes that install position 34 modifications cause intellectual disability, mitochondrial myopathy, infantile liver failure and deafness; the modification pathway is dysregulated in multiple tumor types; and the sulfur relay that supports it is the same relay that supports iron-sulfur cluster assembly, whose failure is covered in Chapters 19 and 20.

[F] Inosine at 34 is an RNA phenomenon with no bearing on DNA medicine. The catalytic core of the first adenine base editors was derived from an enzyme whose native substrate is anticodon position 34. The reaction performed on DNA in a patient is the reaction the cell performs on transfer RNA, redirected. Chapter 14 shows what that implies for off-target assessment, and the implication is not small.

65. Tests

[F] Three measurements would settle questions this chapter leaves open, and all three use existing methods.

• **Thiolation state as a function of cysteine availability.** Quantify 2-thiouridine at position 34 by mass spectrometry across a cysteine titration, with frameshifting measured in parallel by a dual-reporter assay. The prediction is a monotonic relationship, and its slope is the quantity nobody has measured.

• **Editing level at 34 under adenine base editor expression.** If an adenine base editor and the native deaminase compete for the same transfer RNA substrates, expressing the editor [VOL p.128] should shift position 34 editing levels. Measurable by inosine-specific chemical sequencing of transfer RNA in edited cells, which is a published method.

• **Frame fidelity after cluster-assembly perturbation.** Because one desulfurase feeds both cluster assembly and wobble thiolation, a defect in the relay should produce a coordinated phenotype: respiratory deficiency and frameshifting together, with a fixed ratio between them. If frameshifting appears without respiratory loss, the shared-supply model is wrong.

[O] The open question is priority. When sulfur is scarce, does the cell preserve cluster assembly at the expense of the wobble modification, preserve the wobble modification at the expense of clusters, or degrade both proportionally? The answer would reveal which of the two the cell treats as more urgent, and nothing in the current literature settles it.

66. Notes to Chapter 7: position thirty-four, measured

Quantities worth carrying

[E] Modification inventory. More than one hundred and fifty chemically distinct modified nucleosides are cataloged in cellular RNA, with transfer RNA the most densely modified species and the anticodon loop its most densely modified region. Positions 34 and 37 carry the largest share of functionally characterized modifications.

[E] Deamination targets. The eukaryotic ADAT2/ADAT3 enzyme acts on a defined subset of cytosolic transfer RNAs carrying adenosine at position 34; the number in human cells is in the range of seven to a dozen species depending on how isoacceptors are counted.

[E] Pairing consequences. Inosine at 34 reads codons ending in U, C and A. 2-thiouridine at 34 pairs with A and discriminates against G, and raises the melting temperature of the codon-anticodon duplex measurably in model studies.

[E] Conformational bias. Replacing the 2-oxygen of uridine with sulfur biases the ribose toward the C3′-endo pucker strongly, which is the structural basis of the pairing restriction. The effect is one of the clearest cases in nucleic acid chemistry of a single atom substitution changing conformational equilibrium.

[E] Clinical weight. Mutations in enzymes that install position 34 and 37 modifications cause intellectual disability, mitochondrial myopathy with lactic acidosis, deafness, and acute infantile liver failure. The sulfur relay that supplies them is shared with iron-sulfur cluster assembly.

[VOL p.129] ### Methods box: detecting inosine and thiolation

[F] Inosine, chemically. Because inosine reads as guanosine in ordinary sequencing, it must be distinguished chemically. Acrylonitrile treatment forms a cyanoethyl adduct at inosine’s N1 that stalls reverse transcription, converting an invisible substitution into a positional signal. Comparing treated and untreated libraries gives site-level inosine calls.

[F] Inosine, enzymatically and by mass. Nucleoside-level quantitation by liquid chromatography-mass spectrometry gives total inosine content reliably but no position information; the two methods are complementary and are best run together.

[F] 2-thiouridine. Thiolated nucleosides can be separated electrophoretically using thiol-reactive compounds that retard the modified species, giving a direct gel-level readout of thiolation extent. Mass spectrometry gives quantitation; the gel method gives a cheap, robust assay suitable for titration experiments.

[F] Frameshifting. Dual-reporter constructs with a program d shift site report frame fidelity, and are the natural partner assay to thiolation measurements because the two are predicted to move together under sulfur restriction.

Further reading, oriented

[E] Crick's 1966 wobble paper is short and worth reading in the original; it names inosine explicitly and predicts the three-codon reading.

[E] The modification literature is best entered through the MODOMICS compilation, which gives structures, enzymes and organisms for each modified nucleoside, and then through the reviews on anticodon loop modification and translational fidelity.

[E] For the sulfur relay, the literature on NFS1 and the ISC machinery connects cluster assembly and wobble thiolation; the human disease literature on MTU1 and on NFS1 deficiency gives the clinical consequences.

Problems

[O] 7.1 A transfer RNA carrying inosine at 34 reads three codons. Compute the reduction in the number of transfer RNA species a cell needs if every anticodon beginning with A were deaminated, and compare with the actual number of human cytosolic species.

[O] 7.2 Both corrections at position 34 affect the same property — the breadth of codon recognition — in opposite directions. Design a cell in which both are abolished. Which codons become unreadable, and which become ambiguously read?

[VOL p.130] **[O] 7.3** The chapter claims that sequencing a transfer RNA carrying inosine reports a G. Work out exactly where in the reverse transcription the information is lost, and whether any polymerase property could preserve it.

[O] 7.4 Given that one desulfurase supplies both cluster assembly and wobble thiolation, propose a measurable signature that would distinguish a cell that has sacrificed thiolation from one that has sacrificed clusters.

[O] 7.5 Adenine base editors derive from an enzyme whose native substrate is position 34. Predict the consequence of high editor expression for the cell's own transfer RNA editing, and name the assay that would detect it.

[O] 7.6 Estimate the sulfur flux required to maintain wobble thiolation in a dividing human cell, given transfer RNA abundance and turnover, and compare with the flux required for glutathione synthesis. Which is the larger sink?

Connections

[F] This position is where the volume's two elements meet, and it returns in Chapter 8, where inosine's readout ambiguity becomes a general principle; in Chapter 14, where the same chemistry is performed by a clinical agent; in Chapter 19, where the sulfur relay is set out; and in Chapter 20, where the competition among the relay's outputs is the open question.

Worked example: a cell short of cysteine, followed at one position

[F] Restrict cysteine availability in a cultured human cell and follow the consequences to anticodon position 34. The chain has five steps, each measurable.

[F] Step one: the thiol buffer draws first. Glutathione synthesis is limited by cysteine, and glutathione is present at millimolar concentrations with a turnover

measured in hours. The first consequence of restriction is a falling glutathione pool, measurable within hours by mass spectrometry or enzymatic assay.

[F] Step two: the desulfurase relay competes. The same cysteine is the sulfur source for the relay that serves cluster assembly, wobble thiolation, lipoate and the molybdenum cofactor.

As free cysteine falls, these outputs compete. The order in which they are sacrificed is the open question of Chapter 20.

[F] Step three: thiolation at 34 falls. Measurable by thiol-specific gel retardation or by nucleoside mass spectrometry, reported as the fraction of the relevant transfer RNA species carrying the modification.

[VOL p.131] **[F] Step four: the codon-anticodon duplex destabilizes.** 2-thiouridine raises duplex stability and restricts wobble; its absence loosens both. The predicted consequence is reduced accuracy at the third codon position and increased frameshifting, measurable by dual-reporter assay.

[F] Step five: the proteome degrades in a specific way. Errors concentrate at codons read by the affected anticodons rather than being distributed randomly. This is the step that distinguishes a translational-fidelity defect from a general stress response, and it is measurable by proteomics with error-tolerant searching.

[F] What the sequence record shows at every step. Nothing. The genome is unchanged, the transfer RNA genes are unchanged, and the transcript sequences are unchanged. A study designed around sequence will report a cell under stress with no genetic explanation.

[F] What would falsify the chain. If thiolation falls and frameshifting does not, the link between the modification and frame fidelity is weaker than claimed in this cell type. If glutathione falls and thiolation does not, the outputs are not competing for one pool and the shared-supply model of Chapter 20 needs revision. Both outcomes are informative and both are cheap to obtain.

[VOL p.132] **CHAPTER 8**

Four Letters for Eight Species: The Blind Spots of the Alphabet

Abstract. A sequence record assigns one of four symbols to each position of a polymer. That is two bits per position, and the two bits are spent entirely on identity. Everything else about the position — which isotope, which modification, which tautomer, what is bound to it, what oxidation state the protein that reads it is in — is outside the representation. This chapter sets out what that costs, in three classes of error ordered by how far outside the record they fall, and states the general principle that governs all three: a four-symbol record can represent a substitution and nothing else.

67. What two bits can carry

[F] Begin with the representation rather than with biology. A position in a sequence record holds one of four values. Over a genome of three billion positions this is an enormous amount of information, and the field's instruments are extraordinarily good at reading it: a modern run calls billions of positions at high accuracy for a few hundred dollars.

[F] What the record cannot do is hold any second quantity at the same position. There is no field for modification state, no field for occupancy, no field for the chemical identity of the molecule that the letter stands for when more than one molecule maps to that letter. This is not a limitation of current technology. It is the definition of the data structure. Adding depth adds confidence in the call; it does not add a dimension to what is being called.

[E] The field is aware of this in a piecemeal way and has built separate instruments for individual exceptions: bisulfite conversion and its enzymatic successors for 5-methylcytosine, nanopore current deviation for a growing set of modifications, chemical probing methods for specific RNA modifications. Each of these is a second instrument answering a question the primary record cannot. None of them is part of standard validation for a genetic medicine, and the ones that exist cover a small fraction of the modifications known to occur.

68. Three classes of error

[F] Errors introduced by a therapeutic agent, or arising spontaneously, sort into three classes by their relation to the record.

[VOL p.133] • **Primary off-target: the errors the alphabet can write down.** An editor acts at an unintended locus and changes one letter into another. The record represents this perfectly. Detection is a sequencing problem, the field has built good tools for it, and the remaining difficulties are about sampling depth and about which cells were sequenced rather than about representability.

• **Secondary off-target, first kind: same letter, different molecule.** A chemical change occurs that maps onto an existing letter, so the record shows either no change or a change that misdescribes what happened. Inosine read as guanosine is the canonical case: the molecule in the polymer is not guanosine, pairs differently from guanosine in some contexts, is recognized differently by the innate immune system, and reads as G. 5-methylcytosine read as cytosine is the inverse case: a change with large functional consequence that leaves the letter alone and is therefore invisible unless a second assay is run.

• **Secondary off-target, second kind: no letter at all.** A change occurs in a layer the alphabet does not address — which cofactor is loaded into a protein, which cysteine pairs are oxidized, which metal sits in a site, what the thiol redox poise of the compartment is. There is no symbol to be wrong. The record is not misleading here; it is silent.

[F] The three classes are not equally studied, and the imbalance is almost exactly inverted with respect to their likely clinical importance. The class the record handles well absorbs most of the field's off-target effort. The class the record cannot represent at all receives almost none.

69. Where the second class comes from

[E] The count of chemically distinct modified nucleosides found in cellular RNA now exceeds a hundred and fifty. In DNA the catalog is smaller but not small: 5-methylcytosine, 5hydroxymethylcytosine and its further oxidation products, N6-methyladenine, uracil arising from cytosine deamination, 8-oxoguanine from oxidative damage, and a range of alkylation adducts.

[F] Several of these are chemically one step from a lettered base, which is exactly what makes them invisible. Deamination of cytosine gives uracil, which is read as thymine after replication. Deamination of adenine gives hypoxanthine, read as guanine. Deamination of guanine gives xanthine. Oxidation of guanine gives 8-oxoguanine, which pairs with adenine and is read as a G-to-T transversion only after it has been replicated through. In each case the chemistry is a small change at one atom, and in each case the record either misses it or reports it as something it is not.

[F] Two of those products are the volume's unlettered bases. Hypoxanthine and xanthine are both intermediates of purine metabolism and both products of deamination damage, which [VOL p.134] means the same two molecules appear in the cell by two entirely different routes — one metabolic and intended, one damage-driven and not — and the alphabet has no way to say either.

70. Where the third class comes from

[E] A protein's function depends on more than its sequence. Which iron-sulfur cluster it carries and whether that cluster is intact; which disulfide pairs are formed and in which register; whether a particular cysteine is reduced, oxidized to a sulfenic acid, persulfidated, nitro-sylated or disulfide-bonded; which metal occupies a site that could accept more than one; whether a lipoate arm is attached. None of these is a sequence property, all of them change function, and several of them are reversible on timescales of seconds.

[F] This is the layer in which the volume's second leg operates, and the reason it is invisible is structural rather than accidental. A sequence record describes a polymer's composition. The cofactor layer describes what has been done to that polymer after it was made, by chemistry that is supplied metabolically rather than encoded. The two are different kinds of fact, and no amount of improvement in sequencing will convert one into the other.

[E] The clinical reality of this layer is not in doubt. PTEN, one of the most frequently inactivated tumor suppressors in human cancer, is inactivated by a reversible disulfide between two cysteines as well as by deletion. A tumor with a wild-type

PTEN sequence and an oxidized PTEN protein is genotypically normal and functionally PTEN-null, and no genotype-based selection will find it. Chapter 22 follows that case into the trial record.

71. Four letters, eight nucleotides

[E] The genetic code is written in four letters. The cell's own nucleotide chemistry is not. De novo purine synthesis does not build adenine or guanine; it builds inosine monophosphate, whose base is hypoxanthine, and only then branches to AMP and GMP. De novo pyrimidine synthesis builds orotate, which becomes UMP and from there CMP, with thymine made later by methylating a uracil already in DNA. Guanine deamination produces xanthine on the route to urate. Counting the species the cell actually manufactures and handles as purine and pyrimidine bases, there are eight. The code letters five of them, and uses four at a time. **base symbol has a code letter where it sits in the chemistry** adenine A yes purine branch product of IMP [VOL p.135] **base symbol has a code letter where it sits in the chemistry** guanine G yes purine branch product of IMP cytosine C yes pyrimidine, from orotate through UMP uracil U yes pyrimidine, from orotate through UMP thymine T yes uracil methylated by thymidylate synthase hypoxanthine I no IMP, the trunk both purines branch from xanthine X no guanine deaminated, on the way to urate orotate O no the pyrimidine ring before it is ever a nucleotide **Table 2.** The eight bases the cell makes, and the five the code letters.

[F] The omission is not at the periphery. Hypoxanthine is the trunk. Adenine and guanine are its branches, and every purine in every nucleic acid in the body passed through it on the way to being made. The code's missing letter is the molecule its two lettered purines are built from.

[F] An unlettered base is not merely absent from the table. It is absent from the instrument. A sequencer reports one of four symbols per position. When it meets a base that is not one of the four, it does not report an exception; it reports whichever of the four the chemistry of the read step made it resemble. Inosine base-pairs like guanine, so reverse transcriptase puts a cytosine opposite it and the sequencer writes a G. The record shows a guanine. There was no guanine.

72. Primary off-target: the errors the alphabet can write down

[F] Define the primary class as any off-target event that changes which of the four letters occupies a position. Nuclease cutting at a mismatched site; indels, inversions and large deletions at and around the target; bystander deamination inside the editing window; guide-independent deamination wherever the genome transiently opens. All of these are letter changes.

[F] Everything that makes this class tractable follows from that one property. A letter change can be predicted in silico because the search space is a string search. It can be found because the assay that finds it is the same assay that confirmed the edit. It can be counted, reported to a regulator, and compared between two editor

variants. And it can be engineered against, which is why narrowed-window editors and high-fidelity nucleases exist and work.

[VOL p.136] **[F]** The field's confidence in editing rests almost entirely on its success with this class, and that confidence is earned. The error in generalizing from it is to assume that the class is exhaustive - that an off-target effect which does not show up as a letter is an off-target effect that did not happen.

73. Secondary off-target, first kind: same letter, different molecule

[E] A deaminase mounted on a DNA-binding protein is still a deaminase, and it does not stop at DNA. In the published transcriptome-wide survey, the cytosine editor BE3 produced tens of thousands of C-to-U edits in RNA across HepG2 and HEK293T cells, affecting something between thirty-eight and fifty-eight percent of expressed genes, at frequencies from a fraction of a percent to over eighty percent, including missense and nonsense changes and splice sites. The adenine editor ABEmax produced a comparable burden of A-to-I edits, affecting roughly half of expressed genes. Approximately ninety-eight percent of the edited cytosines and ninety-five percent of the edited adenines had no corresponding change anywhere in the DNA.

[F] Those numbers are the center of this chapter. A DNA off-target assay of any depth whatsoever returns clean for the overwhelming majority of what a base editor actually did to the cell. The standard safety package is not merely incomplete; it is pointed at the wrong molecule.

[F] And the recording problem is sharper still for the adenine editor. Its product is inosine, which has no letter. The published method detects it by sequencing cDNA and finding guanines where the genome has adenines - that is, by letting reverse transcriptase commit the misreading and then reading the misreading. The only way the notation can register inosine is by writing down a base that is not there. Any site where that misreading is incomplete, or where the inosine sits in a transcript the pipeline does not cover, produces no record at all.

[F] The same blindness covers every chemical state of an unchanged letter. 5-methylcytosine reads as C, and is the entire mechanism of the epigenetic silencer in Section 135. N6-methyladenosine reads as A. Pseudouridine reads as U. 2-thiouridine, the sulfur-bearing wobble base of the lysine, glutamate and glutamine tRNAs, reads as U. In each case the molecule has changed, the biology has changed, and the symbol has not. This is the first secondary class: the letter is right and the chemistry is different.

74. Secondary off-target, second kind: no letter at all

[F] The second secondary class is not a modified letter but a layer with no letters in it. A gene specifies a sequence of amino acids. It does not specify the four-iron, four-sulfur cluster [VOL p.137] seated in aconitase, the lipoamide arm swinging on pyruvate dehydrogenase, the sulfonium center of S-adenosylmethionine, or which

cysteine in a secreted protein pairs with which. Those are installed after translation by machinery that is a chemistry rather than an instruction, and no editor reaches them because there is nothing there to edit.

[F] An edit can therefore be perfect in the notation and wrong in the cell. Suppose an editor corrects a mutation, the amplicon reads correct, the exome reads clean, the transcript reads clean. The protein is still assembled under whatever thiol redox potential and whatever cluster-assembly capacity that cell has at that moment. If the editing process itself perturbed either - and lipid-nanoparticle delivery, transient nuclease expression, interferon response and proliferative stress all do - then the protein produced from the corrected gene is a different molecule from the protein the correction was meant to produce, and nothing in the verification package has any channel through which to say so.

[F] The three classes can now be stated together. Primary: wrong letter, visible. Secondary of the first kind: right letter, wrong molecule, visible only to an instrument nobody runs by default. Secondary of the second kind: no letter involved, visible only to an assay of the chemistry itself. The field has industrialized the detection of the first and has no standard practice for either of the others.

The three classes against the assays that would see them Filled means the assay detects the event as a matter of course. Open means it detects it only with a method chosen for the purpose. Blank means the event leaves no signature the assay can carry.

On-target letter change Nuclease cut at a mismatched site Bystander deamination in the window Guide-independent genomic deamination Indel, inversion or large deletion SECONDARY I Disulfide register and persulfidation Iron-sulfur cluster occupancy Lipoamide and SAM suffi-ciency **Table 3.** What each assay can see. Every row in the primary block is covered by an assay already in the standard package. No row below it is.

75. The principle, stated once

[F] A four-symbol record can represent a substitution and nothing else. Every consequence in this chapter and in Chapters 13, 14 and 15 is a corollary of that one sentence.

[F] Three corollaries deserve to be stated as separate propositions, because each is independently testable.

1. Any change that preserves the letter is unrepresentable. Methylation, hydroxymethylation, thiolation, oxidation that does not alter pairing, and every protein-level modification [VOL p.138] fall here. Detecting them requires a different instrument, not a deeper run of the same one.

2. Any change that maps onto a different letter is misrepresented rather than missed. This is worse than the first case in one specific respect: it produces a confident, wrong answer.

Inosine reported as guanosine is not a gap in the data; it is an error in the data that carries the same quality scores as every correct call around it.

3. Any change in a layer with no symbol is silent. Cofactor occupancy, disulfide register, metal loading and redox poise are not in the alphabet in any form, so no reading of the record, however deep, can bear on them at all.

76. What this does not claim

[F] Three boundaries matter, because the argument is easy to overstate and an overstated version is easy to dismiss.

[F] It does not claim that sequencing is unreliable. For the question sequencing answers — what is the identity of the base at this position in this molecule in this sample — it is excellent, and its error modes are well characterized.

[F] It does not claim that the missing layers are unmeasurable. Every one of them has at least one established assay: mass spectrometry for modified nucleosides and for cofactor content, non-reducing immunoblot and differential alkylation for disulfide and thiol state, inductively coupled plasma mass spectrometry for metal loading, enzymatic or nanopore methods for methylation. The assays exist. They are not run as part of edit verification.

[F] It does not claim that the field is unaware. It claims something more specific and more awkward: that awareness is distributed across specialist literatures while validation practice is standardized around the one instrument that cannot see any of it, and that the mismatch is institutional rather than intellectual.

77. Four predictions

[F] Each can be checked against published data or with commercially available reagents.

• **Prediction one.** In any adenine base editing experiment, the fraction of A-to-G calls that reflect genuine genomic guanosine rather than inosine in RNA or in an unreplicated strand should be less than one hundred percent, and the deficit should scale with the proportion of RNA carried into the library preparation. Testable by inosine-specific chemistry on existing libraries.

• **Prediction two.** Epigenetic editors validated by sequencing alone should show guide-independent off-target methylation at a rate detectable by whole-genome methylation analysis [VOL p.139] but absent from their published off-target reports, because those reports sampled sequence rather than methylation.

• **Prediction three.** In cells carrying a defect in iron-sulfur cluster assembly, the mutational spectrum should shift measurably even though no repair gene is mutated, because several repair enzymes are cluster proteins. The sequence record will show the consequence — mutations — while remaining silent about the cause.

• **Prediction four.** In a tumor series selected for wild-type PTEN sequence, a measurable fraction will be functionally PTEN-deficient by redox state, and that

fraction should be enriched in tumors with high oxidative tone. The assay is a non-reducing immunoblot, and the samples already exist in biobanks.

78. Consequences

[F] For a development program the consequence is a rule about instruments: the validation instrument must be matched to the chemistry of the agent, not to the convention of the field. An agent that deaminates requires an assay that distinguishes inosine from guanosine. An agent that methylates requires an assay that reads methylation genome-wide rather than at candidate loci. An agent that depends on a cofactor-loaded protein requires an assay that reports occupancy. In each case the right assay exists and costs less than one arm of the trial that would otherwise fail for reasons nobody can name afterward.

[O] For the field the open question is how large the gap is in aggregate. Each individual case in this chapter is documented. What nobody has done is estimate, across a defined set of approved and investigational agents, what fraction act through, or fail through, chemistry their own validation cannot represent. The estimate is possible with public data, and it would convert this chapter's argument from a structural claim into a number.

79. Notes to Chapter 8: what the record holds

Quantities worth carrying

[E] Information per position. Two bits, exactly, for a four-symbol alphabet with no side channel. A human genome is therefore about 6.2 x 10^9 bits of identity information, under a gigabyte, which is a useful number to hold when the genome is described as containing everything about an organism.

[E] Modification catalog. More than one hundred and fifty modified nucleosides in RNA; in DNA, 5-methylcytosine at roughly 3 to 5 percent of cytosines in human somatic tissue, plus [VOL p.140] 5-hydroxymethylcytosine at a tenth of that or less depending on tissue, with neural tissue the highest.

[E] Deamination rates. Spontaneous cytosine deamination in DNA occurs at a measurable rate per genome per day, and the product, uracil, is removed by a dedicated glycosylase. Adenine deamination to hypoxanthine is slower and is also repaired by a dedicated activity, which is itself evidence that the cell treats the unlettered purine as damage when it appears in DNA.

[E] ADAR editing scale. Millions of adenosine-to-inosine editing sites have been reported in the human transcriptome, overwhelmingly in repetitive elements in untranslated regions. The flux is large, constitutive, and invisible to DNA sequencing.

[E] Oxidative lesions. 8-oxoguanine is present at low but measurable levels per million guanines in normal tissue, rising under oxidative stress. It pairs with adenine and is therefore read as a transversion only after replication.

Methods box: the second instruments

[F] Methylation. Bisulfite conversion deaminates unmethylated cytosine to uracil and leaves 5-methylcytosine intact, converting a modification into a sequence difference. Enzymatic conversion methods achieve the same without the DNA damage bisulfite causes. Both give genome-wide, base-resolution methylation when sequenced deeply enough; both are more expensive than ordinary sequencing, which is why candidate-locus versions are common.

[F] Inosine. Cyanoethylation plus reverse transcription stalling, as described in the notes to Chapter 7, with the comparison between treated and untreated libraries giving positional calls.

[F] Direct reading. Nanopore sequencing measures ionic current deviations that depend on the chemical identity of the bases in the pore, and can therefore in principle report modifications directly. Base-calling models exist for a growing subset; the limitation is model coverage rather than physics.

[F] The protein layer. Non-reducing versus reducing gel comparison for disulfide status; thiol trapping with maleimide reagents of differing mass for free-thiol quantitation; inductively coupled plasma mass spectrometry for metal content; native mass spectrometry for intact cofactor occupancy.

A note on what "off-target" has come to mean

[F] The term is used in the editing literature almost exclusively for sequence-representable events: edits at unintended loci. The usage is so settled that the second and third classes of this chapter [VOL p.141] are rarely called off-target at all, which means the field's vocabulary encodes the same blind spot as its instruments. Readers auditing a validation package should check whether the package defines off-target in the narrow sense, because the definition determines what was looked for.

Problems

[O] 8.1 Take a published off-target analysis for a base editor. Classify every event it reports into the three classes of this chapter. Then list the events in classes two and three that the method used could not have detected.

[O] 8.2 Compute how much additional information would be needed, per position, to record modification state for the known DNA modifications. How does the required record size compare with the sequence record?

[O] 8.3 The chapter claims that depth does not convert an unrepresentable quantity into a representable one. Construct the strongest counterexample: a case where very deep sequencing does recover information about a modification indirectly.

[O] 8.4 For the three classes, rank the likely clinical importance and the current research effort. The inversion between the two rankings is the chapter's claim; defend or refute it with a literature count.

[O] 8.5 Design a validation package for a hypothetical agent that deaminates adenosine in DNA and incidentally in RNA. Specify assays, sampling frames and

acceptance criteria, and estimate the cost relative to a standard package.

[O] 8.6 Inosine and hypoxanthine arrive in the cell by two routes — metabolic synthesis and deamination damage. Propose a way to distinguish the two sources in a sample, and say what it would take to make the method quantitative.

Connections

[F] The principle stated here is the engine of Part Four. It is applied to protein chemistry in Chapter 13, to three clinical modalities in Chapter 14, and to an order statistic at the chromosome end in Chapter 15. It also sets the bound on editing stated in Chapter 23: an editor can write a substitution, which is exactly what the record can hold, and nothing else.

Worked example: classifying one off-target report

[F] Take a published off-target analysis for an adenine base editor and classify everything in it against the three classes.

[VOL p.142] **[F] What such a report typically contains.** Whole-genome sequencing of edited and control cells; a list of candidate sites identified by homology to the guide or by an unbiased biochemical method; the observed editing frequency at each; and a statement that edits above background were detected at some small number of sites.

[F] Class one, representable and reported. Every A-to-G call in the report is class one. The record can hold it, the method can find it, and the analysis is appropriate to the question. This is where nearly all of the report’s content lies.

[F] Class two, misreported by construction. Each A-to-G call is a report of a letter. The molecule produced by the enzyme is inosine, and whether a given call reflects inosine still in the strand or a guanosine installed after replication is not determined by the method. For DNA edits in dividing cells the distinction resolves itself; for edits in non-dividing cells it does not, and the report does not address it. Also in class two: any editing of RNA, which the analysis does not sample at all, although the enzyme’s ancestral substrate is RNA.

[F] Class three, outside the record. Nothing in the report bears on cofactor occupancy, thiol redox state or nucleotide pool composition in the edited cells, each of which can change as a consequence of the delivery procedure, of the editing event’s repair, or of the selection applied during expansion. The report is silent, and silence here is not evidence of absence.

[F] The arithmetic of effort. Count the pages. In a typical report, class one occupies nearly all of the figures and supplementary tables; class two occupies a sentence, if anything; class three does not appear. The inversion between effort and likely clinical consequence is the chapter’s claim, and this count is the way to check it on a specific document rather than in general.

[F] What to ask for. Three additions would close most of the gap and none is expensive: inosine-specific chemistry on DNA and RNA in parallel; a catalytically dead control construct to separate enzyme-dependent from delivery-dependent

effects; and the four-assay state panel of Appendix E on the edited population before and after expansion.

[VOL p.143] # Review of Part II

What Part Two established

[F] Five chapters, each adding one step to a single argument about notation and supply.

[F] The chain begins one term earlier than it is taught. Nucleotides to DNA to RNA to proteins, with returns from proteins to nucleotides and from proteins to the elements. The addition converts a diagram about information into a diagram with a source term, a rate, a cost and failure modes that are not mutations: pool depletion, pool imbalance, cofactor misloading and redox state.

[E] De novo synthesis builds eight species, not four. On the purine side, the trunk nucleotide and the xanthine nucleotide alongside the two lettered products; on the pyrimidine side, the orotidine gate alongside uridine, cytidine and thymidine nucleotides. Three of the eight are one-way gates, and the three gates are precisely the three with no letter. Remove any one and the cell makes no nucleic acid at all.

[F] The notation is an elemental notation in disguise. Each base names an element, so each codon rewrites as a string of atoms. Two results follow: no codon string contains sulfur, although two amino acids are built on it; and the three stop codons' hydrogen counts and positions correspond, in order, to the three adenine-nucleotide states. The second is marked open and carries three falsifiable predictions.

[E] One position carries two opposite corrections. At anticodon position 34, deamination to inosine widens recognition and thiolation at the second carbon of uridine narrows it. Both are essential, both are supplied metabolically rather than encoded, and neither appears in a sequence record — one because it reads as a different base, the other because it reads as its unmodified parent.

[F] The general principle. A four-symbol record can represent a substitution and nothing else. Changes that preserve the letter are unrepresentable; changes that map onto another letter are misrepresented rather than missed; changes in a layer with no symbol are silent.

What Part Two did not establish

[O] It did not establish how large the consequences are. That a record cannot carry a class of chemistry is structural; what fraction of biological or clinical variance that chemistry accounts for is a quantity nobody has measured, and the volume says so each time it arises.

[VOL p.144] **[O]** It did not establish the stop-codon reading. That is an open hypothesis with three named falsifiers, isolated so that nothing else in the volume depends on it.

[O] It did not establish that editing the letter is insufficient in any particular case. The experiment comparing a thymine made by thymidylate synthase with one produced by cytosine base editing has not been run, and until it is, the objection in Chapter 4 is a stated possibility rather than a demonstrated effect.

The numbers worth keeping

[E] Six high-energy phosphate equivalents per purine by de novo synthesis, about one by salvage.

Eight nucleotide species; three one-way gates; four letters. More than one hundred and fifty modified nucleosides cataloged in cellular RNA. Two bits per position in the record, spent entirely on identity.

Questions a reader should be able to answer

[O] R2.1 Name the three gates and say what accumulates when each fails.

[O] R2.2 Why are the adenine and guanine arms of purine synthesis energetically cross-linked, and what does the arrangement accomplish without any transcriptional regulation?

[O] R2.3 Write the atom string for the start codon and for each stop codon. State what the translation assumes and what it does not.

[O] R2.4 Two transfer RNAs differ only in the chemistry at position 34. Describe what a sequencing readout reports for each, and why the two reports differ in kind.

[O] R2.5 Classify these into the three error classes of Chapter 8: an edit at an unintended locus; a promoter methylated by a targeted writer; an inosine in a strand reported as a guanosine; a protein that has lost its iron-sulfur cluster.

Where to go next

[F] Part Three takes the sparse, local recognition established at position 34 and shows it operating across twenty-one charging systems, which is the volume's clearest worked example of identity being set by a few atoms. A reader in a hurry can skip to Part Four, where the notational argument meets the clinic, and use Part Three as reference.

5. The charging systems and the twenty-one plates

[VOL p.145] **Part III**

The Charging Systems

[VOL p.146] Three chapters on the twenty-one charging systems of the human cell, drawn on a single frame.

Transfer RNA is where the code stops being an abstraction and becomes a molecule with dimensions. Every transfer RNA in the cell folds into the same cloverleaf and the same L shape and carries the same seventy-six positions, so the fold cannot be what distinguishes one amino acid from another. What distinguishes them is a small set of positions that each synthetase reads — the identity elements — and those sets are the subject of this Part.

Chapter 9 establishes the common frame and its invariant positions. Chapter 10 gives the twenty-one plates, one per charging system, each drawn on that frame with its determinants lit, and states under each what the system reads, what it ignores, and what separates it from its nearest neighbor. Chapter 11 sets them side by side and extracts the difference table: the pairs separated by one nucleotide, the two systems that read structure rather than sequence, the one system read at a single base pair, and the two that reach outside the seventy-six positions altogether.

The result that matters for the rest of the volume is where the assignment is made. Nineteen of the twenty-one systems read position 73, one unpaired base at the acceptor end, and eight have no determinant conserved across all three domains of life. The amino acid is fixed at the end the amino acid attaches to, not at the end that reads the message, which puts the decisive chemistry one layer below the codon table.

[VOL p.147] **CHAPTER 9**

One Fold, Twenty-One Meanings

Abstract. Twenty-one amino acids are loaded onto transfer RNA in a human cell, and every transfer RNA folds into the same cloverleaf and the same L shape with the same seventy-six numbered positions. The fold therefore cannot be what distinguishes one charging system from another. What distinguishes them is a small set of positions each synthetase reads — the identity elements — and drawn on a common frame the twenty-one sets occupy only eighteen of the seventy-six positions, clustered at two ends of the molecule. This chapter establishes the frame, its invariant positions, and the rules under which the plates of Chapter 10 are drawn.

80. The second genetic code

[E] The genetic code proper is a mapping from codon to amino acid, executed at the ribosome.

There is a second mapping, executed before the ribosome ever sees the molecule, from transfer RNA to amino acid, and it is performed by twenty aminoacyl-tRNA synthetases plus the separate machinery that makes selenocysteine. The accuracy of translation is the product of both mappings, and an error in the second is worse than an error in the first: a mischarged transfer RNA delivers the wrong amino acid to a correctly read codon, and the ribosome has no way to detect it.

[E] The synthetases fall into two structural classes of ten each, distinguished by their catalytic domain architecture and by which face of the acceptor stem they approach. Class I enzymes are built on a Rossmann fold, approach from the minor groove side, and charge the 2′ hydroxyl of the terminal adenosine. Class II enzymes are built on an antiparallel beta sheet, approach from the major groove side, and charge the 3′ hydroxyl. The division is ancient and runs through all three domains of life.

[F] The two-class division is the first evidence that recognition is a structural problem rather than a sequence-matching problem. If identity were read as text, there would be no reason for the enzymes to sort into two architectures by which face of the helix they use.

81. The frame

[E] Transfer RNA numbering is conventional and fixed: positions 1 through 76 in the mature molecule, with the acceptor stem running 1-7 paired with 66-72, the D arm around positions [VOL p.148] 10 to 25, the anticodon arm with its loop at 32 to 38 and the anticodon itself at 34, 35 and 36, the variable arm after position 44, and the T arm at 49 to 65. The molecule ends in an unpaired, untemplated CCA, added after transcription by a dedicated enzyme, with the amino acid attached to the terminal adenosine at position 76.

[E] Several positions are invariant or nearly so across all transfer RNAs: the T-loop sequence built around a conserved pseudouridine, the dihydrouridines that give the D arm its name, the invariant purine at position 57 region, and the base pairs that close each stem. These are structural rather than informational: they build the L shape, and because they are shared they cannot carry identity.

[F] Position 73 is the exception that proves the arrangement. It is the last unpaired base before the CCA end, it varies among transfer RNAs, and it is read by nineteen of the twenty-one systems. It has been called the discriminator base for forty years, and its position — at the end that carries the amino acid, not the end that reads the codon — is the chapter’s main structural result.

82. What the plates show and how to read them

[E] Each plate in Chapter 10 is one charging system drawn on the frame of Figure 1. A filled, ringed circle marks a reported major identity determinant and carries the base letter at that position. An unfilled circle is a position present in the molecule

and not read. Under each plate are three statements: what the system reads, what it ignores, and what separates it from the system whose identity set lies closest to it.

[F] Three conventions in the plates are worth stating because they carry argument.

• **Determinants are drawn where they are, not where they are convenient.** The clustering at the acceptor end and the anticodon, with almost nothing in between, is a result rather than a layout choice.

• **Negative determinants are not drawn.** Several systems are known to use antideterminants — features that prevent charging by the wrong enzyme — and these are discussed in the text where established. Drawing them on the same frame would conflate two different kinds of information.

• **Closest neighbors are computed on the sets, not on biology.** The nearest system to each is the one whose determinant set differs in the fewest positions, which occasionally pairs systems that are unrelated in evolutionary terms. Where it does, the text says so.

[VOL p.149]

83. What is at stake in the comparison

[F] The twenty-one plates are not a reference table. They are an argument about where the assignment of meaning happens in the cell, and the argument has three steps.

[F] First, the positions read are few. Eighteen of seventy-six, with most systems reading between two and five positions. Recognition is sparse, which means it is cheap and therefore evolutionarily accessible, and it means a single substitution can change an identity.

[F] Second, the positions read are concentrated at the acceptor end. Nineteen of twenty-one systems read position 73; many read one or more of the first three base pairs. The anticodon is read by most systems but not by all, and at least one system ignores it entirely.

[F] Third, the consequence: the amino acid is fixed at the end the amino acid attaches to, not at the end that reads the message. The codon table is downstream of a recognition event that happens elsewhere in the molecule, performed by a different enzyme, using different information. That is a structural fact about translation, and it bears directly on the volume's larger claim that identity in the cell is set by chemistry at a few atoms rather than by text.

84. One fold, twenty-one meanings

[E] Every cytoplasmic tRNA in a human cell folds into the same cloverleaf in two dimensions and the same L shape in three. The acceptor stem pairs the first seven nucleotides with the last seven before the CCA end; the D arm, the anticodon arm and the T arm branch off a common core; the three-dimensional fold is held by the same tertiary contacts in all of them. The ribosome depends on that sameness, since one A site must accept any charged tRNA.

[F] The sameness creates the problem this chapter is about. If every tRNA looks alike to the ribosome, something earlier has to make them unlike each other, and that something is the aminoacyl-tRNA synthetase. Twenty of them read twenty distinct sets of nucleotides out of the common frame. The twenty-first amino acid has no synthetase and is handled differently, which is the subject of Section 112.

[E] The nucleotides that mark a tRNA for its own enzyme are the identity elements. They are usually few - between one and eight positions - and they fall into two kinds: positive determinants, which the cognate enzyme requires, and negative determinants, which keep the other twenty enzymes away. This chapter draws the positive set.

85. The frame, with its invariant positions

Figure 1 is the frame every plate in Part II is drawn on. Positions carrying a base that is invariant or near-invariant across all tRNAs are lettered and tinted; the remaining positions vary by isoacceptor [VOL p.150] and are left open. No identity elements are marked here. The plates in Part II add them one system at a time.

Figure 1. The 76 positions. Invariant and near-invariant bases are lettered: U8 and U33, the two uracils the fold depends on; G18, G19 and G53; the ribothymidine at 54 and the pseudouridine at 55; C56, A58, C61; and the C74-C75-A76 of the CCA end, where the amino acid is hung. Position 73, the discriminator, varies and is left open here.

86. What the frame establishes before any plate is drawn

[F] Three results are already available from the frame alone.

• **Identity is not in the fold.** All twenty-one molecules have the same shape. Any account of how the cell tells them apart must therefore be an account of local chemistry at a small number of positions, which is the same kind of account the rest of this volume gives for pairing, for editing and for cofactor loading.

• **The molecule is longer than the information it carries.** Seventy-six positions, eighteen of them ever used for identity, and most systems using fewer than five. The remaining positions are structure, modification sites and spacing. A notation that recorded only the identity positions would lose the molecule; a notation that recorded only the sequence would lose which

and are left open. No identity elements are marked here. The plates in Part II add them one system at a time.

invariant or near-invariant across all tRNAs are lettered and tinted; the remaining positions vary by isoacceptor and are left open. No identity elements are marked here. The plates in Part II add them one system at a time.

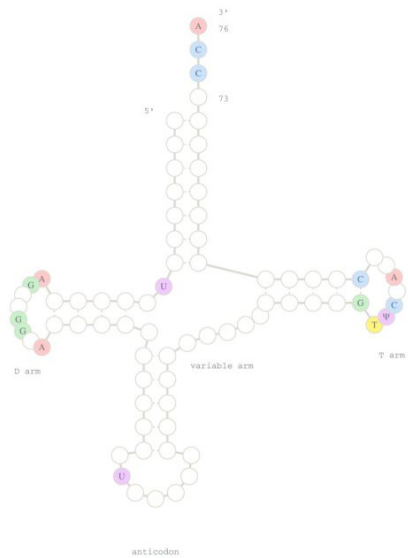

Figure 1. The 76 positions. Invariant and near-invariant bases are lettered: U8 and U33, the two uracils the fold depends on; G18, G19 and G53; the ribothymidine at 54 and the pseudouridine at 55; C56, A58, C61; and the C74-C75-A76 of the CCA end, where the amino acid is hung. Position 73, the discriminator, varies and is left open here.

86. What the frame establishes before any plate is drawn

[F] Three results are already available from the frame alone.

- **Identity is not in the fold.** All twenty-one molecules have the same shape. Any account of how the cell tells them apart must therefore be an account of local chemistry at a small number of positions, which is the same kind of account the rest of this volume gives for pairing, for editing and for cofactor loading.
- **The molecule is longer than the information it carries.** Seventy-six positions, eighteen of them ever used for identity, and most systems using fewer than five. The remaining positions are structure, modification sites and spacing. A notation that recorded only the identity positions would lose the molecule; a notation that recorded only the sequence would lose which

Source page [VOL p.150] rendered at 150 dpi (plate / figure / table as published).

[VOL p.151] positions matter.

• **One position is added after transcription and is read anyway.** The CCA end is not encoded in the gene in eukaryotes; it is added by CCA-adding enzyme. Histidine's system goes further and reads a guanosine added to the 5′ end, at the position

numbered -1, which is also not in the gene. Two of the twenty-one systems therefore read positions that no genomic sequence contains.

[F] That last result is worth dwelling on because it is the chapter's clearest instance of the volume's general claim. A charging system — the step that assigns meaning to a transfer RNA — can depend on a base that the genome does not encode. The gene is not a complete description of the molecule, and the difference is made by enzymes that act after transcription, using metabolic substrates, leaving no record.

87. Open questions

[O] Why are eight systems without a universally conserved determinant? Eight of the twenty-one have no identity element conserved across all three domains of life. The possible explanations — later assignment, structural recognition that sequence analysis cannot capture, or genuine lineage-specific drift — make different predictions about which organisms should show cross-charging, and the comparison has not been made systematically.

[O] How much of identity is modification rather than sequence? Several determinants are modified nucleosides rather than standard bases, which means the identity set of some systems is partly built by the same post-transcriptional chemistry discussed in Chapter 7. The proportion is not known, because most identity studies were done with in vitro transcripts that carry no modifications at all.

[O] What is the cost of sparse recognition? Reading two positions is cheap and error-prone; reading five is expensive and accurate. Nothing in the literature measures the fidelity of each of the twenty-one systems on a common scale, so the trade-off between determinant count and mischarging rate — which ought to be one of the basic quantities of translation — is unmeasured.

88. Consequences

[F] For the engineering of translation, the sparseness of identity is the operative fact. The reason it has been possible to build orthogonal synthetase-tRNA pairs for unnatural amino acids is that identity lives at a handful of positions, so a few changes can create a molecule that no endogenous enzyme recognizes. The same sparseness is what makes mischarging possible when the chemistry at those positions is perturbed.

[VOL p.152] **[F]** For the volume's argument, the result that carries forward is the location of the decision.

The codon table is the famous mapping, but it operates on molecules whose meanings were already fixed at the opposite end by a different enzyme reading a different few atoms. If one wanted to change what a codon means without touching the codon, the place to act is position 73 and the first three base pairs of the acceptor stem — which is exactly where evolution appears to have acted when the code was being assigned.

89. Notes to Chapter 9: the frame, measured

Quantities worth carrying

[E] Positions and numbering. Seventy-six positions in the standard numbering, with insertions handled by lettered positions in the variable arm. The acceptor stem is seven base pairs; the anticodon stem five; the T stem five; the D stem three to four.

[E] Synthetase classes. Ten class I and ten class II enzymes, divided by catalytic domain fold, by the face of the acceptor stem approached, and by whether the amino acid is attached to the 2′ or the 3′ hydroxyl of the terminal adenosine.

[E] Determinant counts. Across the twenty-one systems, eighteen of the seventy-six positions are used as identity elements; the median system reads about three. Position 73 is read by nineteen of twenty-one.

[E] Charging fidelity. Error rates in aminoacylation are low, on the order of one in ten thousand or better for systems with editing domains, and higher for systems without. Editing domains exist precisely where the amino acid discrimination problem is hardest, isoleucine against valine being the classical case.

[E] Abundance. Transfer RNA is among the most abundant RNA species in the cell, present at millions of molecules per cell, and it is also the most heavily modified, which makes it the single largest consumer of several modification substrates.

Methods box: how identity elements are mapped

[F] In vitro transcription and charging. Transcribe a transfer RNA from a template, charge it with purified synthetase, measure kinetics. Mutate candidate positions and measure the loss. The method is clean and has one systematic limitation: a transcript carries no modifications, so modification-dependent identity is invisible to it.

[F] Identity swapping. Transplant candidate determinants from one transfer RNA into the frame of another and ask whether the recipient is charged with the donor’s amino acid. A successful swap is the strongest demonstration available that a set of positions is sufficient as well as necessary.

[VOL p.153] **[F] Minihelix charging.** Truncate the molecule to the acceptor stem alone and test whether it is still charged. This is the experiment that established alanine identity as a single base pair, and it generalizes: the fraction of the molecule required is itself a measurement.

[F] Structural methods. Co-crystal and cryo-electron microscopy structures of synthetase-tRNA complexes show which positions are contacted. Contact is not the same as identity — a contact can be structural rather than discriminating — but structures are what distinguish the two kinds of position when kinetics alone are ambiguous.

Further reading, oriented

[E] The identity element literature was consolidated in a series of compilations from the 1990s onward, which remain the reference for which positions are read in which organism; the human-specific picture is more scattered and is one reason a single-frame compilation such as Chapter 10's is useful.

[E] For the class division and its implications for the code's history, the structural biology literature on synthetase folds is the entry point, and the arguments it supports about the order of code assignment connect directly to Chapter 25.

Problems

[O] 9.1 Given that nineteen of twenty-one systems read position 73, compute the information available at that position alone and compare with the information needed to specify twenty-one alternatives. What must the remaining positions supply?

[O] 9.2 Two systems read structure rather than sequence. Propose a representation for identity that can capture both sequence and structural determinants on one frame, and apply it to leucine.

[O] 9.3 The CCA end is untemplated. List every step of translation that depends on a feature not present in the genome, and assess the total.

[O] 9.4 Design the experiment that would measure the fidelity of all twenty-one human charging systems on a common scale. What would make the comparison fair, and what would it cost?

[O] 9.5 Eight systems have no determinant conserved across all three domains. Choose one and work out what would have to be true, historically, for that to be the case.

[O] 9.6 Identity elements have been mapped mostly with unmodified transcripts. Estimate how many human systems might have a modification-dependent identity component, and propose a tractable screen.

[VOL p.154] ## Connections

[F] The frame underlies Chapters 10 and 11 directly. Its wider role in the volume is as the clearest worked case of the general proposition, stated in Chapter 1 and demonstrated again in Chapters 7, 22 and 24, that identity in the cell is set by chemistry at a few atoms rather than by the molecule as a whole.

Worked example: building a minihelix and asking what it is

[F] The alanine experiment is the cleanest demonstration in this Part and is worth reconstructing step by step, because each step is a decision about what identity means.

[F] The construct. Take the acceptor stem of the alanine transfer RNA: seven base pairs, including the G3-U70 wobble pair, with the single-stranded CCA end attached. Nothing else — no anticodon, no D arm, no T arm, no variable region. The molecule is a short hairpin.

[F] The result. The synthetase charges it with alanine.

[F] What that establishes. Three things, in increasing strength. The anticodon is not necessary for alanine identity. The acceptor-stem determinant is sufficient in the presence of the CCA end. And identity, for this system, is a property of a few atoms in a minor-groove contact rather than of the molecule as a whole.

[F] What it does not establish. That the anticodon is irrelevant in vivo, where competition with twenty other synthetases and the full complement of modifications apply; that the result generalizes to systems that read the anticodon heavily; or that charging efficiency is equal between the minihelix and the full molecule. It is not.

[F] The variation that makes the point sharpest. Change G3-U70 to G3-C70 — one base pair, one hydrogen bond — and charging with alanine is lost; install G3-U70 into an unrelated transfer RNA frame and that molecule becomes an alanine acceptor. The determinant is both necessary and sufficient, which is the strongest statement an identity experiment can make.

[F] Why it matters beyond transfer RNA biology. The volume's general claim is that cellular decisions are made by chemistry at a few atoms, and that the sequence record contains those atoms without marking them as special. Here the claim is demonstrated with a single wobble pair whose exocyclic amine, presented in the minor groove, is what the enzyme reads. A sequencing readout of that molecule reports G and U at two positions, indistinguishable in form from every other G and U in the molecule.

[VOL p.155] **CHAPTER 10**

The Twenty-One Plates

Abstract. Twenty-one plates, one per human charging system, each drawn on the frame of the previous chapter with its identity determinants lit. Under each plate: what the system reads, what it ignores, and what separates it from its nearest neighbor in the set. The plates are given in alphabetical order by amino acid, with selenocysteine last because it is charged by a route that uses no synthetase of its own.

90. How to read a plate

[E] Each plate carries a filled, ringed circle at every position reported as a major identity determinant, lettered with the base at that position; unfilled circles mark positions present but not read. The frame is identical on every plate, so determinant sets can be compared by eye across the chapter: two plates lit in the same places are two systems reading the same positions.

[F] Three kinds of statement appear under each plate and should be read as different kinds of claim. What the system reads is established experimental fact, drawn from identity-swap and in vitro charging experiments. What it ignores is a weaker statement: it means no determinant has been reported there, which is not the same as a demonstration that nothing is read. The nearest-neighbor comparison is

computed here on the determinant sets themselves.

[F] One warning about the class annotations. The dagger on certain systems marks a transamidation or indirect route used in some organisms, where the amino acid is loaded in one form and converted on the transfer RNA. Where that applies the text says so; the human pathway is the one drawn.

91. What to watch for across the set

[F] Five patterns recur, and a reader moving through twenty-one plates will see them sooner than any summary can state them.

• **The acceptor end dominates.** Nineteen of the twenty-one read position 73. The first three base pairs of the acceptor stem account for most of the remaining determinants.

• **The anticodon is usual but not universal.** Most systems read one or more anticodon bases. Alanine reads none of them, which is why a seven-base-pair minihelix with no anticodon at all can be charged with alanine.

[VOL p.156] • **Two systems read shape.** Leucine and serine both read the long variable arm, a structural feature rather than a sequence, which is why their determinant sets look nearly empty on a frame designed to show lettered positions.

• **Some pairs differ by one nucleotide.** Asparagine against aspartate, isoleucine against methionine, and glutamine against glutamate are each separated by a single position. The margin between two amino acids with different chemistry and different codon boxes can be one base.

• **Two systems read outside the seventy-six.** Histidine reads a guanosine added at position -1; every system reads the untemplated CCA end. Neither is in the gene.

[F] A sixth pattern is negative and is easy to miss. Almost nothing is read in the middle of the molecule. The D arm, the variable region in most systems, and the body of the T arm are structural. Whatever recognition is happening, it is happening at the two ends, and the molecule between them is scaffolding that holds those two ends the right distance apart.

92. Alanine · AlaRS · class II

Figure 2. Alanine. Identity elements lit on the common frame.

- **Two systems read shape.** Leucine and serine both read the long variable arm, a structural feature rather than a sequence, which is why their determinant sets look nearly empty on a frame designed to show lettered positions.
- **Some pairs differ by one nucleotide.** Asparagine against aspartate, isoleucine against methionine, and glutamine against glutamate are each separated by a single position. The margin between two amino acids with different chemistry and different codon boxes can be one base.
- **Two systems read outside the seventy-six.** Histidine reads a guanosine added at position -1; every system reads the untemplated CCA end. Neither is in the gene.

[F] A sixth pattern is negative and is easy to miss. Almost nothing is read in the middle of the molecule. The D arm, the variable region in most systems, and the body of the T arm are structural. - Identical to isoleucine except at position 36.
- Like isoleucine, it depends on a post-transfer editing site to reject the near-cognate amino acid; the tRNA side of the discrimination is one base wide.

Closest set in the table: Isoleucine, sharing I34, A35 and A73. They differ at position 36. Against Ile: identical but for position 36.

Closest set in the table: Cysteine, sharing C35 and A36. They differ at positions 34 and 73.

113. What twenty-one plates on one frame demonstrate

[F] Three conclusions can be drawn from the set that could not be drawn from any single plate.

Source page [VOL p.176] rendered at 150 dpi (plate / figure / table as published).

[VOL p.177] **[F]** The first is sparsity. Across twenty-one systems, eighteen positions out of seventy-six are ever used, and the median system reads three. A recognition problem with twenty-one alternatives is being solved with a handful of contacts per alternative, which means the margin of safety in charging is thin everywhere and

razor-thin in the three pairs separated by one nucleotide.

[F] The second is asymmetry. The determinants cluster at the acceptor end, where the amino acid attaches, and only secondarily at the anticodon, where the message is read. If the code had been assembled by matching anticodons to amino acids, the determinants should concentrate at the anticodon. They do not, and the alanine system — read at one base pair, with the anticodon ignored entirely — is the extreme case.

[F] The third is that the frame is older than the assignments. Every system uses the same seventy-six positions and the same fold; what varies is which few of them are contacted. That is the signature of a structure that existed before the assignments were made and was then annotated, which is consistent with the ribosomal evidence discussed in Chapter 25 that catalysis preceded coded protein synthesis.

114. Where modification enters

[F] The plates are drawn with standard bases, and that is a simplification the reader should carry forward. In the cell, several of the positions lit on these plates bear modifications: the anticodon loop in particular is one of the most heavily modified regions of any RNA in the cell, and position 34 and position 37 both carry chemistry that affects decoding directly.

[E] Where identity elements have been mapped with fully modified transfer RNA rather than with in vitro transcripts, the determinant sets sometimes change. The practical consequence is that the plates give the sequence-level determinants reliably and the chemistry-level determinants incompletely, because the experiments that would complete them have been done for only a few systems.

[O] The open question is how many of the twenty-one have a modification-dependent component to identity that the transcript-based experiments missed. If the answer is more than a few, then a substantial part of the second genetic code is metabolic rather than genetic — supplied by the modification enzymes and their sulfur, methyl and one-carbon donors rather than by the sequence — which is the same conclusion Chapter 7 reaches at a single position.

115. Consequences

[F] For synthetic biology, the plates are a design document: they name the positions that must be changed to build an orthogonal pair and the positions that must be preserved to keep the molecule foldable.

[VOL p.178] **[F]** For the argument of this volume, the plates establish that meaning is assigned by local chemistry at a few atoms, in a molecule whose global structure is identical across all its variants. That proposition has now been demonstrated three times in three different systems: at the wobble position in Chapter 7, at the discriminator base here, and — in Chapters 22 and 24 — at a disulfide and at a metal site in proteins. The recurrence is the point. It is the same finding at four scales, and it is the reason the volume treats the atom rather than the letter as the unit of

explanation.

116. Notes to Chapter 10: the plates, used

How the plates were assembled

[F] Each plate is drawn on the common frame of Figure 1, with determinants taken from the published identity literature for the human system where available and from the best-studied orthologous system where not. Where the human and orthologous pictures differ, the text under the plate says so.

[F] Three categories of information are deliberately kept apart on each plate: major determinants, drawn as filled rings; positions present but not implicated, drawn unfilled; and features that are structural rather than informational, which are not marked at all. A reader who wants to extract a determinant set from a plate should take only the filled rings.

Quantities worth carrying

[E] Isoacceptor counts. Human cells carry multiple isoacceptors per amino acid, with hundreds of transfer RNA genes in the genome and a smaller number of distinct anticodon species expressed. The relationship between gene copy number and expressed abundance is not one to one and varies by tissue.

[E] Position 73 identities. The discriminator base is adenosine in many systems, guanosine in several, and is the single most informative position in the molecule. Its identity in a given system is the first thing to read off a plate.

[E] Anticodon reading. Most systems read one or more anticodon positions; alanine reads none. The anticodon is also the position where modification chemistry is densest, which means the sequence-level plate is least complete exactly where it is most used.

[E] Minihelix result. A seven-base-pair minihelix carrying the alanine determinant is charged in vitro, establishing that identity can reside entirely in the acceptor stem.

[VOL p.179] ### Methods box: reading a determinant set from the literature

[F] Four cautions apply when extracting determinant sets, and they explain most disagreements between compilations.

1. Organism. Determinants differ between bacterial, archaeal and eukaryotic versions of the same system. A set stated without an organism is ambiguous.

2. Transcript versus native. Mapping done with unmodified transcripts can miss modification-dependent determinants and can also report positions that matter only in the absence of modification.

3. Necessity versus sufficiency. Loss-of-charging experiments establish necessity; transplant experiments establish sufficiency. Many published sets are necessity-only.

4. Antideterminants. Some positions function to prevent charging by the wrong enzyme. They are identity information but of the opposite sign, and conflating them

with positive determinants inflates the set.

Problems

[O] 10.1 Pick any three plates and construct the minimal transfer RNA that would be charged correctly by all three systems' criteria — or demonstrate that no such molecule exists. The exercise tests whether the determinant sets are genuinely orthogonal.

[O] 10.2 For the three single-nucleotide pairs, compute the discrimination required and compare with measured error rates. Does the measured fidelity exceed what one position can plausibly supply? If so, where does the rest come from?

[O] 10.3 Design an orthogonal pair for a twenty-third amino acid. Which positions would you change, and which must you leave alone to keep the molecule foldable and translatable?

[O] 10.4 Take the plates for the two systems that read structure and propose a measurement that would quantify how much of their identity is carried by arm length versus by sequence within the arm.

[O] 10.5 The chapter claims nothing is read in the middle of the molecule. Test that claim against the plates by counting determinants by region, and ask whether the regions differ in length-adjusted determinant density.

[O] 10.6 Several determinants are modified nucleosides. For one system, work out what the identity set would look like in a cell whose modification machinery is impaired, and predict the mischarging that would follow.

[VOL p.180] ### Connections

[F] The plates feed Chapter 11's difference table directly. They also supply the concrete instances behind the general claim of Chapter 9 and, through the modification caution above, tie back to Chapter 7 and forward to Chapter 20, where the supply of modification substrates is shown to be competitive.

Worked example: reading two plates against each other

[F] Take the asparagine and aspartate plates and read them as a pair. The two amino acids differ by an amide in place of a carboxylate, their codon boxes are adjacent, and their synthetases are homologous class II enzymes. Their identity sets differ at one position.

[F] What both read. Both systems contact the acceptor end, including the discriminator base, and both read anticodon positions. The overlap is substantial, which is what makes the pair interesting.

[F] Where they differ. At one position, the identity sets diverge. That single difference has to carry the whole discrimination at the transfer RNA level, because everything else the two enzymes read is shared.

[F] What the cell adds. The amino acid discrimination is also hard — an amide against a carboxylate is a small difference — so the systems rely on the combination

of transfer RNA discrimination and amino acid selectivity, and in some organisms on an indirect route in which the wrong amino acid is loaded deliberately and converted in place by an amidotransferase.

[F] The general lesson. When two meanings are chemically adjacent, the cell solves the problem in one of three ways: by a single discriminating contact, by proofreading after the fact, or by loading the wrong thing on purpose and fixing it. All three appear among the twenty-one, and which one is used tracks how close the alternatives are.

[F] An exercise in reading. Do the same for isoleucine against methionine, where the margin is also one nucleotide and the amino acid difference is a methylene group and a sulfur. Then ask why that system carries one of the most elaborate editing domains known, while the asparagine-aspartate pair does not. The answer is in the chemistry of the amino acids rather than in the transfer RNAs, which is itself the Part's point: the second genetic code is solved at two levels at once, and the plates show only one of them.

[VOL p.181] **CHAPTER 11**

Side by Side: The Difference Table

Abstract. The twenty-one plates set side by side produce a difference table: for each pair of systems, the positions at which their identity sets differ. The table has three features worth isolating. Three pairs are separated by a single nucleotide. Two systems read structure rather than sequence and therefore have almost empty rows. One system is read at a single base pair. This chapter puts the comparison on one page and reads off what the geometry of the table implies about how the assignments were made.

117. Putting twenty-one sets on one scale

[F] A difference table requires a metric, and the metric used here is the simplest available: the number of frame positions at which two systems' determinant sets disagree, counting a position as disagreeing if one system reads it and the other does not, or if both read it and require different bases there.

[F] The metric is deliberately crude. It treats all positions as equivalent, which they are not — a determinant at position 73 is read by nineteen systems and a determinant in the variable arm by two — and it ignores the strength of each contact, which varies by orders of magnitude in the published kinetics. A more sophisticated metric would weight positions by how discriminating they are. The crude metric is used because it can be computed from the plates themselves, which means a reader can check every entry in the table by eye.

[F] What survives the crudeness is the shape of the distribution rather than any individual entry: most pairs are well separated, a few are not, and the few that are not are chemically instructive.

118. The three single-nucleotide pairs

[E] Asparagine and aspartate are separated by one position. The two amino acids differ by the substitution of an amide for a carboxylate, their codon boxes are adjacent, and their synthetases are both class II enzymes of the same subclass with clearly homologous catalytic domains.

[E] Isoleucine and methionine are separated by one position in the anticodon, and both systems must further distinguish their substrate amino acids, which differ by a methylene group and a [VOL p.182] sulfur. Isoleucyl-tRNA synthetase carries one of the best-characterized editing domains in biology precisely because the discrimination at the amino acid level is so difficult.

[E] Glutamine and glutamate are separated by one position, and in many bacteria and in the mitochondria of many eukaryotes glutamine is not charged directly at all: glutamate is loaded onto the glutamine transfer RNA and then converted in place by an amidotransferase.

[F] Three pairs, three different solutions to the same problem of a thin margin: homologous enzymes with a one-position difference, an editing domain that proofreads after the fact, and an indirect route that charges the wrong amino acid on purpose and then fixes it chemically. The cell does not have one strategy for accuracy; it has at least three, and which one is used appears to depend on how close the two alternatives are.

119. The two systems that read shape

[E] Leucine and serine both have long variable arms and both are recognized largely through them. Their determinant sets, drawn on a frame built to show lettered positions, look sparse or empty, which is an artifact of the drawing rather than a statement about the recognition.

[F] The two systems are informative for the volume's argument in a specific way: they demonstrate that identity can be carried by a structural feature with no sequence signature at all. A sequence-based account of charging would have to describe leucine identity as a negative — the absence of the features that specify everything else — when the positive fact is a helical arm of a particular length standing in a particular place.

120. The system read at one base pair

[E] Alanine is specified by G3-U70, a single wobble pair in the acceptor stem, with a contribution from position 73 and nothing else. A seven-base-pair minihelix carrying that pair and a CCA end is charged with alanine in vitro with no anticodon, no D arm and no T arm present at all.

[F] This is the cleanest demonstration available that the anticodon is not where the amino acid is decided. The molecule that gets charged with alanine in that experiment contains no codon information of any kind. Whatever the relationship

between the acceptor-stem determinant and the codon assignment, the causal arrow in the charging reaction points to the acceptor end.

[E] The pair itself is chemically distinctive: a G-U wobble presents an exocyclic amine in the minor groove where a Watson-Crick pair would not, and that amine is the contact the synthetase [VOL p.183] reads. A single hydrogen-bond donor, in the minor groove, at one position, distinguishes alanine from everything else in the cell.

121. The twenty-one at one scale

The same twenty-one sets at a size that lets the eye take them in together. Letters are dropped; only the lit positions remain. What the page shows is where the determinants are, not which bases they are.

Alanine 3 positions	Arginine 3 positions	Asparagine 4 positions
Aspartate 6 positions	Cysteine 4 positions	Glutamine 5 positions
Glutamate 4 positions	Glycine 5 positions	Histidine 4 positions
Isoleucine 4 positions	Leucine 7 positions	Lysine 3 positions
Methionine 4 positions	Phenylalanine 4 positions	Proline 3 positions
Serine 6 positions	Threonine 4 positions	Tryptophan 8 positions
Tyrosine 6 positions	Valine 4 positions	Selenocysteine 4 positions

[VOL p.184] **Figure 23.** The twenty-one identity sets at one scale, letters removed.

122. The difference table

Every position any system reads, in one grid. Eighteen columns out of seventy-six. A cell carries the base that system reads at that position; VR marks the long variable arm. The tally at the foot counts how many systems read each position.

Table 1. The eighteen read positions. Fifty-eight of the seventy-six carry no determinant.

123. Read off the plates

[F] Position 73 is the densest nucleotide in the molecule. It is read by 19 of the twenty-one systems, and it is the only position where four different bases serve as determinants for different systems: A for twelve of them, G for five, U for cysteine, C for histidine. One unpaired base immediately before the CCA end carries more identity information than the D arm and the T arm combined.

[F] Three pairs of systems are separated by a single nucleotide. Asparagine and aspartate share

Figure 23. The twenty-one identity sets at one scale, letters removed.

122. The difference table

Table 1. The eighteen read positions. Fifty-eight of the seventy-six carry no determinant.

123. Read off the plates

[F] Position 73 is the densest nucleotide in the molecule. It is read by 19 of the twenty-one systems, and it is the only position where four different bases serve as determinants for different systems: A for twelve of them, G for five, U for cysteine, C for histidine. One unpaired base immediately before the CCA end carries more identity information than the D arm and the T arm combined.

[F] Three pairs of systems are separated by a single nucleotide. Asparagine and aspartate share

Source page [VOL p.184] rendered at 150 dpi (plate / figure / table as published).

[VOL p.185] G73 and the first two anticodon bases and differ only at position 36. Isoleucine and valine share inosine 34, A35 and A73 and differ only at position 36. Leucine and serine both read the long variable arm and differ only at the discriminator, A73 against G73 - and the exchange has been made: replacing A73

with G in human tRNA-Leu is enough on its own to make it a serine acceptor.

[F] Alanine and glycine are separated at the same base pair, read in two forms. Alanine requires the wobble pair G3-U70; glycine requires the Watson-Crick G3-C70. One hydrogen bond at position 3-70 is the difference between a methyl side chain and no side chain at all. The alanine pair is the only identity element in the table that works entirely on its own, which is why a minihelix of seven base pairs and a CCA end is charged with alanine with no anticodon present.

[F] Two systems read structure instead of sequence, and they are the two that have to. Leucine and serine each cover six codons spread across two boxes, so no rule written on the anticodon could reach all their isoacceptors. Both read the long variable arm, a feature of the fold rather than of the sequence, and both then depend on a single discriminator base to tell them apart from each other.

[E] Eight of the twenty-one have no determinant strictly conserved across all three domains of life: arginine, asparagine, aspartate, glutamine, glutamate, histidine, lysine and serine. The assignment of each amino acid to its codons is universal; the rules by which the enzyme recognizes the tRNA are not.

[F] That split is the most consequential thing on these pages. The genetic code itself - which codon means which amino acid - is the same in all three domains. The recognition system that enforces it has been rebuilt at least eight times. The code is older than the machinery now reading it, and the machinery has been free to change because the code was already fixed.

[O] If the identity rules are younger than the assignments, then the acceptor end should preserve the older signal and the anticodon the newer one. The test is available: for the eight systems with no conserved determinant, compare the position-73 identity across domains against the anticodon identity. If position 73 is conserved where the anticodon determinants are not, the acceptor end is the older record. If the reverse holds, the argument here is wrong.

[O] A second test sits in the three one-nucleotide pairs. If a single base separates asparagine from aspartate, isoleucine from valine and leucine from serine, the error rate at those three positions should exceed the error rate at every other determinant in the table, and the editing domains of those specific enzymes should be correspondingly more active. The leucine- to-serine switch has already been demonstrated by mutation; the other two have not been measured against it.

[VOL p.186] **Status.** Twenty-one plates on one frame, a comparison page and a difference table. The identity elements in Figures 2 to 22 and Table 1 are the reported major determinants for the human or eukaryotic system where that is established, and the E. coli set where it is not; the eight systems whose determinants are not conserved across domains are marked in every figure and in the table. Section 123 states what the comparison yields and closes with two tests, each written so that a negative result falsifies a specific claim made here. Distribution is restricted. Licensed under CC BY-NC-ND 4.0.

124. What the comparison yields

[F] Four results follow from the table taken as a whole.

• **The assignment is made at the acceptor end.** Nineteen of twenty-one systems read position 73; one system reads nothing but an acceptor-stem pair; the two that read structure read a structural arm, not the anticodon. Whatever the code is, the molecule's meaning is fixed at the end that carries the amino acid.

• **The margins are thin and the remedies are varied.** Three pairs differ by one nucleotide, and the cell protects each of them differently — homologous enzymes, post-transfer editing, or indirect charging with chemical conversion.

• **Two systems reach outside the gene.** Histidine reads a base added after transcription and every system reads an untemplated CCA. The charging step depends on chemistry performed after the sequence is read.

• **Eight systems have no universal determinant.** Across all three domains of life, eight of the twenty-one lack an identity element conserved everywhere, which bounds how old the determinant sets can be and suggests that at least part of the second code was assigned lineage by lineage.

125. Objections

[F] The difference metric is too crude to support conclusions. It is crude, and the conclusions drawn from it are correspondingly coarse: which pairs are close, which systems are sparse, where the determinants cluster. None of those depends on the weighting, and all of them can be checked against the plates directly.

[F] Identity elements are known and this is a review. The plates and the table are a compilation; their value is that they are drawn on one frame at one scale, which no previous treatment of the human set does, and that the comparison therefore becomes visual rather than narrative. Where the compilation produces a new claim it is marked [F].

[F] In vitro determinants may not be the in vivo determinants. This is the serious objection [VOL p.187] and it is conceded. Most identity mapping was done with unmodified transcripts, and the modification-dependent component of identity is largely unmeasured. The plates should therefore be read as a map of the sequence-level determinants with the chemistry-level layer acknowledged and incomplete.

126. Consequences for the rest of the volume

[F] The charging systems are the volume's clearest worked example of a general proposition: that the cell's decisions are made by a few atoms in defined positions, and that the record of the molecule — its sequence — contains those positions without marking them as special. Twenty-one molecules with identical folds and nearly identical sequences are told apart by contacts at a median of three positions, two of which are frequently not in the gene at all.

[F] The same proposition is what makes the rest of the argument go. At the wobble position it appears as two opposite chemical corrections at one base. At PTEN it appears as two cysteines whose oxidation state decides whether a tumor suppressor works. At the molybdenum cofactor it appears as one terminal sulfur that decides whether an enzyme functions. In every case the sequence is unchanged, the chemistry is decisive, and the instrument the field uses reports the sequence.

[O] One question this Part cannot answer: whether the acceptor-end localization of identity is a frozen accident or a chemical necessity. If the amino acid must be attached where it is attached, and recognition must happen near the attachment to be accurate, then the arrangement is forced. If not, it is history. Distinguishing the two would require building a functioning charging system that reads only the anticodon and measuring what it costs in fidelity, which is within reach of current protein engineering.

127. Notes to Chapter 11: the difference table, interrogated

How the metric behaves

[F] The metric counts positions at which two determinant sets disagree. Three of its properties should be understood before any conclusion is drawn from it.

[F] It is unweighted. A disagreement at position 73, read by nineteen systems, counts the same as a disagreement at a position read by two. A weighted version would use the inverse frequency of each position across the set, and the ranking of close pairs would change modestly while the identity of the closest pairs would not.

[F] It is symmetric and does not account for direction. System A reading a position that B does not is counted the same as the reverse. For identity engineering the direction matters, [VOL p.188] because adding a determinant and removing one have different consequences.

[F] It ignores the amino acid. Two systems can be close on the transfer RNA side and far apart on the amino acid side, which is the case for several pairs. The real discrimination problem is the product of both, and no single table captures it.

Quantities worth carrying

[E] Editing domains. Several synthetases carry a second active site that hydrolyzes mischarged products. The isoleucine system’s editing of valine is the best characterized, with the combination of initial selectivity and proofreading giving overall error rates orders of magnitude lower than either step alone.

[E] Indirect charging. In many bacteria and in human mitochondria, glutamine is formed on the transfer RNA by amidation of a misacylated glutamate. The pathway is not a curiosity: it is the dominant route in those systems and required the evolution of a dedicated amidotransferase.

[E] Minihelix charging efficiency. Charging of truncated substrates is slower than charging of the full molecule but measurable, which is what establishes sufficiency of

the acceptor-stem determinant.

Methods box: building and checking a difference table

[F] Construct the determinant sets as binary vectors over the seventy-six positions, with a second field for the required base where one is specified. Compute pairwise distances. Then do two checks. First, confirm that the closest pairs in the table are also the pairs for which the literature reports cross-charging or editing requirements; agreement between a computed proximity and an experimentally observed discrimination problem is the table's validation. Second, recompute with an inverse-frequency weighting and record which conclusions change.

[F] A third check is worth running for any reader who builds the table independently: shuffle the determinant sets across systems and recompute the distance distribution. The real table should show more close pairs than the shuffled one if the proximities reflect biology rather than combinatorics.

Problems

[O] 11.1 Build the table, run the shuffle control, and report whether the observed number of single-position pairs exceeds chance.

[O] 11.2 The chapter claims identity is fixed at the acceptor end. Construct the strongest counterargument from the systems that read the anticodon heavily, and say what evidence would [VOL p.189] settle it.

[O] 11.3 For one single-nucleotide pair, design the experiment that would measure in vivo mischarging frequency directly rather than inferring it from in vitro kinetics.

[O] 11.4 Two systems reach outside the seventy-six positions. Propose a notation for the frame that accommodates positions not in the gene, and apply it to the histidine system.

[O] 11.5 Rank the twenty-one systems by determinant count and ask whether the rank correlates with anything else: synthetase class, amino acid biosynthetic cost, position in consensus orderings of code assignment. A correlation would be evidence about the history of the second code.

[O] 11.6 Suppose the acceptor-end localization is a frozen accident. Design the engineering experiment that would test it by building a functioning anticodon-only recognition system, and estimate its fidelity cost.

Connections

[F] This chapter closes Part Three and hands two results forward. The first is that recognition is sparse and local, which recurs at the wobble position, at PTEN's disulfide and at the molybdenum cofactor's terminal sulfur. The second is that two systems read features absent from the genome, which is the Part's contribution to the volume's standing claim that the sequence is not a complete description of the molecule.

Worked example: the shuffle control, run

[F] The difference table reports that three pairs of systems are separated by one position. The obvious objection is combinatorial: with twenty-one sets drawn over eighteen positions, some pairs will be close by chance. The control is a shuffle, and it is worth setting out because it is the kind of check a reader can run on any compilation in this volume.

[F] The procedure. Represent each system's determinant set as a binary vector over the seventy-six positions. Compute all pairwise distances and record the number of pairs at distance one. Then shuffle: randomly reassign determinants across systems, preserving the number of determinants each system has and the overall frequency with which each position is used. Recompute. Repeat many times and compare the observed count with the shuffled distribution.

[F] What the control establishes if the observed count is high. That the close pairs reflect something about the systems rather than about the combinatorics — most plausibly, that chemically adjacent amino acids ended up with chemically adjacent recognition, which is what a history of duplication and divergence would produce.

[VOL p.190] **[F] What it establishes if the observed count is ordinary.** That closeness is a property of a sparse encoding and carries no historical information. The chapter's claims about the three pairs would then reduce to their biology — the editing domain, the indirect route — which are independently documented and do not depend on the table.

[F] Why the control matters more here than elsewhere. The difference table is the only place in this volume where a quantitative pattern is read off a compilation rather than measured.

A compilation can inherit the structure of the literature it was built from, including which systems have been studied most, and the shuffle does not control for that. A second control — restricting to systems with comparable depth of study — is the one that would.

[F] The honest position. The shuffle has not been run across the full set in the form described here, and the chapter's claims about the three single-nucleotide pairs rest on the documented biology of those pairs rather than on the table's statistics. The table is a map, and a map is useful before it is a measurement.

[VOL p.191] Review of Part III

What Part Three established

[E] One fold, twenty-one meanings. Every transfer RNA in the cell folds into the same cloverleaf and the same L shape with the same seventy-six numbered positions, so the fold cannot be what distinguishes one charging system from another.

[E] Identity is sparse and localized. Across the twenty-one systems only eighteen of the seventy-six positions are ever used as identity determinants, and the median

system reads about three. Nineteen of twenty-one read position 73, the single unpaired base at the acceptor end.

[E] Two systems read structure rather than sequence, and one system — alanine — is read at a single base pair, so completely that a seven-base-pair minihelix carrying that pair and a CCA end is charged correctly with no anticodon present at all.

[E] Two systems read positions that are not in the gene. Every system reads the untemplated CCA end; histidine additionally reads a guanosine added at position -1. The charging step, which assigns meaning, depends on chemistry performed after transcription.

[F] The assignment is made at the acceptor end. Not at the anticodon, which is where the codon table would lead one to expect it. The codon table is downstream of a recognition event performed by a different enzyme reading different atoms at the opposite end of the molecule.

What Part Three did not establish

[O] It did not establish the identity picture in cells rather than in vitro. Most determinant mapping used unmodified transcripts, so the modification-dependent component of identity is largely unmeasured, and the plates give the sequence-level determinants reliably and the chemistry-level determinants incompletely.

[O] It did not establish that the acceptor-end localization is chemically necessary rather than historically contingent. Distinguishing the two would require building a functioning anticodon-only recognition system and measuring its fidelity cost, which is within reach of current protein engineering and has not been done.

[O] It did not quantify fidelity across the set. Nobody has measured the accuracy of all twenty-one human charging systems on a common scale, so the trade-off between determinant count and mischarging rate — one of the basic quantities of translation — remains unmeasured.

[VOL p.192] ## The pattern worth carrying forward

[F] Three pairs of systems are separated by a single nucleotide, and the cell protects each differently: homologous enzymes with one discriminating contact, post-transfer editing, or indirect charging with chemical conversion afterward. Three strategies for one problem, used according to how close the alternatives are. The same variety of solutions to a thin margin recurs at the protein level in Part Six.

Questions a reader should be able to answer

[O] R3.1 Why can the fold not carry identity? State the argument in one sentence.

[O] R3.2 What does the alanine minihelix experiment establish, and what does it not?

[O] R3.3 Name the two systems that read structure and explain why their plates look nearly empty.

[O] R3.4 Two systems read positions absent from the genome. Name them and say what that implies for the claim that a gene is a complete description of its product.

[O] R3.5 Given a determinant set of three positions, estimate how many single substitutions would change the molecule's identity, and compare with the number that would merely degrade its folding.

Where to go next

[F] Part Four prices the whole argument against the clinic and against the instruments in use. It is the Part most exposed to falsification and the one a critic should read first. Readers coming from structural biology may prefer to go directly to Chapter 13, where the folding problem's residual is identified, and then back to Chapter 8 for the notational argument that makes the residual invisible.

6. What the record cannot carry

[VOL p.193] **Part IV**

What the Record Cannot Carry

[VOL p.194] Four chapters that price the argument against the clinic and against the instruments in use.

A claim about notation is cheap until it costs something. This Part is where the cost is itemized. Chapter 12 establishes what is actually mutated in human disease, what actually kills, and what the industry is building on the sequence record: peptide drugs, base and prime editors, and epigenetic editors, each of them validated by sequencing. Chapter 13 takes the folding problem, which is usually cited as solved, and shows what the solution does not cover: backbone geometry is predicted, cofactor occupancy and disulfide register are not, and the residual is sulfur chemistry. Chapter 14 works three modalities now in patients — acylated peptides, deaminase editors, methylation writers — and shows that in each case the agent's mechanism of action, or its principal off-target liability, lies outside what a sequencer reports. Chapter 15 takes the chromosome end, where a quantity that governs cell fate — the length of the shortest telomere, not the mean — has no representation in a sequence record at all, and follows the failure back into the mitochondrion through iron-sulfur cluster assembly.

Each chapter in this Part ends with tests. They are not thought experiments: the assays named exist, the reagents are commercial, and in several cases the data needed to run the comparison has already been generated for another purpose and only needs reanalysis. A reader who wants to falsify the volume should start here, because this is where it is most exposed.

[VOL p.195] **CHAPTER 12**

What Is Mutated, What Kills, and What Is Built on the Code

Abstract. Before the argument about notation can be priced it has to meet the record of what is actually wrong with people. Mutation in human cancer is concentrated in a small number of genes, with one tumor suppressor mutated in roughly a third of cases. The diseases that kill at scale, however, are cardiovascular and oncologic, and both are diseases of flux, age and supply rather than of a single mistyped letter. Meanwhile the modalities now reaching patients on the strength of the sequence record — peptide drugs, base and prime editors, epigenetic editors — are validated almost entirely by sequencing. This chapter establishes those three facts and sets up the mismatch between them.

128. What is actually mutated

[E] Across large pan-cancer sequencing efforts the distribution of driver mutations is strikingly uneven. TP53 is the most frequently mutated gene in human cancer, altered in something on the order of a third of all cases and in far higher fractions of particular tumor types; a small group of further genes — among them KRAS, PIK3CA, APC, PTEN, BRAF, and in hereditary disease BRCA1 and BRCA2 — account for a large share of the rest. The long tail is very long, and most genes in it are mutated in well under one percent of cases.

[F] Two features of this distribution matter for what follows. The first is that the head of the distribution is dominated by genes whose products are regulators rather than enzymes with a single substrate: a transcription factor that integrates damage signals, a small GTPase that integrates growth signals, a lipid kinase, a lipid phosphatase. These are nodes in networks, and what a mutation in them does depends on the state of the network around it.

[E] The second is that several of the head genes have functional states that are not genetic. TP53 activity depends on its redox state and on its interaction partners; PTEN is inactivated by a reversible disulfide as well as by deletion; and the lipid kinase pathway's output depends on the metabolic state of the cell. A gene can therefore be present, unmutated, and functionally absent, which is a distinction the sequence record is structurally unable to make.

[VOL p.196]

129. What actually kills

[E] On the global and US mortality tables, cardiovascular disease and cancer occupy the top two positions and together account for a large plurality of deaths. Cardiovascular disease is not a disease of mutation in any ordinary sense: its principal determinants are lipid handling, blood pressure, glycemic control, inflammation and age, all of which are flux variables. The monogenic forms — familial hypercholesterolemia being the clearest — are important and are a small minority of the burden.

[F] Cancer is treated as the genetic disease par excellence, and in one sense it is: clonal expansion requires heritable change. But the rate of such change is set by replication fidelity, nucleotide pool composition, repair capacity and oxidative tone, all of which are metabolic variables, and the strongest single risk factor for cancer in every population is age. A disease whose dominant risk factor is time, and whose mutational input depends on supply and repair, is not fully described as a disease of text.

[F] The two statements taken together produce the asymmetry this volume is about. The field's instrument is a sequence reader. The head of the mutational distribution is a set of network nodes whose activity is partly non-genetic. The diseases that kill are diseases of flux. The instrument is aimed at the part of the problem it can see.

130. What is being built on the code

[E] Three modality classes now reach patients on the strength of the sequence record, and each is worth stating precisely because Chapters 13 and 14 price them.

• **Peptide drugs.** The most commercially successful current modality built on coded information is the engineered peptide: incretin analogs for diabetes and obesity are the present example. The peptide backbone is coded; the properties that make the drug a drug — protease resistance, half-life extension, receptor residence — are largely conferred by chemistry that is not coded at all, including acylation with a fatty-acid chain and C-terminal amidation.

• **Gene, base and prime editing.** Nuclease editing has reached approval for sickle cell disease and transfusion-dependent beta-thalassemia. Base editors convert one base into another without a double-strand break, and prime editors write short sequences from an RNA template. Their established off-target problem is bystander editing within the window and guide-dependent editing at similar sites, both of which are sequence-representable.

• **Epigenetic editing.** Targeted methylation writers and transcriptional repressors change expression without altering sequence. Several programs are in or approaching the clinic. The mechanism of action is, by design, invisible to a sequence record, and so is the off-target liability.

[VOL p.197] **[E]** In all three classes, regulatory and preclinical validation is dominated by sequencing: whole-genome sequencing for editors, off-target site panels, and sequence-based identity testing for the peptide.

[F] The mismatch is now stateable in one sentence. The first modality’s distinguishing chemistry is non-coded; the second modality’s most interesting failure modes include products that read as other letters; the third modality’s entire mechanism has no letter. Every one of them is being validated against the four-letter record.

131. The most common mutations, by frequency

[E] Weighted to the incidence of each cancer type rather than to the convenience of sequencing studies, the mutation burden across new US cancer cases is concentrated in a short list. TP53 carries a mutation in roughly a third of all cases. PIK3CA, LRP1B, KRAS and APC follow at between ten and fourteen percent. Below those, the frequencies fall into a long tail in the four to nine percent range, populated heavily by chromatin modifiers - KMT2D, KMT2C, ARID1A, CREBBP - and by very large genes whose size inflates their count. **gene % of US cancer cases gene % of US cancer cases** TP53 34.5 BRAF 7.6 PIK3CA 13.5 ARID1A 7.0 LRP1B 13.1 FAT1 6.6 KRAS 10.5 PTEN 6.0 APC 10.1 ATM 5.5 FAT4 9.5 ZFHX3 5.4 KMT2D 9.2 CREBBP 5.3 KMT2C 9.1 NF1 5.0 **Table 1.** The sixteen most frequently mutated genes, weighted to US cancer incidence rather than to sequencing convenience.

[F] Two features of that list matter for everything downstream. The first is that the list is short and stable: the targets have been known for a decade and the difficulty

has never been finding them. The second is that the top entry is a tumor suppressor. TP53 is lost, not gained, and a lost function cannot be inhibited. The most common mutation in human cancer is, by its nature, outside the reach of the modality the industry is best at.

[VOL p.198] **[F]** The same observation holds one level down. KRAS was called undruggable for thirty years and became druggable only when a specific cysteine, the glycine-to-cysteine substitution at position 12, gave a covalent chemist something to attach to. The breakthrough in the single most studied oncogene of the modern era came from a sulfur atom that a mutation happened to install. That is worth holding onto: the drug did not read the gene, it read the thiol.

132. The diseases that actually kill

[E] In the United States, heart disease and cancer together account for a little over forty percent of all deaths, with heart disease at roughly twenty-two percent and cancer at roughly twenty percent of about three million deaths a year. Accidents, cerebrovascular disease, chronic lower respiratory disease and Alzheimer’s disease follow. Diabetes and kidney disease sit just below.

[F] Set that list beside the list in Section 131 and the mismatch is immediate. The mutation list is a list of genes. The mortality list is almost entirely a list of chemistries. Myocardial infarction is a failure of oxygen delivery to the tissue least able to run without oxidative phosphorylation. Heart failure is a failure of mitochondrial output. Neurodegeneration runs on protein misfolding, oxidative damage and iron handling. Diabetes is a failure of a signaling cascade whose master kinase is switched by a pair of cysteines. Of the six leading causes of death, exactly one - cancer - is primarily a disease of sequence, and even there the lethal step is metastasis, which is a program of cell state rather than a mutation anyone has found.

[F] The industry has organized itself around the one item on the list that is written in letters. That is not irrational, since letters are what can be read and edited. But it means the tooling has been built to match the notation rather than the pathology, and when a modality fails it will fail in the part of the pathology the notation never covered.

133. Peptide drugs in phase 3

[E] The most commercially successful application of the genome in the clinic today is not an editor. It is the peptide drug: a gene product, read forward out of the code and manufactured chemically rather than translated. Lilly’s retatrutide, a single molecule that agonizes the GIP, GLP-1 and glucagon receptors at once, reported up to 30.3 percent average weight loss in the phase 3 TRIUMPH-1 trial, and in July 2026 reported TRIUMPH-2 and TRIUMPH-3: about 20.8 percent weight reduction at 80 weeks in patients with obesity and type 2 diabetes, 22.6 percent in patients with severe obesity and established cardiovascular disease, with A1C falling about 1.5 points from a 7.7 percent baseline. Orforglipron, an orally available non-peptide

agonist of the same receptor, and the amylin and dual-amylin agents behind it, occupy [VOL p.199] the same late-stage field.

[F] Now look at what is actually in the molecule. These drugs do not work as bare peptide sequences. Semaglutide carries a C18 fatty diacid chain attached through a linker to a lysine side chain, and that acylation is what binds albumin and converts a peptide with a short half-life into a once-weekly drug. The disulfide bonds in insulin and in the amylin analogs hold the fold. Neither the acyl chain nor the disulfide register is specified by any gene. The entire commercial success of the peptide era rests on chemistry added after the sequence was read, by chemists, because the code does not contain it.

[F] That is the pattern this chapter is about, appearing first in the modality nobody thinks of as controversial. The code gave the sequence. The sequence was not the drug. The drug was the sequence plus an atomic-layer modification the code has no way to specify and no way to record.

134. Gene editing, base editing, prime editing

[E] Nuclease editing, base editing and prime editing are now all in human trials, and the first approved CRISPR therapy treats sickle cell disease by disrupting a repressor rather than correcting the causative mutation. Base editors convert one base to another without a double-strand break: cytosine editors deaminate C to U, which replicates as T; adenine editors deaminate A to inosine, which replicates and is read as G. Prime editors write a short program d sequence through a reverse transcriptase fused to a nickase.

[E] Their characteristic error is the bystander edit. A base editor does not select a single nucleotide; it exposes a window of roughly five to ten bases and deaminates what is editable inside it. Published analysis puts about eighty-two percent of the disease mutations correctable by adenine editors in sequence contexts containing more than one adenine. In a CFTR W1282X correction model, the high-activity editor ABE8e produced roughly sixty-two percent editing at a bystander adenine three positions away, generating an R1283G substitution the authors classify as likely pathogenic, while engineered variants cut that bystander rate several-fold and raised the yield of perfectly corrected alleles about six-fold.

[F] This is the healthy case. The error is a letter in the wrong place, it was found by sequencing, it was quantified, and it was engineered down. Every step of that loop was possible because the mistake had a symbol in the notation. Hold that example as the control for the rest of the paper.

[VOL p.200] 135. Epigenetic editing

[E] Epigenetic editors do not change sequence at all. A programmable DNA-binding protein is fused to an effector that writes or erases a chromatin or DNA mark, and the gene is silenced or activated while its letters stay exactly as they were. The modality has now produced clinical results. TUNE-401, delivered as

lipid-nanoparticle RNA, expresses a protein in the liver that methylates both the episomal and the integrated DNA of hepatitis B virus. In phase 1b/2a, repression of surface antigen was seen in every participant above the lowest dose level, several participants lost additional viral markers, and repression after a single dose has been observed out to seventeen months.

[F] Consider what a whole-genome sequence of a treated hepatocyte would return. It would return an unchanged genome. The drug worked, durably, for more than a year, by changing nothing a sequencer can see. 5-methylcytosine is read as cytosine by every standard sequencing chemistry; distinguishing it requires bisulfite conversion, an enzymatic equivalent, or direct nanopore signal analysis - a different instrument, run on purpose.

[F] The consequence for safety is structural rather than incidental. The case that CRISPR nucleases are acceptably specific was built on genome sequencing: find the mismatched sites, count the indels, show the number is small. That argument cannot be made for an epigenetic editor, because the agent's own mechanism of action is invisible to the assay.

Wherever else a fusion methyltransferase landed and deposited a mark, the genome still reads clean. The off-target question for this modality has to be asked methylome-wide, at depth, in the right tissue, and the public clinical record does not yet show that being done at the scale the nuclease field learned to do for sequence.

136. Three questions the record cannot answer

[F] Having established what is mutated, what kills and what is being built, three questions can be posed that the sequence record cannot settle and that later chapters take up.

• **Why do agents that correct the letter so often fail to correct the phenotype?** The question is not rhetorical: it has a specific answer in the cases where the phenotype depends on a cofactor, a redox state or a pool composition that the edit leaves untouched. Chapter 13 develops the protein-level version and Chapter 15 the chromosome-end version.

• **Why does inhibiting a central node fail while inhibiting a peripheral one succeeds?** This is the clinical pattern of Chapter 23: five Phase 3 programs against one hub with no overall-survival benefit, four of four against single spokes with one. The explanation offered is architectural, and the architecture is not in the sequence.

[VOL p.201] • **What fraction of unexplained variability in these programs is non-coded chemistry?** Nobody knows, because the measurement has not been attempted. That is the open question of the Part and it is stated again, with a proposed design, at the end of Chapter 14.

137. What this chapter does not argue

[F] It does not argue that sequencing-based medicine is misconceived. Two approvals for a previously untreatable hemoglobinopathy are an enormous achievement and were reached precisely by acting on the letter, because in that disease the letter is the cause and the edit is curative at the level the disease operates.

[F] It argues something narrower: that the class of diseases for which that logic holds is smaller than the class of diseases that kill, and that the modalities now being extended beyond that class carry validation practices designed inside it. An instrument that was sufficient for a monogenic hemoglobinopathy is not thereby sufficient for an acylated peptide, a deaminase editor acting in a cell full of RNA, or a methylation writer whose product is by construction sequence-neutral.

138. Consequences

[F] Two practical consequences follow immediately, before any of the later chapters' detail.

• **Match the instrument to the chemistry.** For each modality, name the chemical event that constitutes both its mechanism and its principal liability, and choose an assay that reports that event. For acylated peptides this is a chemistry question, not a sequence question. For deaminase editors it requires distinguishing inosine from guanosine. For methylation writers it requires genome-wide methylation rather than candidate-locus sequencing.

• **Report the metabolic state of the system.** Nucleotide pool composition, thiol redox poise and one-carbon availability are measurable, cheap relative to the cost of the experiments they would qualify, and almost never reported. They are the variables that determine whether an intervention that worked in one cell line will work in a patient's tissue.

[O] The open question that Part Four exists to answer is quantitative: of the agents now in clinical development whose mechanism or liability is non-coded, how many have a validation package that could detect the relevant event? The answer is obtainable from public regulatory and trial documents, and the volume's prediction is that the number is small. If a survey finds it is large, the central claim of this Part is wrong and should be withdrawn.

139. Notes to Chapter 12: the record, in numbers

[VOL p.202] **Quantities worth carrying**

[E] **Mutation frequency by gene.** TP53 is the most frequently altered gene across pan-cancer datasets, with alteration frequencies exceeding half of cases in several tumor types and approximately a third overall. A small group of further genes follows; the great majority of genes are altered in well under one percent of cases.

[E] **Hotspot structure.** Within TP53, alterations concentrate at a handful of codons in the DNA-binding domain, which is why a short panel captures much of the burden.

The hotspot structure is itself evidence that what matters is a specific structural consequence rather than loss of the gene as such.

[E] Mortality. Cardiovascular disease and cancer occupy the first two places on mortality tables in most high-income countries and together account for a large plurality of deaths. Neither is monogenic in the great majority of cases.

[E] Age as risk factor. Cancer incidence rises steeply with age in every population measured, with the rise typically approximated by a power law. Any model of carcinogenesis must reproduce that dependence, and models based purely on fixed per-division mutation rates do so only with additional assumptions.

[E] Approved editing therapies. Nuclease-based editing has reached approval for sickle cell disease and transfusion-dependent beta-thalassemia; base and prime editing programs are in clinical development across several indications.

Methods box: reading a validation package

[F] A reader auditing a program's evidence should look for five things, in this order.

1. The definition of off-target used. Narrow, sequence-only definitions exclude the second and third classes of Chapter 8 by construction.

2. The sampling frame. Whether candidate sites were chosen by guide homology, by unbiased genome-wide methods, or by the enzyme's intrinsic chemistry. For guide-independent liabilities, homology-based frames are the wrong frame.

3. The cells assayed. Edited cell products are heterogeneous; bulk assays average over clones, and a rare clone with a consequential event is precisely what matters.

4. The chemistry reported. Whether the package distinguishes the molecule produced from the letter it reads as.

5. The state variables. Whether anything was measured about pool composition, redox state or cofactor status in the edited cells.

[VOL p.203] ### Further reading, oriented

[E] The pan-cancer genomics consortia reports are the reference for mutation frequency and hotspot structure, and their supplementary tables are more useful than their summaries for the arithmetic above.

[E] For the peptide modality, the medicinal chemistry literature on acylation and half-life extension sets out exactly which features are coded and which are installed chemically.

[E] For the clinical editing programs, the regulatory review documents are the most informative public source on what was measured, because they state the validation package in detail that journal articles usually omit.

Problems

[O] 12.1 Take the top ten most frequently mutated genes in a pan-cancer dataset and classify each as enzyme, regulator or structural protein. Then ask, for each,

whether its activity can be altered non-genetically, and by what chemistry.

[O] 12.2 Using public mortality and incidence data, estimate the fraction of deaths attributable to conditions in which a single coding mutation is the dominant cause. Compare with the fraction of therapeutic programs targeting the sequence.

[O] 12.3 For one approved editing therapy, reconstruct the validation package from public documents and classify every assay by what class of event it could detect.

[O] 12.4 The chapter claims age is the strongest risk factor for cancer. Construct a model in which the age dependence arises from supply-side variables — pool composition, repair capacity, oxidative tone — rather than from accumulated mutations alone, and state what would distinguish it from the standard model.

[O] 12.5 Design a stratification for a trial at a signaling hub that includes a non-genetic measure of pathway activity. What assay, what threshold, and how many additional patients would be needed to detect a difference between strata?

[O] 12.6 List the incretin analogs now in use and identify, for each, which pharmacological properties are specified by sequence and which by chemistry. The ratio is the chapter's coded fraction, computed for a real molecule.

Connections

[F] This chapter sets the clinical baseline for Part Four. Chapter 13 takes the protein layer, Chapter 14 the three modalities, and Chapter 15 the chromosome end. Its findings return [VOL p.204] in Chapter 23, where the trial record at one hub is read against the architecture of Chapter 22.

Worked example: the two diseases that kill, side by side

[F] Put the two leading causes of death next to each other and ask, for each, where in the volume's three layers the causal variable sits.

[F] Cardiovascular disease. The dominant determinants are lipid handling, blood pressure, glycemic control, inflammation and age. Each is a flux variable: a rate of production, transport or clearance, measured as a concentration that is the result of a balance. The monogenic forms exist and are informative, and they account for a small minority of the burden. The successful interventions — statins, antihypertensives, antiplatelet agents, and now lipoprotein-directed agents — act on flux, and all of them are given continuously because stopping restores the original balance.

[F] Cancer. The causal variable is heritable change in a clone, which looks like a text problem. But the rate of such change is set by replication fidelity, pool composition, repair capacity and oxidative tone, and the dominant risk factor in every population is age. The successful interventions divide: for tumors driven by a single altered protein, an inhibitor of that protein; for the rest, agents acting on supply — the antimetabolites — and on the cell's tolerance of damage.

[F] The comparison. Both diseases are diseases of accumulated imbalance in which the sequence record is necessary and insufficient. For cardiovascular disease the record identifies who is at elevated risk and does not describe the state that produces an event. For cancer the record identifies which clone is present and not why clones arise at the rate they do.

[F] What this does not say. It does not say that sequencing is unhelpful in either disease. In both, sequence identifies the subset where a letter is the cause and is the appropriate target. The claim is about proportion: the subset is real and it is small relative to the burden, and the instruments and the research effort are distributed as if the proportions were the other way around.

[F] The measurement that would settle the proportion. For a defined population, estimate the fraction of events attributable to monogenic coding causes and compare with the fraction of therapeutic development aimed at sequence-level intervention. Both numbers are obtainable from public sources, and the exercise is the first problem in Appendix G for that reason.

[VOL p.205] **CHAPTER 13**

The Folding Problem Is an Occupancy Problem

Abstract. The protein folding problem is usually described as solved. What was solved is a specific and important part of it: predicting backbone geometry from sequence. What was not solved, and is not solvable from sequence alone, is the layer that decides whether the folded backbone does anything — which cofactor is loaded, which cysteines are paired and in which register, which metal occupies a site that could take more than one, and what the redox poise of the compartment is. That residual is sulfur chemistry, and this chapter sets out why it is structurally outside the prediction problem rather than merely harder than the part that was solved.

140. What was solved

[E] Structure prediction from sequence reached a level of accuracy for single-domain globular proteins that is comparable to experimental structures in many cases, and the consequences for biology have been large and immediate. The methods learn from the structural database and produce backbone coordinates and side-chain placements with calibrated confidence estimates.

[F] The achievement is a statement about one mapping: sequence to fold. It is accurate because that mapping is largely determined — the information for the fold is in the sequence, as Anfinsen’s experiments established, and a sufficiently good model of the statistics of known folds can recover it.

[E] Prediction of complexes, of conformational ensembles and of the effects of point mutations on stability has progressed less far, and prediction of cofactor binding and metal loading is addressed in current systems only partially and with much lower confidence. Methods now exist that place some ligands and ions; what they predict is

a plausible site, not the occupancy of that site in a particular cell at a particular moment.

141. What is not in the sequence

[F] Four properties of a working protein are not determined by its sequence, in the strict sense that two molecules with identical sequence can differ in them, and all four change function.

• **Cofactor occupancy.** Whether an iron-sulfur protein actually carries its cluster, and whether that cluster is the four-iron or a degraded two-iron form, depends on assembly machinery, on [VOL p.206] iron and sulfur availability, and on oxidative exposure. Cluster loss is rapid on oxidation and is the normal regulatory mechanism for some proteins, including the iron-responsive element binding protein.

• **Disulfide register.** Which cysteine pairs with which is determined during folding in the secretory pathway by oxidoreductases and isomerases; mis-paired isomers are a known failure mode of recombinant protein manufacture. The sequence specifies the available cysteines, not the pairing.

• **Metal selection.** Several sites can accept more than one metal. Which one is bound depends on the relative availability and affinity in the compartment — the Irving-Williams series imposes a chemical hierarchy that cells must actively work against — and on dedicated metallochaper-ones.

• **Thiol redox state.** Cysteine thiols exist as thiolate, sulfenic acid, disulfide, persulfide, S-nitrosothiol or further oxidized forms, and the distribution shifts on a timescale of seconds with the redox poise of the compartment. For a regulatory protein this distribution is the regulation.

[F] These four are not exotic. Perhaps a quarter to a third of all proteins bind a metal; the secretory proteome is full of disulfides; the entire respiratory chain is strung on clusters; and reversible cysteine oxidation is now recognized as a signaling modality comparable in scope to phosphorylation.

142. Why this is a sulfur problem

[F] In each of the four, sulfur is the atom doing the work. Clusters are ligated by cysteine thiolates. Disulfides are sulfur-sulfur bonds. Metal selection in many sites is mediated by cysteine and methionine ligands. Redox state is the oxidation state of a sulfur atom.

[E] Sulfur's chemistry makes this possible and makes it hard to predict. The element supports a ladder of stable oxidation states, several of them interconvertible under physiological conditions, which is exactly what a reversible switch requires and exactly what a static structural model cannot represent. Chapter 17 sets out the ladder in full.

[F] The consequence for prediction is structural. A sequence-to-structure model can predict where a cysteine is. It cannot predict what oxidation state that cysteine is in,

because the oxidation state is not a property of the protein at all: it is a property of the protein's compartment, its supply line and its history. No increase in training data changes that, because the information is not in the input.

[VOL p.207] ## 143. Where the folding problem went

[E] The folding problem as it was posed for fifty years - given a sequence, predict the three-dimensional structure - has been answered well enough for most practical purposes. Current predictors also place ligands, ions and cofactors when those are supplied as part of the input, and they do it imperfectly: chirality violations occur at a few percent, metal placement remains the weakest area, and the model returns one static structure where the molecule in the cell is an ensemble.

[F] But the limitation that matters is not accuracy, and it is not a limitation a better model removes.

A structure predictor is told which cofactors are present and asked where they sit. The question a treatment developer actually needs answered is the opposite one: in this cell, at this moment, under this redox state and this assembly capacity, did the cofactor get installed at all? That is an occupancy question. The sequence contains no occupancy information, so no model trained on sequence can supply it, however good the model becomes. The question is not hard; it is absent from the input.

[F] This is the folding problem's second half, and it has been quiet because the first half absorbed the attention. A protein with its cluster and a protein without its cluster have the same sequence, nearly the same predicted fold, and entirely different behavior - the apo form is typically less stable, more aggregation-prone and catalytically dead. Half of what a cell calls misfolding is not a geometry error at all. It is an unfinished molecule.

144. The layer underneath is sulfur

[F] Name the contents of that layer and the same element appears in every entry. Iron-sulfur clusters, assembled only in the mitochondrion and exported to every cluster protein in the cytosol and nucleus, including DNA primase, the replicative polymerases, and the repair helicases and glycosylases. Thioesters, which carry every acyl group that moves in metabolism.

The lipoamide arm on the dehydrogenase hubs. The sulfonium of S-adenosylmethionine, donor for essentially every biological methyl group - including, directly relevant here, the one an epigenetic silencer writes. The thiol redox buffer of glutathione, thioredoxin and the peroxiredoxins. The persulfide pool. The 2-thio group on the wobble uridine of three human tRNAs.

[F] Each of those is invisible in the way Section 74 describes, and together they are not a list of pathways but a single variable with many readers. Disulfide register is set by the thiol redox potential and the disulfide isomerases, not by sequence. Persulfidation converts a cysteine into a chemically different residue that the notation still spells C. Cluster occupancy is set [VOL p.208] by mitochondrial assembly

flux. Wobble thiolation is set by the cytosolic sulfur relay, which draws from the same mitochondrial cysteine desulfurase that builds the clusters - which means that translational fidelity at the wobble position and cofactor installation in the product draw on one sulfur supply.

[F] That last connection closes a loop worth stating plainly. If sulfur supply is constrained, the wobble base of the tRNA is under-thiolated, codon reading at the third position loosens, and the sequence that gets translated is not reliably the sequence that was written. A mistranslated protein has no genomic signature whatsoever. The gene is correct, the transcript is correct, and the polypeptide is wrong. There is no assay in any editing safety package that would see it, and the upstream cause is the same supply line that decides whether the correctly translated proteins got their cofactors.

145. The assays exist and are not being run

[F] The gap is not technical. It is that none of these is part of what anyone means by verifying an edit. The verification package is a sequence package, because the modality is thought of as a sequence modality, and the instruments follow the notation rather than the chemistry. A developer who added two of these assays to an existing editing program would be the first to have looked.

146. Four predictions

[O] Prediction 1. Adenine base editors are unregulated ADARs, and their RNA off-target sites will overlap the native editome. An adenine editor produces inosine from adenosine in RNA, which is precisely the reaction ADAR performs, and the published off-target sites for ABEmax fall preferentially in a UA context, which is also ADAR's preferred neighbor. The prediction is that editor-induced A-to-I sites will be significantly enriched in the cataloged human editome and in Alu repeat regions, and that the off-target burden will scale with endogenous ADAR expression in the treated cell type. This is testable today against public data, with no new experiment. Falsified if the editor's sites are randomly distributed with respect to the known editome once sequence context is controlled for.

[O] Prediction 2. Epigenetic editors deposit off-target marks at a rate that would be disqualifying if it were a letter, and nobody has looked at the right depth. The prediction is that whole-methylome analysis of cells treated with a fusion methyltransferase will show hundreds to thousands of differentially methylated regions unexplained by the on-target site, concentrated at loci sharing partial sequence identity with the guide and at loci with open chromatin.

[VOL p.209] Falsified if deep methylome analysis of a treated primary tissue returns a flat background.

[O] Prediction 3. Editing outcome depends on the thiol redox state of the target cell, with no genomic correlate. Delivery and transient effector expression impose oxidative stress; the editing enzymes, the repair pathways that resolve their

products, and the chaperones that fold what follows all carry reactive cysteines. The prediction is that shifting the glutathione couple toward oxidation, or raising persulfide tone by expressing CBS, CSE or MPST, will change both editing efficiency and the ratio of perfect to imperfect outcomes in isogenic cells, with no change in guide, editor or target sequence. Falsified if editing outcomes are indifferent to the redox couple across a range that cells tolerate.

[O] Prediction 4. A measurable fraction of corrected cells make an unfinished protein. For any edit that restores a gene whose product requires a cofactor - a cluster enzyme, a lipoylated dehydrogenase, a disulfide-bonded secreted protein - the prediction is that the holo fraction of the restored product will lag the allele-correction frequency, and that the lag will be largest in the cells most stressed by delivery. Falsified if holo fraction tracks allele

147. What this says to a developer

[F] The practical content of the argument is short. Verify the edit in the notation, which the field already does well. Then verify the molecule, which it does not do at all. Three additions would cover most of the exposure: an RNA-seq arm on any program using a deaminase, since the DNA package is blind to the majority of that enzyme’s activity; a methylome arm on any program using a chromatin effector, since the genome package is blind to all of it; and a cofactor-occupancy readout on any program restoring a protein that needs one.

[F] The deeper content is about where to aim next rather than what to check. If the leading causes of death are chemistries and the modality is a notation, then the modality will keep converging on the subset of disease that happens to be written down. The layer underneath is not harder to reach - sulfur metabolism is pharmacologically accessible, and four oncology programs currently filed under other names already operate there. It is harder to see, because the field’s primary instrument reports four symbols and the chemistry has more states than that.

[F] The code was never a complete description of the cell. It is a complete description of one thing, the amino acid sequence of a polypeptide, and the industry has mistaken a complete description of one layer for a complete description of the system. Every off-target class in Table 3 below the primary block is a consequence of that single substitution.

Status. The argument is complete as stated and each link can be checked independently. Sections 131 through 5 report the current clinical and epidemiological position and are sourced to the [VOL p.210] primary literature and to trial reports; Sections 71 through 9 carry the classification of off-target error that is the substance of the paper; Sections 143 through 12 relocate the folding problem to cofactor occupancy and name the assays; Section 146 states four predictions, the first of which can be run against public data without a new experiment, and each written so that a negative result falsifies a specific claim made here. Distribution is restricted. Licensed under CC BY-NC-ND 4.0.

148. The assays exist and are not run

[F] For every property named in this chapter there is at least one established measurement, and the reason they are absent from validation packages is convention rather than capability.

property	established assay	typical cost tier	run as part of edit verification?
cluster occupancy	UV-visible and EPR spectroscopy; iron and sulfide quantitation	moderate	no
cluster integrity in	mitochondrial aconitase activity ratio	low	rarely
cells			
disulfide register	non-reducing immunoblot; differential alkylation with mass spectrometry	low to m oderate	no
free thiol state	thiol trapping with maleimide reagents; redox proteomics	moderate	no
metal loading	inductively coupled plasma mass spectrometry	moderat e	no

[VOL p.211] **property established assay typical cost tier run as part of edit verification?** cofactor identity and occupancy native mass spectrometry moderate no compartment redox poise genetically encoded redox sensors, compartment-targeted low no **Table.** Measurements that would report the layer a sequence record cannot, with their status in current practice.

[F] The practical argument is simple arithmetic. Each of these assays costs a small fraction of one arm of a clinical trial, and each reports a variable that could plausibly

determine whether an agent works. The field's current practice optimizes the measurement it can standardize rather than the measurement that would be informative.

149. Objections

[F] Structure prediction will absorb this layer soon. It may absorb parts of it: predicting which sites are likely to bind which cofactors is a tractable learning problem. What cannot be absorbed is state in a particular cell at a particular time, because that is not a function of sequence. A model that predicts a protein's most probable cofactor is answering a different question from one that asks what is in it now.

[F] These are manufacturing concerns, not biology. Disulfide register and cofactor occupancy are indeed manufacturing concerns, which is informative: the biotechnology industry already knows it must measure them, because product that is correct by sequence and wrong by disulfide pairing fails. The argument here is that the same variables matter inside the patient and are not measured there.

[F] Redox biology is too noisy to be a useful variable. It is noisy, and that is a reason to measure it with compartment-resolved sensors rather than to ignore it. The alternative on offer is to leave a variable that changes protein function unmeasured because it is inconvenient.

150. Predictions

[F] Three predictions, each falsifiable with existing data or reagents.

• **Prediction one.** Among proteins whose variants are classified as of uncertain significance in clinical databases, variants at cysteines involved in metal ligation or disulfide bonding will [VOL p.212] be enriched for pathogenicity relative to matched non-cysteine variants, beyond what current predictors capture. Testable against public variant databases today.

• **Prediction two.** In cells with impaired iron-sulfur cluster assembly, the activity of cluster-dependent DNA repair enzymes will fall before any transcriptional change is detectable, producing a mutational phenotype without a transcriptional signature.

• **Prediction three.** For a recombinant protein therapeutic with multiple disulfides, lot-to-lot variability in clinical potency will correlate with disulfide isomer distribution measured by differential alkylation, and that correlation will be stronger than any correlation with sequence-level identity testing.

151. Consequences

[F] The folding problem, properly stated, has two halves: where the backbone goes, and what is bound to it. The first half is largely solved and the solution is one of the major achievements of computational biology. The second half is not a harder version of the first; it is a different problem, with a different input, and the input is metabolic.

[F] That reframing has one immediate practical implication for this volume's third leg. If occupancy is set by supply, and supply is organelle-specific — cluster assembly in the mitochondrion, disulfide formation in the endoplasmic reticulum, metal handling distributed across compartments with dedicated transporters — then the protein-level layer is itself organized by the organelle map of Chapter 16. The architecture that predicts which drug targets are redundant is the same architecture that predicts which proteins will be mis-assembled when a compartment fails.

152. Notes to Chapter 13: occupancy, measured

Quantities worth carrying

[E] Metalloprotein prevalence. Estimates of the fraction of proteins that bind a metal cluster around a quarter to a third of the proteome, with zinc the most common and iron next. Any statement that sequence determines function has to account for that fraction.

[E] Cluster types. The common biological iron-sulfur clusters are [2Fe-2S] and [4Fe-4S], with more elaborate forms in nitrogenase and in a few other enzymes. Cysteine thiolate is the standard ligand; histidine, aspartate and serine substitutions occur and shift the redox potential.

[E] Redox potentials. Iron-sulfur clusters span a wide range of midpoint potentials, from strongly negative in ferredoxins to near zero in the Rieske center, and the span is set largely [VOL p.213] by the ligand set and the protein environment. The same cluster chemistry therefore covers the whole range the respiratory chain needs.

[E] Disulfide isomers. A protein with n disulfide bonds has many possible pairings; for four disulfides there are one hundred and five distinct pairings, of which one is correct. Oxidative folding in the endoplasmic reticulum solves that search, and manufacturing failures are mispairings.

[E] Cysteine abundance and oxidation. Cysteine is one of the rarer amino acids in proteins, around one to two percent of residues, and a substantial fraction of cysteines in the proteome are reversibly oxidized at any moment under normal conditions, as measured by redox proteomics.

Methods box: the occupancy assays in practice

[F] Differential alkylation. Block free thiols with an alkylating reagent; reduce reversibly oxidized forms; label the newly freed thiols with a second reagent of different mass or reactivity. The ratio of labels at each cysteine gives its oxidation state. The method's weaknesses are artifactual oxidation during lysis, controlled by working under argon and with chelators, and incomplete blocking, controlled by titration.

[F] Cluster quantitation. In purified protein, ultraviolet-visible absorbance gives cluster content from the characteristic bands, and electron paramagnetic resonance distinguishes cluster types and oxidation states. In cells, the aconitase activity ratio — mitochondrial aconitase, which is cluster-dependent, against a

cluster-independent enzyme — is the standard functional proxy.

[F] Metal quantitation. Inductively coupled plasma mass spectrometry gives total metal content per protein or per cell with high sensitivity. The interpretive difficulty is assignment: total zinc does not say which sites are occupied, so metal quantitation is usually paired with native mass spectrometry or with site-directed mutants.

[F] Native mass spectrometry. Electrospray under non-denaturing conditions preserves noncovalent complexes, so cofactor occupancy can be read directly as a mass shift on the intact protein. It is the most direct answer to the chapter's question and is the least used.

Worked example: a variant of uncertain significance

[F] Consider a missense variant that replaces a cysteine in a protein annotated as a cluster-binding enzyme, found in a patient with a phenotype consistent with that enzyme's [VOL p.214] deficiency. The sequence-based pipeline reports a missense change at a conserved position, and most predictors will score it as probably damaging on conservation alone.

[F] What the chapter's argument adds is a mechanism and a measurement. If the cysteine is one of the four cluster ligands, the predicted consequence is loss of cluster binding, and the measurable consequences are: reduced cluster content on the purified variant, measured spectroscopically; reduced activity in the cluster-dependent assay but normal abundance on immunoblot; and, in patient cells, a normal transcript level with reduced enzymatic activity.

[F] The point of the example is that the variant's pathogenicity is not predicted from sequence in any deep sense — it is predicted from knowing what the cysteine does — and that the three measurements convert a classification into a mechanism. They also distinguish this variant class from one in which the same gene is mutated at a position that affects abundance rather than occupancy, a distinction that matters for whether a chaperone or a cofactor supplementation strategy could help.

Problems

[O] 13.1 Take a protein with four disulfides and enumerate the possible pairings. Then find, in the manufacturing literature, how mispairing is detected and at what level it is tolerated.

[O] 13.2 For a cluster-dependent DNA repair enzyme, design an experiment that separates loss of cluster from loss of protein, and specify the controls that rule out artifactual cluster loss during preparation.

[O] 13.3 Structure prediction gives a confidence score per residue. Propose an analogous score for cofactor occupancy, state what data would be needed to train it, and say why the problem is not simply a harder version of structure prediction.

[O] 13.4 Classify, for a protein family of your choice, which cysteines are structural, which are catalytic, which are metal ligands and which are regulatory. What information beyond sequence did you need?

[O] 13.5 The chapter claims redox state is a property of the compartment, not of the protein.

Construct the strongest counterexample: a protein whose cysteine oxidation state is largely independent of its compartment.

[O] 13.6 Estimate how many of the variants currently classified as of uncertain significance in a clinical database affect cysteines, and propose a triage scheme based on the role of the cysteine rather than on conservation alone.

[VOL p.215] ## Connections

[F] The occupancy layer is supplied by the organelle machinery of Chapter 20, is the mechanism of the switch in Chapter 22, and is the subject of the graded clinical series in Chapter 24. The notational claim behind it is Chapter 8's third class: a change with no letter at all.

Worked example: two proteins with identical sequence and different function

[F] Take a cluster-containing enzyme expressed in two cell populations. The gene is identical, the transcript is identical, the protein's abundance is identical by immunoblot, and the enzyme's activity differs twofold.

[F] The candidate explanations, in the order a laboratory usually tries them. A post-translational modification; a difference in a partner protein; an assay artifact; a difference in the preparation.

[F] The explanation the volume adds. Cluster occupancy. One population assembled the cluster fully; the other, grown under conditions that impaired mitochondrial assembly or raised oxidative tone, did not. Occupancy is not a modification of the protein — nothing is added to the polypeptide — and it is not visible by any method that measures the polypeptide.

[F] How to distinguish it in a week. Three measurements. First, the aconitase activity ratio in both populations, which reports cluster supply independently of the enzyme under study. Second, native mass spectrometry or spectroscopy on the enriched protein, which reports occupancy directly. Third, reconstitution: incubate the low-activity preparation with iron and sulfide under reducing conditions and ask whether activity is restored. Restoration is diagnostic.

[F] Why this matters beyond one enzyme. The same logic applies to every variant classification exercise in which a cysteine is involved, to every recombinant protein whose potency varies between lots, and to every experiment in which a cell line behaves differently after a change in culture conditions. Occupancy is a hidden variable that moves with mitochondrial state, and mitochondrial state moves with passage number, confluence, medium formulation and oxygen tension — four things that differ between laboratories and are rarely reported.

[F] The claim this supports. Not that sequence is uninformative, but that two molecules with the same sequence can differ in a property that decides function, that the property is measurable, and that it is not measured. The appendix on

measurement names the assays; this example is what they are for.

[VOL p.216] **CHAPTER 14**

Three Modalities, One Instrument

Abstract. Three modalities now carry a large share of the translational program: acylated peptide drugs, deaminase-based editors, and targeted methylation writers. Each is validated principally by sequencing. In the first, the chemistry that makes the molecule a drug is not coded. In the second, the product of the reaction reads in the record as a different base than the one that is physically present. In the third, the entire mechanism of action leaves the sequence unchanged by design. The three failures are one failure, and this chapter states it per modality with the assay that would close each gap.

153. Why these three

[F] The three were not chosen to be convenient. They were chosen because each is commercially or clinically significant now, each is mechanistically distinct, and each fails the record in a different way — one by chemistry outside the code, one by an ambiguity inside the code, one by acting on a layer the code does not address. If the argument of this volume is right, these are the three places it should be visible with the least interpretation.

[F] The structure of each case is the same. Name the chemical event that makes the agent work.

Ask what a sequencing readout would report about that event. Show the gap. Name the assay that reports it, and the experiment that would falsify the claim that the gap matters.

154. Case one: the coded fraction of an acylated peptide

[E] An incretin analog of the current generation is a peptide of roughly thirty to forty residues carrying substitutions at protease-sensitive positions, a fatty-acid chain attached through a linker to a lysine side chain, and in several cases a C-terminal amide. The peptide backbone is coded information: it can be written as a gene, and in manufacturing it often is.

[F] The pharmacokinetics are not coded. Albumin binding through the fatty-acid chain is what converts a peptide with a half-life of minutes into a drug with a half-life of days. Nothing in any sequence record represents that chain, its length, its attachment point or its linker, and two molecules identical by sequence with different acylation are different drugs.

[E] C-terminal amidation makes the point sharper. The amide is installed by peptidylglycine alpha-amidating monooxygenase, which consumes the glycine encoded at the C-terminus [VOL p.217] and converts it into the amide of the preceding residue. The gene encodes a glycine whose only function is to be destroyed. A

sequence record of the mature product cannot contain that glycine, and a sequence record of the gene reports a residue that is not in the drug.

[F] The coded fraction of such a molecule — the proportion of its atoms, and of its pharmacologically decisive features, that a sequence specifies — is therefore well under one hundred percent, and the uncoded remainder includes the features that determine dosing interval.

155. Case two: a deaminase that was always an RNA enzyme

[E] The catalytic core of the first adenine base editors was an engineered variant of a bacterial tRNA adenosine deaminase whose native substrate is adenosine at anticodon position

34. The enzyme was evolved in the laboratory to accept DNA. Its ancestral reaction is the one described in Chapter 7.

[F] Two consequences follow and are not speculative. The first is that RNA editing by such constructs is not a side effect of an unrelated activity; it is the ancestral reaction running on its original substrate, and it runs at scale wherever the editor is expressed. The second is that the product of the DNA reaction is inosine, which is read as guanosine by every polymerase-based readout. The assay that verifies the edit reports a base that is not the base present until replication has converted it.

[E] The same chemistry is performed constitutively by the human ADAR enzymes on double-stranded RNA, at a scale of millions of sites in the human transcriptome, with the same product and the same readout ambiguity. The human body already runs this reaction continuously, which is why the off-target question for an expressed deaminase is a question about adding to an existing flux rather than about creating a new one.

[F] The falsification path costs nothing extra: inosine-specific chemistry applied to RNA from edited cells, run alongside the standard DNA panel, with the two compared. If RNA editing by clinical-grade constructs is negligible under therapeutic expression levels, the objection fails.

156. Case three: an epimutation nobody can see

[E] A targeted methylation writer silences a gene by placing 5-methylcytosine at its promoter.

Standard short-read sequencing does not distinguish methylated from unmethylated cytosine: the base reads as C either way. Detection requires a dedicated method — bisulfite or enzymatic conversion, affinity enrichment, or a nanopore signal — and those methods are run at candidate loci far more often than genome-wide.

[VOL p.218] **[F]** The off-target liability has a particular shape. Much of the reported off-target methylation from such constructs is guide-independent, arising from the writer domain acting where it happens to dwell, so a candidate-locus panel chosen by guide similarity is the wrong sampling frame: it samples the sites the agent is least

likely to hit by that mechanism.

[E] An epimutation at a tumor suppressor promoter is clonally heritable through maintenance methylation and is oncogenic in exactly the same way a deletion would be. The best-documented natural examples silence mismatch repair genes and produce the same tumor spectrum as the corresponding germline mutations. Nothing in the sequence changes.

[F] So the third case is the cleanest: an agent whose mechanism is invisible to the record, with an off-target liability that is invisible to the record, whose worst consequence would be inherited through cell divisions and remain invisible to the record. The assay that would see it exists and is genome-wide methylation analysis.

157. What is actually in the molecule

[E] Semaglutide is [Aib8, Arg34]GLP-1(7-37) bearing, on the epsilon-amine of Lys26, a gamma-glutamyl residue extended by two 8-amino-3,6-dioxaoctanoyl spacers and terminated in oc-tadecanedioic acid. Three modifications, each solving a separate failure mode of the parent hormone. Aib at position 8 replaces the alanine that dipeptidyl peptidase-4 cleaves after, and 2-aminoisobutyric acid is not a proteinogenic amino acid: there is no codon for a disubstituted alpha carbon. The Lys34-to-Arg substitution exists for synthetic reasons, to leave Lys26 the only acylation site. The diacid provides reversible albumin binding, which both shields the molecule from renal filtration and recruits it into neonatal Fc receptor recycling.

[E] Tirzepatide follows the same design with a C20 diacid at Lys20 and Aib at positions 2 and

13. Insulin’s tertiary structure is held by three disulfides, A6-A11 intrachain plus A7-B7 and A20-B19 interchain, and the dominant manufacturing failure mode in recombinant insulin production is not mistranslation but disulfide scrambling. The amylin analogs carry a Cys2- Cys7 loop and a C-terminal amide.

158. The coded fraction, computed

[F] Native GLP-1(7-37) has a plasma half-life on the order of two minutes. Semaglutide’s is approximately one week. That is a factor of roughly five thousand in systemic exposure, and every bit of it is purchased with chemistry the genome cannot specify. The receptor phar-macophore - the part of the molecule that actually engages the GLP-1 receptor extracellular domain and transmembrane core - is the coded part, and it is also the part that was already there in the endogenous hormone and was never a drug.

[VOL p.219] **[F]** State it as a ratio and the asymmetry is hard to look away from. By residue count, the non-coded content of semaglutide is one substituted alpha carbon and one side-chain conjugate: on the order of five percent of the molecular architecture. By contribution to the property that made it a medicine rather than a physiological curiosity, it is essentially all of it. The coded fraction supplies specificity; the non-coded fraction supplies the drug.

[F] This is worth stating plainly because the modality is routinely filed under genomic medicine, as though reading the sequence had been the achievement. Reading the sequence was never the obstacle. The GLP-1 sequence has been known since 1983. Four decades separate the sequence from the drug, and what was happening in those four decades was medicinal chemistry on the atomic layer: half-life engineering, protease hardening, conjugation chemistry, and the albumin-binding problem. The genome contributed the starting material and then contributed nothing further, because it had nothing further to contribute.

159. Amidation, or a codon whose product is its own destruction

[E] The amylin analogs and a long list of neuropeptides terminate in a C-terminal amide rather than a carboxylate. The amide is not translated. It is produced by peptidylglycine alpha-amidating monooxygenase, a bifunctional, copper-dependent and ascorbate-dependent enzyme that hydroxylates the alpha carbon of a C-terminal glycine and then lyses the resulting carbinolamide, releasing glyoxylate and leaving the preceding residue amidated.

[F] Follow what that means for the record. The gene encodes a glycine codon. The glycine is translated. Its entire biological function is to be destroyed, and the functional group that results - the terminal amide that is frequently essential for receptor binding and for resistance to carboxypeptidases - has no codon, no letter, and no representation anywhere in the sequence.

A reader with the complete coding sequence in hand, reasoning only from the code, would write down a peptide ending in glycine with a free carboxylate. That peptide does not exist in the organism and would not work as a drug. Two copper atoms and an ascorbate did the decisive chemistry, and neither has a letter.

[F] The amidation case is the acylation case stripped to its minimum. In semaglutide a chemist added non-coded chemistry; in amidation the cell itself does it, routinely, to a substantial fraction of the human peptide hormone repertoire. The code is not even a complete description of the polypeptide. It is a complete description of the polypeptide as it leaves the ribosome, which is not the molecule that does anything.

[VOL p.220] ## 160. TadA’s day job is position 34

[E] The deaminase in every adenine base editor descends from Escherichia coli TadA. TadA is a tRNA-specific adenosine deaminase, it is an essential gene, and it has exactly one known natural substrate: adenosine 34 in the anticodon wobble position of tRNA-Arg2, which it converts to inosine, read by the ribosome as guanosine. ABEmax carries the laboratory-evolved variant TadA*7.10; ABE8e carries TadA-8e, evolved further for rate and operating with a window on the order of ten base pairs against roughly five for the earlier constructs.

[F] So the construct is not a synthetic DNA-modifying enzyme that happens to have an RNA liability. It is a wobble-position tRNA deaminase that has been forced, by directed evolution and by tethering to a nickase, to act on single-stranded DNA in an

R-loop. Its activity on RNA is not an artifact of the engineering. It is what the enzyme was before the engineering, incompletely removed.

[F] The element this chapter's key assigns to inosine therefore appears twice in the same system, for the same chemical reason. It appears at position 34 of a transfer RNA, where the ancestral enzyme put it, and it appears across the transcriptome of a treated patient's cells, where the descendant enzyme puts it. Nobody designed the second one. It is the first one, off the leash.

161. The editome the DNA assay cannot see

[E] In the transcriptome-wide survey, ABEmax induced tens of thousands of A-to-I events in HEK293T cells, affecting between fifty-one and fifty-nine percent of expressed genes, at allele frequencies from about a tenth of a percent to saturation. BE3, the cytidine counterpart built on APOBEC1, induced tens of thousands of C-to-U events across thirty-eight to fifty-eight percent of expressed genes in HepG2 and HEK293T, including missense and nonsense changes and splice-site positions, with a strong ACW context preference. Approximately ninety-eight percent of the edited cytosines and ninety-five percent of the edited adenines had no corresponding DNA change. Engineered variants carrying deaminase-domain substitutions suppress the RNA activity while retaining DNA editing, which establishes that the two activities are separable and that the unmodified constructs did not separate them.

[F] Three consequences follow that are not usually stated together. First, an A-to-I event in a coding exon is a recoding event: the ribosome reads inosine as guanosine, so the cell translates a protein that no gene in that cell encodes. The resulting missense product has no genomic signature of any kind. Second, A-to-I at a 3' splice acceptor converts the invariant AG, and the editing literature documents both creation and destruction of splice sites by this chemistry; an isoform shift is therefore available as an off-target outcome with no mutation anywhere. Third, and most awkward for the regulatory framing: the detection method works [VOL p.221] by sequencing cDNA and scoring guanosines at genomic adenosines. It does not detect inosine. It detects reverse transcriptase's misreading of inosine, and reports a base that was never in the molecule.

[F] That last point deserves to be uncomfortable. The field's measurement of its own most prevalent off-target activity is an artifact of an enzyme's error, standardized into an assay. Wherever the misincorporation is incomplete, wherever the transcript is below the pipeline's expression threshold, wherever the inosine sits in a structured region the library prep depletes, the event happened and nothing records it.

162. The convergence with ADAR

[E] ADAR1 and ADAR2 perform the identical chemistry on human RNA: hydrolytic deamination of adenosine to inosine in duplex regions, with a 5' neighbor preference for uridine and adenosine over cytidine and guanosine. The overwhelming majority of cataloged human A-to-I sites fall in Alu elements, where inverted repeats create the

double-stranded substrate ADAR requires. ADAR1 p150 is interferon-inducible. The published ABEmax off-target sites show a UA context preference.

[F] Set those facts beside each other. Same reaction, same product, overlapping nearest-neighbor preference, and a delivery vehicle - lipid nanoparticle with an RNA payload - that is itself a potent inducer of the interferon response that drives ADAR1 p150 expression. The conclusion available from this is not subtle: an adenine base editor is pharmacologically an unregulated ADAR, administered to a cell whose own regulated ADAR is being induced by the same injection.

[F] If that is right, the off-target burden is not a fixed property of the construct. It is a function of the patient's inflammatory state, the tissue's baseline ADAR1 expression, and the dsRNA content of the transcriptome at the time of dosing. Those vary between patients by consider-ably more than the fold-changes that separate one editor variant from another, and none of them appear in any release specification.

163. The falsification path, which costs nothing

[O] Prediction 1. Editor-induced A-to-I sites are enriched in the known human editome. Take the published ABEmax RNA off-target call set, intersect it with a cataloged A-to-I site database, and test enrichment against a permutation null that matches expression level, trinucleotide context and repeat annotation. The prediction is significant enrichment surviving all three controls, with the residual concentrated in Alu inverted repeats. This requires no new ex[VOL p.222]periment and no new reagent. Falsified if enrichment collapses once context and repeat annotation are matched, which would mean the editor and ADAR share a motif and nothing else.

[O] Prediction 2. Off-target burden scales with ADAR1. In isogenic cells, ADAR1 knockdown and interferon-alpha pretreatment should move the editor's RNA off-target count in opposite directions, with on-target DNA editing unchanged. The direction at shared sites is itself informative: competition for substrate predicts that knockdown raises the editor's signal at sites ADAR normally occupies, while independent access predicts no change there and a global shift driven by dsRNA availability. Falsified if the RNA off-target count is indifferent to ADAR1 dosage.

[O] Prediction 3. The recoding is translated. Ribosome profiling or targeted proteomics on editor-treated cells should recover peptides corresponding to A-to-I recoded codons in genes that were never targeted and carry no mutation. The prediction is that such peptides are detectable at the higher-frequency editing sites. Falsified if deep proteomic search returns none, which would mean the edited transcripts are degraded before translation - itself a finding, and itself unrecorded by any current assay.

164. What a sequencer would report about a cured patient

[E] TUNE-401 is lipid-nanoparticle-delivered RNA encoding a targeted protein that methylates hepatitis B covalently closed circular DNA and integrated viral DNA in hepatocytes. In the phase 1b/2a study, surface antigen repression was observed in all

participants above the lowest dose level, a majority of evaluable HBeAg-negative participants lost pregenomic RNA, and repression after a single dose has been durable to seventeen months. By the standards of chronic hepatitis B this is a significant result.

[F] Now specify the verification problem exactly. Both Illumina sequencing-by-synthesis and standard long-read basecalling report 5-methylcytosine as cytosine, because the methyl group at C5 does not alter Watson-Crick pairing and polymerases incorporate guanosine opposite it indifferently. A thirty-fold whole-genome sequence of a treated hepatocyte returns the reference genome. The agent achieved a durable therapeutic effect by making a change that the industry’s principal safety instrument is constitutionally incapable of registering. This is not a gap in coverage or a question of read depth. It is a chemistry the assay does not interrogate.

[VOL p.223] 165. The off-target literature, and the sampling fraction nobody mentions

[E] The systematic genome-wide comparison of dCas9-based methylation epimodifiers reports results that would end a nuclease program. Across constructs and timepoints the study identifies 34,785 differentially methylated regions at a beta threshold of 0.1. For direct DNMT3A fusions a non-targeting control guide produced average beta values around fifty percent at a locus the targeting guide was aimed at - that is, off-target methylation comparable in magnitude to on-target methylation, at a site the guide does not address. The effects were largely independent of guide sequence, occurred at loci with no homology to the guide, but required the guide-protein complex, and scaled with effector expression level. Roughly fifty-five percent of changes measured at day three persisted at least a week. Off-target methylation was largely decoupled from transcription, and persistent transcriptional alterations were observed that methylation at the same genes did not explain.

[F] Note the instrument. That study profiled genome-wide methylation on an Infinium EPIC array, which interrogates on the order of nine hundred thousand CpG sites. The human genome contains roughly twenty-eight million. The array samples something near three percent of the positions at which the enzyme can act. Thirty-five thousand differentially methylated regions is what three percent coverage returned.

[F] Two caveats are owed and neither rescues the position. The published work uses constitutively expressed dCas9 fusions in immortalized cells, while a clinical agent delivered as lipid-nanoparticle RNA is expressed transiently, which bounds exposure. And a different DNA-binding module may have different residence-time behavior. But the central finding was that off-target methylation is largely guide-sequence-independent and tracks effector expression. That locates the hazard in the catalytic module and its dose, not in the targeting module. Transience limits the integral; it does not change the mechanism, and the mark outlives the enzyme.

[F] One detail in that study is worth isolating. The R882H catalytic mutant roughly halved on-target efficiency and reduced off-target activity as well. R882H is the dominant-negative DNMT3A hotspot of acute myeloid leukemia and of clonal hematopoiesis. The field is characterizing its therapeutic enzyme by comparison with the specific lesion that drives a myeloid malignancy, and appears not to have drawn the obvious line.

166. An epimutation is heritable, oncogenic, and unreadable

[E] A 5-methylcytosine mark at a CpG is not a transient perturbation. DNMT1 recognizes the hemimethylated CpG produced at replication and restores the mark on the daughter strand.

[VOL p.224] An off-target methylation event in a dividing cell is therefore clonally inherited on the same footing as a mutation.

[E] Promoter hypermethylation of a tumor suppressor is an established mechanism of human cancer, not a theoretical hazard. Epigenetic silencing of MLH1 produces mismatch-repair deficiency and the microsatellite-instable phenotype in sporadic colorectal carcinoma; CDKN2A silencing by promoter methylation is among the most common events across tumor types. In both cases the coding sequence is intact and wild-type.

[F] Put the three facts in series. The off-target event is heritable. Its mechanism at a tumor suppressor promoter is a recognized route to malignancy. And it is invisible to whole-genome sequencing. The hazard class that genotoxicity testing was constructed to exclude is reproduced exactly by this modality in a form the test cannot detect. A nuclease that caused insertional events at CDKN2A would not reach a patient; a methyltransferase that silences CDKN2A leaves a genome that passes every sequencing-based release criterion in use.

[F] The argument is not that epigenetic editing should not proceed. The TUNE-401 result is real and chronic hepatitis B is a disease worth this risk profile. The argument is that the safety case for this modality has not been made, cannot be made with the assays that made it for the nucleases, and is currently resting on the absence of evidence produced by an instrument that was never pointed at the question.

167. What the assay would have to be

[F] Specify it rather than gesture at it. Whole-genome bisulfite sequencing converts unmethylated cytosine to uracil and leaves 5-methylcytosine intact, but it degrades the great majority of input DNA, reduces sequence complexity to three bases and demands high coverage; enzymatic conversion avoids the degradation. Nanopore with modification-aware basecalling reads the mark directly and preserves long-range phasing, which matters because a differentially methylated region is a regional object rather than a per-base one. To resolve a five to ten percent shift at a single CpG with confidence requires depth in the high tens; to do that genome-wide,

in the correct primary tissue, at several timepoints, with enough animals or donors for a background distribution, is a serious and expensive program.

[O] Prediction 4. Deep methylome analysis of a clinically formulated targeted methyltransferase, in the correct primary tissue, will reveal hundreds to thousands of unexplained differentially methylated regions, concentrated in low-methylated regulatory regions and at open chromatin, and largely independent of guide homology. Falsified if an adequately powered whole-methylome study in treated primary tissue returns a flat background outside the target locus - which would be a genuinely important result and is nowhere in the public record.

[VOL p.225] ## 168. One instrument, three blind spots

[F] The three cases are not analogous; they are the same case in three chemistries. A peptide drug's decisive content is a side-chain conjugate and a non-proteinogenic alpha carbon, which the record cannot write because the record has twenty residue symbols. A base editor's dominant activity is deamination to inosine, which the record cannot write because the record has four base symbols and inosine is not one of them - it is registered only as a guanosine that does not exist. A methyltransferase's entire mechanism is a methyl group on C5, which the record cannot write because 5-methylcytosine and cytosine are the same symbol.

[F] In each case the field's response has been to treat the modality as a genomic one, validate it with a genomic assay, and report the result as clean. The result is clean. The assay has a four-symbol alphabet and the therapeutic mechanism occupies a chemical state space with far more states than four. A clean result from an instrument that cannot represent the event is not evidence of absence; it is a category error with a p-value attached.

[F] The practical remedy is short and is not research: an RNA arm on every deaminase program, a methylome arm on every chromatin-effector program, and a cofactor-occupancy readout on any program restoring a protein that requires one. The conceptual remedy is longer. The genetic code is a complete description of one thing - the order of residues leaving the ribosome - and the industry has been operating as though it were a complete description of the cell. Every blind spot in this chapter is a consequence of that one substitution, and no amount of sequencing depth addresses any of them, because depth is not the limitation. The alphabet is.

Status. Each of the three cases is sourced to primary literature or to a trial report and can be checked independently. Sections 157 through 3 rest on published peptide chemistry and pharmacokinetics; Sections 160 through 6 on the TadA and base-editor literature and on the transcriptome-wide off-target survey; Sections 164 through 10 on the clinical report and on the systematic dCas9 epimodifier comparison, with the limits of that comparison stated where they apply. Sections 163 and 11 state four predictions, the first of which is a reanalysis of existing public data requiring no new experiment, and each written so that a negative result falsifies a specific claim made here. Distribution is **Sources for the reported figures**

169. One failure, three faces

[F] The three cases share a structure that can be stated independently of any of them: an agent whose action is chemical is being validated by an instrument that reports identity. Where the chemistry changes identity, the instrument works. Where the chemistry preserves identity, or maps one identity onto another, or operates on a layer with no identity at all, the instrument returns a confident answer to a question that was not asked.

modality	the chemical event	what a sequencer reports	assay that closes the gap
acylated	fatty-acid chain on a lysine;	the coded backbone, including	intact-mass and tandem mass
peptide	C-terminal amidation	a glycine that is destroyed	spectrometry of the product
deaminase	adenosine to inosine, on	guanosine, on DNA; nothing,	inosine-specific chemical
editor	DNA and on RNA	on RNA	sequencing, DNA and RNA in parallel
methylation	5-methylcytosine at a	cytosine, unchanged	genome-wide methylation, not
writer	promoter		candidate loci

Table. Three modalities, the event that matters, and the instrument that would see it.

170. What it would take to be wrong

[F] Each case carries a specific falsifier, and they are cheap.	
•	**Peptides.** If the acylation and amidation of a clinical peptide turn out to be fully specified by the sequence of its precursor gene plus known processing rules, so that no product-level chemistry is needed to predict its pharmacokinetics, the first case fails. The test is prediction of half-life from sequence alone across a panel of analogs.

[VOL p.227] • **Deaminase editors.** If inosine-specific analysis of RNA from cells expressing clinical-grade editors at therapeutic levels shows no increase in editing over background ADAR activity, the second case fails as an off-target concern, though the readout ambiguity on DNA remains.

• **Methylation writers.** If genome-wide methylation analysis of cells treated with a targeted writer shows that off-target methylation is confined to guide-similar sites, then the candidate-locus sampling frame is adequate and the third case fails.

[F] None of those three experiments requires a new method, a new instrument or a new reagent class. Each requires a decision to run an assay that reports the chemistry rather than the letter.

171. Consequences for how a program is designed

[F] Four rules follow for a development program that takes the argument seriously.

• **Define the agent’s chemistry before choosing the assay.** Write down the bond that is made or broken. If no sequence change is entailed by that bond, sequencing is not a validation method for it.

• **Sample by mechanism, not by homology.** Guide-independent liabilities are not found by searching for guide-like sites. The sampling frame must follow the enzyme’s intrinsic preference, which for a writer domain is chromatin accessibility and dwell time.

• **Assume the ancestral reaction is still running.** An enzyme evolved from an RNA-acting ancestor will act on RNA. The question is the rate, not the existence.

• **Report the two readouts separately.** An A-to-G call and an adenosine-to-inosine conversion are different observations. Reporting them with the same symbol discards

the distinction that matters.

[O] The open question, stated once more because it is the Part's main unfinished business: what fraction of current clinical-stage agents have a validation package capable of detecting their own principal chemical liability? The survey is feasible from public documents. The prediction of this volume is that the fraction is small, that it is smallest for epigenetic editors, and that where it is large the program in question has already had a clinical surprise and built the assay in response.

172. Notes to Chapter 14: three modalities, measured

Quantities worth carrying

[E] Half-life extension. Native incretin peptides have circulating half-lives measured in minutes; acylated analogs reach half-lives measured in days, supporting weekly dosing. The difference [VOL p.228] is attributable principally to albumin binding through the attached fatty-acid chain and to protease-resistant substitutions.

[E] Amidation. C-terminal amidation is performed by a bifunctional enzyme that consumes a glycine residue; a substantial fraction of human peptide hormones are amidated, and in many the amide is required for receptor activation.

[E] Editing scale in the transcriptome. Adenosine-to-inosine editing sites in human cells number in the millions, concentrated in repeat elements; a much smaller number are recoding events in protein-coding sequence.

[E] Methylation prevalence. In human somatic tissue, a few percent of all cytosines carry a methyl group, with CpG dinucleotides the predominant context and most CpGs methylated outside of CpG islands.

[E] Clonal heritability. Maintenance methylation copies the parental methylation pattern to the daughter strand after replication, which is why an epimutation is inherited through cell divisions without any change in sequence.

Methods box: matching assay to chemistry

[F] For the peptide. Intact-mass measurement confirms the molecular weight including the acyl chain and the amide; tandem mass spectrometry localizes the modification to a residue. Sequence-based identity testing cannot do either, because neither modification is a sequence feature.

[F] For the deaminase. Two readouts run in parallel. On DNA, standard sequencing reports the converted letter but not whether conversion has been replicated through; inosine-specific chemistry distinguishes the molecule present. On RNA, the same chemistry applied to the transcriptome reports editing above the ADAR background, and the comparison requires a matched control expressing a catalytically inactive construct.

[F] For the writer. Genome-wide methylation at base resolution, by bisulfite or enzymatic conversion, run on treated and control cells, with the analysis performed over the whole genome rather than at guide-similar loci. Differentially methylated

region calling is a mature method; the discipline required is in the sampling frame, not in the analysis.

Worked example: computing a coded fraction

[F] Take an acylated peptide of forty residues with one fatty-acid chain of eighteen carbons attached through a short linker, and a C-terminal amide.

[F] By atom count, the peptide backbone and side chains dominate: a forty-residue peptide has [VOL p.229] on the order of six hundred atoms, and the acyl chain plus linker contributes a few tens. By atom count the coded fraction is high, above ninety percent.

[F] By pharmacological consequence the arithmetic inverts. Remove the acyl chain and the half-life falls by two to three orders of magnitude, which removes the product's entire clinical rationale. Remove the amide and receptor activation falls sharply for many amidated peptides. Remove any single coded residue outside the receptor-binding core and the effect is usually modest.

[F] So the coded fraction is above ninety percent by atoms and well below fifty percent by decisive features, and which number one quotes determines whether the molecule looks like a product of the genetic code or like a chemical entity with a coded scaffold. The chapter's claim is that the second description is the accurate one for this modality, and the arithmetic is the reason.

Problems

[O] 14.1 Compute the coded fraction, by both measures, for three marketed peptide drugs. Then ask what a sequence-based identity test establishes about each.

[O] 14.2 Design the control that distinguishes editor-driven RNA editing from endogenous ADAR activity in a cell line with high basal editing. Specify the construct, the comparison and the statistical treatment.

[O] 14.3 For a targeted methylation writer, estimate the number of sites that would need to be sampled to detect guide-independent off-target methylation at a given rate with given power. Compare with the number of sites in a typical published off-target panel.

[O] 14.4 An epimutation at a mismatch repair gene promoter produces a tumor spectrum resembling the germline mutation. Design a diagnostic strategy that would find such cases in a clinic that currently sequences only.

[O] 14.5 The chapter says all three failures are one failure. State the single proposition formally, then construct a modality that fails it in a fourth way — an agent whose chemistry is invisible to the record for a reason not covered by the three classes.

[O] 14.6 Given that adenine base editors derive from a transfer RNA deaminase, predict which cellular RNAs are most likely to be edited by them, and justify the prediction from the enzyme's native substrate preference.

Connections

[F] The three cases apply Chapter 8's principle to agents in patients. The deaminase case depends on Chapter 7's chemistry and feeds Chapter 23's discussion of editing's bounds. The [VOL p.230] methylation case is the clearest instance of Chapter 8's first class — a change that preserves the letter — and the peptide case is the clearest instance of chemistry the code never specified at all.

Worked example: designing the validation package the chapter asks for

[F] Take a hypothetical program: an adenine base editor delivered to hematopoietic stem cells ex vivo, intended to correct a single pathogenic variant, with the product expanded and reinfused.

[F] The standard package. On-target editing efficiency by amplicon sequencing; off-target analysis by an unbiased genome-wide method plus candidate sites; karyotype or structural variant analysis; viability and engraftment potential.

[F] What the chapter adds, modality by modality.

• **Because the agent deaminates:** inosine-specific chemistry on DNA from the edited product, to establish what fraction of the on-target signal reflects inosine still present rather than replicated-through guanosine; and the same chemistry on RNA, with a catalytically dead construct as control, to quantify editing of the cell's own transcriptome by an enzyme whose ancestral substrate is RNA.

• **Because the product is expanded:** replicative reserve measured before release, by the shortest-telomere method of Chapter 15 rather than by mean length, and a clonality assessment that would detect expansion of a pre-existing mutant clone.

• **Because repair decides permanence:** the state panel of Appendix E on the edited population, in particular a cluster-supply proxy, since several enzymes at the repair fork are cluster proteins.

[F] What this costs. Four assays, all established, run once on the product and once on a control arm. Against the cost of the manufacturing run they are negligible; against the cost of a clinical surprise they are trivial.

[F] What each result would mean. If RNA editing is undetectable, the second case of this chapter does not apply to this construct and the program can say so with evidence. If replicative reserve is low, the product's durability is in question before it is infused, which is actionable. If cluster supply is impaired by the procedure, the repair fork was operating under a handicap during editing, which bears on the fidelity of the edit itself.

[F] The general rule the example instantiates. Name the bond the agent makes or breaks, then choose the assay that reports that bond. Everything else in a validation package is inherited convention, and convention is what this chapter argues has been inherited from a modality whose chemistry was simpler.

[VOL p.231] ## CHAPTER 15

The End-Replication Gap and the Loop Through Sulfur

Abstract. Every time a human somatic cell divides it loses fifty to a hundred base pairs from each chromosome end. The quantity that governs what the cell does next is not the mean telomere length but the length of the shortest telomere among the ninety-two ends present, and no sequence record can carry such a quantity: a genome is a string with one symbol per position, and an order statistic over ninety-two distributions is not a property of any position. This chapter follows that gap from the replication fork to the clinic, through a folded structure that manages it, a deamination chemistry that changes it, and a metabolic loop that closes through the mitochondrion.

173. The gap, stated exactly

[E] The end-replication problem is a consequence of the chemistry of DNA polymerases, which extend only in the 5′ to 3′ direction and require a primer. On the lagging strand the final RNA primer lands at some distance from the end, and when it is removed the gap cannot be filled, because there is no upstream 3′ hydroxyl to extend. The position at which that last primer lands is not fixed; it varies across a window, which makes the loss per division a distribution rather than a constant.

[E] Additional processing contributes: the 5′ end is resected to generate the 3′ single-strand overhang required for end protection, so the net loss per division exceeds the strict end-replication deficit. Measured attrition in human somatic cells is in the range of fifty to a hundred base pairs per division.

[F] Two features of this make the quantity awkward for a sequence-based account. It is stochastic per end per division, and it is per-end rather than per-genome: a cell has forty-six chromosomes and therefore ninety-two independent ends, each with its own history.

174. Why the governing variable is an order statistic

[E] The experimental literature is clear that the trigger for replicative senescence is not average length. A single critically short telomere is sufficient to initiate a persistent DNA damage response and drive the cell into senescence, and cells with normal mean length but one uncapped end behave like cells at the end of their replicative lifespan.

[F] The governing variable is therefore the minimum of ninety-two values, each drawn from its [VOL p.232] own distribution, each updated stochastically at every division. That is an order statistic, and order statistics have properties that averages do not: the minimum of many draws falls faster than the mean, its variance behaves differently, and it is sensitive to the tail of the distribution rather than to its center.

[F] The consequence for measurement is severe. Standard clinical telomere measurement reports a mean — by quantitative PCR relative to a single-copy gene,

or by flow cytometry with in situ hybridization — and the mean is not the variable that governs the cell. The methods that report the distribution, single telomere length analysis and its successors, are laborious and are rarely used at scale.

[F] The consequence for the record is categorical. A genome sequence can report the sequence at an end if it can be assembled at all, which for long tandem repeats is difficult. It cannot report the distribution across ninety-two ends in one cell, and it cannot report the minimum, because the minimum is a property of the cell's population of ends rather than of any sequence.

175. The structure that manages the gap

[E] The chromosome end is not a blunt terminus. The 3′ overhang invades the upstream duplex to form a lariat called the t-loop, stabilized by the shelterin complex, and the invading strand displaces the resident strand to create a displacement loop. The arrangement hides the end from the damage-sensing machinery, which would otherwise read it as a double-strand break.

[F] The structure is a managed recombination intermediate. That is the point of interest: the cell solves an end-protection problem by deliberately creating the structure that recombination machinery acts on, and then controls that machinery rather than excluding it.

[E] The characteristic failure mode follows from the structure. If the junction is resolved rather than unwound, the loop is excised as a circle and the end loses its length in one step rather than gradually. The resolvase activity involved has been identified, and the circular products — t-circles — are detectable and are elevated in several settings, including cells using the recombination-based telomere maintenance pathway.

[F] A deletion of that kind leaves no mutation. The remaining sequence is unchanged, the chromosome is intact, and the only trace is that the end is shorter and a circle is present in the cell. Nothing in a sequence record distinguishes a cell that lost two kilobases by gradual attrition from one that lost it in a single resolution event, and the two have different consequences for how many divisions remain.

[VOL p.233]

176. Length as a regulator with no locus

[E] Telomere length also acts in trans on transcription. Expression of genes up to megabases inland from the end varies with telomere length, an effect described as telomere position effect over long distances, and it operates through looping contacts rather than through any cis element at the regulated gene.

[F] This gives a regulatory input with no locus. A geneticist asking which sequence controls such a gene will not find one, because the controlling variable is the length of a repeat array several megabases away and the mechanism is three-dimensional. A sequence record contains the repeat array and the gene, and contains nothing about the relationship between them.

177. The gap, stated exactly

[E] The lagging strand is synthesized discontinuously in Okazaki fragments, each initiated by a short RNA primer laid down by polymerase alpha-primase. At an internal origin this costs nothing, because an upstream fragment supplies the 3’-hydroxyl from which the gap is filled. At a chromosome end there is no upstream fragment. The textbook account stops there, and the textbook account is incomplete in a way that matters.

[E] The specific finding is that the final primer on the lagging daughter strand is not placed at the terminus. It is positioned randomly, roughly seventy to a hundred nucleotides inward from the end, and it is not removed promptly - it persists for over an hour. When it is removed, the tract beyond it cannot be filled. Human telomeres shorten by on the order of fifty to a hundred base pairs per division as a consequence.

[F] Three properties of that statement are usually lost in the retelling and each is load-bearing for what follows. The loss is stochastic: the primer lands somewhere in a thirty-nucleotide window, so the amount spent is drawn from a distribution rather than subtracted as a constant, and the forty-six chromosome ends of one nucleus diverge from one another as divisions accumulate. The loss is asymmetric: the leading and lagging daughters of the same replication fork do not end in the same place, so the two daughter cells do not inherit the same telomere. And the loss is not a defect evolution failed to repair. The position of that primer is a conserved property of the replication machinery, and the apparatus built around it - shelterin, the t-loop, telomerase and its restriction to particular lineages - is expensive and elaborate. The gap is managed, not tolerated.

[VOL p.234] ## 178. The governing variable is an order statistic

[E] The quantity that determines whether a cell continues to divide is not the average telomere length. It is the shortest telomere. The result is explicit in the literature: the shortest telomere, and not average telomere length, is critical for cell viability and chromosome stability, and a single critically short end is sufficient to initiate a damage response and senescence while every other end in the nucleus remains comfortable.

[F] State that in the language it deserves. A diploid human nucleus has ninety-two chromosome ends. Each carries a telomere of its own length. At every division each of those lengths is decremented by an independent draw from the distribution in Section 177. The variable that governs the cell’s fate is the minimum of that set - an order statistic over ninety-two correlated random variables, recomputed every cell cycle.

[F] That is a precise statement and it has a consequence nobody acts on. Essentially every telomere measurement in clinical and epidemiological use reports a mean: quantitative PCR ratios give an average across all ends and all cells in the sample; terminal restriction fragment analysis gives a mean distribution; even flow-FISH

reports per-cell averages. The field measures the mean of a distribution whose minimum is the biologically governing term. Two populations with identical mean telomere length and different variance have different numbers of cells standing at the edge, and the mean cannot distinguish them.

179. A dimension the record does not carry

[F] Here is the structural claim this chapter is built on. A genome, as the instrument records it, is a string: an ordered sequence of positions, one symbol per position, drawn from an alphabet of four. Every operation performed on that record - alignment, variant calling, annotation, editing design, off-target prediction - assumes that representation.

[F] Telomere state is none of those things. It is a quantity, not a symbol. It differs between the ends of a single nucleus. It differs between two cells of the same clone with the same genotype. It changes at every division, stochastically. And the term that governs is a minimum over that set. There is no field in the notation where any of this could be written. Ask a sequence record how much telomere a cell has left and the question is not unanswered - it is ungrammatical.

[E] The practical position confirms the formal one. Telomeric tracts are tandem arrays of a six-base repeat, which short-read assembly cannot span. The ends of human chromosomes were absent or placeholder sequence in the reference assembly until the telomere-to-telomere effort, and what that effort delivered was one consensus length per arm for one genome - not a distribution across a patient’s cells. Measuring the quantity at all requires an orthogonal [VOL p.235] assay: terminal restriction fragment Southern blotting, quantitative PCR ratios, flow-FISH, single telomere length analysis, or long-read sequencing designed for the purpose.

[F] None of those is part of any release package for any gene-editing, epigenetic-editing or cell-therapy product. The verification instrument is a sequencer, and the variable is not a sequence.

180. The t-loop is a managed recombination intermediate

[E] The single-stranded guanine-rich 3’ overhang left by the end-replication problem does not sit exposed. It folds back along the chromosome and strand-invades the upstream double-stranded telomeric tract; the displaced strand at the point of invasion forms the displacement loop. The resulting lariat is the t-loop. The six-protein shelterin complex, with TRF2 and POT1 central to it, stabilizes the arrangement and conceals the chromosome terminus from the double-strand-break sensors, preventing both ATM activation and non-homologous end joining between chromosome ends.

[F] Notice what kind of object that is. It is not a sequence feature; the sequence is a monotonous repeat and is the same whether the loop is folded or open. It is a conformation, held by protein occupancy, with a measurable equilibrium. Everything the cell knows about the state of its chromosome end it knows from that

conformation and that occupancy, both of which are continuous variables and neither of which has a symbol.

[F] The chromosome end is therefore the clearest case in the nucleus of information that is physical rather than written. A damage sensor does not read a sequence to decide whether this end is a chromosome terminus or a broken piece of DNA. It is prevented from asking, by a fold.

181. Resolution: a deletion with no mutation

[E] That fold has a geometric liability. A strand-invaded lariat is structurally a recombination intermediate - it resembles a Holliday junction - and the cell's own homologous recombination machinery can act on it. When TRF2 function is lost or compromised, resolution occurs: the junction-resolving activity, XRCC3 among the implicated factors, cuts the loop, and the entire circled tract departs as a closed telomeric circle, a t-circle. The remaining telomere is abruptly and catastrophically short, and senescence or a persistent damage response follows. In tumors using alternative lengthening of telomeres, t-circles are abundant and serve as rolling-circle templates for telomere extension.

[F] Read that as an off-target class and it is unlike anything in the standard taxonomy. A t-loop deletion removes kilobases of DNA from a chromosome end, in a single stochastic [VOL p.236] event, with no base substitution, no insertion, no deletion at any locus, and no change to any gene. Sequence a treated cell afterward and align the reads, and every position matches the reference. The event consists entirely in a change to how much of a repeat tract is present, and alignment to a consensus is precisely the operation that discards that information.

[F] It is also an event that therapeutic manipulation plausibly provokes, because the loop is held by protein occupancy and opened by recombination enzymes, and nuclease editing, transient effector expression, interferon response and the replication stress of ex vivo expansion all engage that machinery. Whether current editing protocols raise t-circle abundance is a one-assay question that the published record does not appear to answer.

182. Length as a trans-acting regulator with no locus

[E] Telomere length does not govern only the end. Through telomere position effect over long distances, a long telomere loops inward and represses the transcription of genes situated far from the chromosome terminus - reported examples run from under one megabase to roughly ten - and that repression is relieved as the telomere shortens. The change in expression occurs with no change in the sequence or the genotype of the affected gene.

[F] The regulatory logic has no counterpart anywhere in what the code describes. A transcription factor acts through a sequence it binds; a silencer acts through a site. A telomere acts through its length - the same sequence, more or less of it, reaching further or less far along the chromosome. The regulator is a dimension. There is no

binding site to locate, no motif to score, no variant to call, and nothing a genome-wide association study is shaped to detect, because the explanatory variable is not genotype at a locus. It is how many copies of a six-base repeat lie between the gene and the end.

[F] The consequence for expression analysis is specific and uncomfortable. Two cells with identical genomes, identical methylomes and different replicative histories will differ in expression at subtelomeric and near-subtelomeric genes, and nothing in the standard package explains the difference. It will be scored as batch effect, as noise, or as an effect of whatever intervention happened in between.

183. Deamination converts the lettered purines into the unlettered ones

[E] Hydrolytic and oxidative deamination of the DNA bases is continuous and unavoidable.

Adenine deaminates to hypoxanthine. Guanine deaminates to xanthine. Cytosine deaminates to uracil, and 5-methylcytosine to thymine. The cell maintains dedicated machinery against each: the alkyladenine glycosylase excises hypoxanthine, endonuclease V incises at [VOL p.237] both hypoxanthine and xanthine in DNA, the inosine triphosphate pyrophosphatase sanitizes the nucleotide pool before incorporation, and the uracil glycosylases handle the pyrimidine side.

[F] Now place that chemistry where this chapter is standing. The human telomere is a tandem repeat of TTAGGG. Per repeat unit it carries three guanines and one adenine - the two purines that deaminate to the two purines the genetic code does not letter. It is simultaneously the most guanine-rich tract in the nucleus and among the most oxidation-exposed, since guanine has the lowest oxidation potential of the four bases and runs of guanines lower it further, which is why 8-oxoguanine concentrates at telomeres.

[F] So the chromosome end is the region of the genome where lettered purines are most densely packed, most chemically vulnerable, and convert on damage into exactly the unlettered species. Of the eight purine and pyrimidine bases the cell manufactures and handles, the code letters five. Two of the three it omits - hypoxanthine and xanthine - are generated at this locus by ordinary oxidative chemistry, in a tract whose function depends on base identity more acutely than anywhere else in the genome. That is the subject of the next section.

184. One inosine changes the fold

[E] The guanine-rich telomeric strand folds into G-quadruplexes: stacked quartets of four guanines, each quartet closed by eight Hoogsteen hydrogen bonds, with a monovalent cation - potassium in the cell - coordinated between the stacked planes. Each guanine donates from its N1 imino and its N2 amino group and accepts at its O6 carbonyl and its N7. The N2 amino group is the distinguishing feature: it is what guanine has and hypoxanthine does not.

[E] The substitution has been done and measured on the human telomeric sequence. Replacing a guanine with inosine inside a quartet removes one hydrogen bond per substitution. On the (GGG)4 human telomeric repeat, the native melting temperature is about 50 degrees in sodium and about 61 degrees in potassium. A single central substitution, (GIG)4, drops the potassium melting temperature to about 53.5 degrees - roughly eight degrees - and a double substitution, (IGI)4, to about 46 degrees, roughly fifteen. Terminal substitutions give melting curves that are no longer cleanly sigmoidal. With three inosines the structure does not fold detectably at all.

[E] The fold itself changes, not only its stability. The native sequence is antiparallel in sodium and hybrid in potassium. The centrally substituted species are parallel. A single unlettered base at the right position does not merely weaken the quadruplex; it converts it into a different topological object.

[VOL p.238] **[F]** This is, as far as this chapter is concerned, the sharpest available demonstration of what an incomplete alphabet costs. Topology at a telomeric quadruplex is not decorative. POT1 and the shelterin proteins act on specific conformations; RTEL1's documented function is to counteract telomeric quadruplex-DNA so that the replication fork can pass; quadruplex-stabilizing ligands are an active oncology chemotype precisely because the fold is functionally consequential. A hybrid quadruplex and a parallel quadruplex present different surfaces to all of them.

[F] And the sequencer reports a guanine. Inosine base-pairs like guanine, so polymerase in-corporates cytosine opposite it and the read carries a G. The molecule that folded into a parallel quadruplex eight degrees less stable than it should be, at the chromosome end whose conformation determines whether the damage sensors fire, is recorded as indistinguishable from the molecule that did not. There is no depth of coverage that resolves it, because the instrument does not interrogate the chemistry at issue.

[O] Whether deoxyinosine actually accumulates in telomeric repeats at functional levels is not established, and this chapter does not assert it. It is stated here as a prediction, in Section 192, with the assay that would settle it. What is established is the chemistry: that the lesion arises in DNA, that repair pathways exist for it, that those repair pathways include cluster-dependent enzymes under the supply constraint Part IV describes, and that if it is present the structural consequence at this particular locus is large and the sequence consequence is nil.

185. What the record would show

[F] Collect the three failures of Parts I to III into one statement, because they are not variations on a theme - they fail in three different ways. The quantity fails for want of a dimension: there is no field for a length. The t-circle deletion fails for want of a comparison: the bases that remain all match, and the ones that left are not represented as absent. The inosine substitution fails for want of a symbol: the base is present, it is doing something, and it is spelled as a different base.

186. The metabolic output

[E] When telomeres become critically short, the damage response activates p53, and p53 binds and represses the promoters of PGC-1alpha and PGC-1beta, the master transcriptional regulators of mitochondrial biogenesis. Mitochondrial mass and oxidative capacity fall, the cell shifts toward glycolysis, and reactive oxygen species rise.

[F] Take that seriously as a signaling architecture rather than as a pathology. The input is a physical dimension of a chromosome end. The output is a transcriptional program governing [VOL p.239] the organelle population of the cell. No gene's expression level encodes the input; the input is the length itself, read structurally through whether shelterin can still hold the t-loop shut. This is an analog variable sitting upstream of a digital one, and the conversion happens at a fold.

[F] It also runs in the direction opposite to the one the field assumes. The standard hierarchy puts the genome on top and metabolism underneath as its servant. Here the physical state of the DNA sets the metabolic state before any program d transcriptional response occurs, and the next section shows the metabolic state setting the maintenance capacity of the DNA.

187. Cluster assembly is mitochondrial and exclusive

[E] Iron-sulfur cluster assembly in a human cell begins in the mitochondrial matrix and nowhere else. The cysteine desulfurase NFS1, stabilized by ISD11 and by acyl carrier protein, abstracts sulfur from free cysteine and delivers it as a persulfide to the scaffold ISCU; frataxin regulates the rate of that transfer and the iron supply; chaperones hand the nascent cluster to recipient apoproteins; and a separate export step delivers a sulfur-containing intermediate across the inner membrane to the cytosolic assembly machinery. Every cluster protein in the cytosol and every cluster protein in the nucleus depends on that single factory.

[F] A sustained reduction in mitochondrial biogenesis is therefore a sustained reduction in cluster assembly capacity, and the reduction reaches the nucleus. That is the step the telomere literature and the cofactor literature do not generally take together, and it is where this chapter's contribution lies.

188. RTEL1, and the loop that closes

[E] The nuclear cluster clients are concentrated exactly where a replicating cell lives. DNA primase carries a cluster required for initiation. The replicative polymerases delta and epsilon carry clusters in their C-terminal domains. On the repair side, the base excision glycosylases NTHL1 and MUTYH carry them, and so does the iron-sulfur helicase family: XPD of nucleotide excision repair, FANCJ of interstrand crosslink repair, DDX11, and RTEL1.

[E] RTEL1 is the relevant one. Its documented function is to dismantle the t-loop so that the replication fork can traverse the telomere, and to counteract telomeric G-quadruplex DNA. Its catalytic domain is classified in the iron-sulfur helicase family

on family-level homology with XPD, FANCJ and DDX11. Biallelic RTEL1 mutations cause Hoyeraal-Hreidarsson syndrome, the severe end of the telomere biology disorders, and heterozygous variants associate with pulmonary fibrosis and other short-telomere phenotypes.

[VOL p.240] **[F]** The loop closes. Telomere attrition activates p53. p53 represses PGC-1alpha and PGC-1beta.

Mitochondrial biogenesis falls. Cluster assembly and export fall with it. The nuclear cluster clients are under-loaded - among them the polymerases that must replicate the telomere, the glycosylases that must repair the oxidative damage that the same metabolic shift has just increased, and RTEL1, whose specific job is to open the t-loop and clear the quadruplexes so that replication can proceed at all. Telomere replication becomes harder. Unresolved structures accumulate and a destabilized t-loop makes recombinational resolution more likely. Attrition accelerates. The output of the loop is its own input.

[F] Three of the sections of this chapter meet in that paragraph, and they meet through one element. The quadruplex RTEL1 clears is the structure Section 184 shows an unlettered purine reconfigures. The glycosylases that would excise that purine are cluster enzymes on the same supply. The cluster supply is set by the mitochondrial population that telomere attrition has already cut. Every transition in the circuit - promoter occupancy, organelle count, persulfide transfer, cluster occupancy, quadruplex topology, strand-invasion geometry - is chemistry without a letter, and the genome is present and unchanged throughout.

189. Ex vivo editing has a selection problem

[F] Autologous ex vivo cell therapy follows directly from Section 177 into a difficulty nobody measures. Hematopoietic cells are harvested, edited, expanded and returned. Expansion is divisions, and divisions are telomere. The cells that survive the protocol and dominate the returned product are the ones that proliferated most vigorously, which is to say the ones that spent the most reserve.

[F] The release criteria for such a product measure editing efficiency, sequence-level off-target activity, sterility and identity. A product can therefore satisfy every criterion while being enriched for precisely the cells with the least replicative capacity remaining - which is the property that long-term engraftment and durability depend on, and the one property no sequence assay reports. The measurement that would close this gap is a terminal restriction fragment blot on material that is already being banked.

190. Alternative lengthening is the second exit

[E] A tumor that has exhausted its telomere reserve and survived has done so by one of two routes: reactivation of telomerase, which accounts for the large majority, or alternative lengthening of telomeres, which accounts for roughly ten to fifteen percent of tumors and is enriched in particular lineages. Alternative lengthening

runs on homologous recombination and break-induced replication, and uses t-circles among its templates.

[VOL p.241] **[F]** That is a two-route escape structure, and it has a specific therapeutic implication that the telomerase inhibitor programs have learned slowly. Inhibiting telomerase does not close the exit; it applies selection pressure favoring cells already using the other one, and the other one is built from the machinery of Section 181. The two routes are not independent, either: both are downstream of the same geometry, and the recombination activity that resolves a t-loop into a t-circle is the same activity alternative lengthening exploits.

[F] The attraction of attacking this layer is that there are two routes rather than the twenty-odd available at a signaling node. The difficulty is that neither route is a protein the tumor uniquely has, so any agent that reaches them buys its therapeutic window by flux differential rather than by molecular recognition - the harder of the two currencies, and the one the proliferating cell's own demand profile partly supplies.

191. Post-mitotic tissue, stated correctly

[F] The neurodegeneration argument is often made carelessly and the careless version does not survive scrutiny, so it is worth stating the defensible one. A post-mitotic motor neuron does not divide and therefore does not spend telomere by the mechanism of Section 177. Any claim that end-replication attrition directly drives its degeneration is wrong on its face.

[F] The defensible claim has three parts. First, the neuron inherited its telomere state from proliferating progenitors, so its starting position is a property of lineage history rather than of its own biography, and that history differs between individuals by more than most measured covariates. Second, the glia surrounding it do divide, throughout life, and the non-cell-autonomous contribution of glial senescence to motor neuron loss is an active and credible line of work. Third, and most importantly, in a cell that is not dividing, telomere dysfunction is a problem of deprotection rather than of length: loss of shelterin occupancy exposes the end, the damage response fires, and the p53 arm of Section 186 runs - cutting mitochondrial biogenesis in the cell type with the least glycolytic reserve and the highest oxidative demand in the body.

[F] An antisense oligonucleotide delivered into that neuron corrects a transcript in an energetic environment that was reorganized before the drug arrived, by a mechanism that has no sequence signature and is not measured in any trial.

192. Seven predictions

[O] Prediction 1. Cluster-assembly capacity is rate-limiting for telomere maintenance. In cells with induced telomere dysfunction, the holo-to-apo ratio of a reporter cluster enzyme should fall before the attrition rate rises, and restoring mitochondrial biogenesis should slow attrition [VOL p.242] independently of telomerase

activity. Falsified if attrition rate is indifferent to cluster capacity across a tolerated range.

[O] Prediction 2. The loop runs in reverse. Cells with a primary defect in cluster assembly rather than in telomere maintenance - frataxin-deficient Friedreich's ataxia fibroblasts are the obvious and available material - should show accelerated attrition per division and elevated t-circle abundance against matched controls, with no mutation in any shelterin or telomerase component. Falsified if both match controls.

[O] Prediction 3. Deoxyinosine accumulates in telomeric repeats, and more so in senescent and in alternative-lengthening cells than in early-passage controls. Falsified if telomeric hypoxanthine content is at background and invariant across those states.

[O] Prediction 4. Telomeric inosine content tracks quadruplex topology. The published substitution series predicts a shift toward parallel folds and reduced thermal stability as inosine content rises; the prediction here is that the same relationship holds in telomeric DNA isolated from cells rather than in synthetic oligonucleotides alone. Falsified if isolated telomeric DNA shows no conformational shift at measured inosine burdens.

[O] Prediction 5. Editing protocols spend telomere and raise t-circle abundance. In a cell product carried through standard ex vivo expansion and editing, mean telomere length should fall measurably and t-circles should rise relative to the unmanipulated apheresis product. Falsified if both are unchanged.

[O] Prediction 6. Cluster-dependent glycosylase loading predicts telomeric lesion burden. The holo fraction of a reporter cluster glycosylase should anticorrelate with 8-oxoguanine and hypoxanthine burden in telomeric restriction fragments. Falsified if lesion burden is independent of glycosylase metalation.

[O] Prediction 7. The minimum predicts where the mean does not. In banked samples with known clinical outcomes, the shortest-telomere statistic should outperform mean telomere length as a predictor, and two cohorts matched on mean should separate on variance. Falsified if the minimum adds nothing to the mean in a properly powered reanalysis.

193. What each one costs

[F] The predictions above were chosen under a constraint, and the constraint is worth naming because it is unusual in a paper of this scope. None of them requires a new chemical entity, a new instrument, an animal facility, or a sequencing budget. Each is listed below with the apparatus that settles it.

[VOL p.243]

no.	what it tests	what it takes

1	Cluster capacity is rate-limiting for telomere maintenance. Mitochondrial aconitase activity normalized to protein, plus a telomere restriction fragment Southern blot across passages.	A spectrophotometer and a gel.
2	The loop runs in reverse. Frataxin-deficient Friedreich's ataxia fibroblasts against matched controls: attrition rate per passage and t-circle abundance.	Two existing cell lines, a Southern blot and a two-dimensional gel.
3	Deoxyinosine accumulates in telomeric repeats. Endonuclease V cleavage of telomeric restriction fragments, or mass spectrometry of hydrolyzed telomeric DNA, comparing early-passage, senescent and ALT lines.	A restriction digest, a commercial enzyme and a gel, or one mass spectrometry run.
4	Inosine content tracks quadruplex fold in situ. Circular dichroism and UV melting on synthetic telomeric oligonucleotides carrying defined inosine positions, read against the published substitution series.	Synthetic oligonucleotides and a CD spectrometer.
5	Editing protocols spend telomere and raise t-circles. Telomere length and t-circle abundance in a cell product before and after the standard ex vivo expansion and editing protocol.	Samples that are already being taken, and the two assays above.
6	Glycosylase loading predicts telomeric lesion burden. Holo-to-apo ratio of a reporter cluster glycosylase against 8-oxoguanine and hypoxanthine burden in telomeric restriction fragments.	An activity assay and a lesion-specific cleavage assay.
7	Shortest-telomere distribution, not mean, predicts outcome. Single telomere length analysis or long-read telomere sequencing on banked samples with known clinical outcomes, scoring the minimum rather than the mean.	A reanalysis of material that has already been collected.
Table 1. The seven tests and the apparatus each requires.		

[F] Two of the seven are reanalyzes of data and material that have already been collected and paid for. Three more are a Southern blot and a two-dimensional gel on cell lines that are commercially available. The expensive thing about this argument is

not the experiments. It [VOL p.244] is that the variable in question does not appear in the notation the field uses to decide what to measure, so it has not been measured, and a question nobody poses stays open regardless of what it would cost to close it.

[F] That is the general form of the problem and it is the reason for writing the paper rather than simply running one of the assays. Instruments follow notation. A field that records its object as a string will build assays that read strings, will define its release criteria over strings, and will interpret everything that does not reduce to a string as noise. The end-replication gap has been known since the early 1970s and the structures that manage it have been understood for two decades. What has not been done is to treat the quantity it governs as a variable in its own right, equal in standing to sequence, with its own assays and its own place on a release certificate.

Status. Sections 177 through 6 and 10 through 12 rest on established findings in the end-replication, telomere structure, position-effect and cofactor literatures, each checkable against its primary source; the iron-sulfur assignment for RTEL1 is stated at the family level, which is where the published classification stands. The quadruplex substitution data in Section 184 are published measurements on the human telomeric sequence. The loop assembled in Section 188, the deamination argument in Section 183 and the dimensional argument in Section 179 are the contribution of this chapter, built from steps that are individually established and are not usually set in series. Section 184 states explicitly that telomeric deoxyinosine accumulation is predicted rather than demonstrated, and Section 192 gives the assay that would settle it. The seven predictions are written so that a negative result falsifies a specific claim made here rather than the paper in general. Distribution is restricted. Licensed under CC BY-NC-ND 4.0.

194. The unlettered bases at the chromosome end

[F] Two chemistries meet at a telomere, and their meeting is the reason this chapter sits in this volume rather than in a review of aging.

[E] The first is deamination. Adenine deaminates to hypoxanthine and guanine to xanthine, both spontaneously and enzymatically, and both products are unlettered bases. The human telomeric repeat is guanine-rich — TTAGGG — which means the end of every chromosome is an array of the base whose deamination product has no letter, held in a structure whose stability depends on guanine-specific chemistry.

[F] The structural consequence is not subtle. Replacing one guanine with hypoxanthine in a G-quadruplex or in the invading strand of a t-loop removes a hydrogen-bond donor and changes the fold, and a fold that does not form is an end that is not protected. The base change is one atom; the outcome is an exposed chromosome end.

[F] The record consequence follows the rule of Chapter 8: hypoxanthine reads as guanine, so the damaged end and the intact end report the same sequence. A study comparing telomeric sequence between young and old cells will find no difference attributable to this chemistry even if the chemistry is doing the damage.

195. The loop through sulfur

[F] The second chemistry closes a loop back through the mitochondrion, and it runs in four steps, each established separately in the literature.

1. Telomere attrition activates the damage response and stabilizes p53.

2. p53 represses PGC-1alpha and PGC-1beta, the master coactivators of mitochondrial biogenesis, which reduces mitochondrial mass and oxidative capacity.

3. Iron-sulfur cluster assembly is mitochondrial and exclusive: the initial cluster is built on a scaffold in the matrix, using sulfur from the cysteine desulfurase of Chapter 7, and exported for cytosolic use. A cell with fewer and poorer mitochondria assembles fewer clusters.

4. Several enzymes of genome maintenance are cluster proteins, including the helicase family that contains RTEL1 — the helicase that dismantles the t-loop in an orderly way at each replication.

[VOL p.246] **[F]** The loop therefore closes: short telomeres reduce mitochondrial capacity, reduced capacity reduces cluster supply, reduced cluster supply impairs the very helicase that protects the ends from catastrophic loop resolution, and impaired protection shortens telomeres further. Each link is published. The loop as a loop is the claim made here, and its signature is that intervention at any single step should be insufficient.

[O] The quantitative question is open and is the one that matters: what is the gain around that loop? If it is well below one, the loop is a modifier of aging; if it approaches one, it is a driver. Measuring it requires simultaneous assays of shortest-telomere distribution, mitochondrial mass and cluster occupancy in the same cells across passages, which is laborious but entirely feasible with existing methods.

196. What arrives at the clinic

[F] Three consequences reach practice directly.

• **Ex vivo editing has a selection problem.** Manufacturing an autologous cell product requires expansion, and expansion spends divisions. The cells that expand best are not a random sample: they are the ones with the most telomere reserve and, in a population with clonal hematopoiesis, sometimes the ones with a survival advantage conferred by a mutation nobody selected for. The product's replicative reserve is a quantity the release criteria do not report.

• **Alternative lengthening is a second exit.** A fraction of tumors maintain telomeres by recombination rather than by telomerase, with characteristic markers including abundant circles and heterogeneous length distributions. A telomerase-directed therapy does not touch them, and the mechanism of escape is structural rather than mutational.

• **Post-mitotic tissue is not exempt.** Neurons and cardiomyocytes do not divide, so attrition is minimal, but the sulfur and cluster arm of the loop runs in them anyway, because it depends on mitochondrial capacity rather than on division. The prediction is that the two arms separate cleanly by tissue type, which is testable.

197. Tests, and what they cost

[F] Seven measurements would settle most of what this chapter leaves open. All use published methods.

• Shortest-telomere distribution, not mean, in any study that currently reports mean.

• T-circle abundance as a readout of loop resolution, in parallel with length.

• Inosine content of telomeric DNA by inosine-specific chemistry, young versus old cells.

• Cluster occupancy of RTEL1 and its family members as a function of mitochondrial mass.

[VOL p.247] • Mitochondrial mass and PGC-1 expression across a telomere-length panel in primary cells.

• Replicative reserve of manufactured cell products, measured before release.

• The same panel in post-mitotic tissue, where the division arm of the loop is absent.

[F] The costs are in the range of ordinary laboratory work rather than of a trial, and three of the seven could be run on existing banked material.

[O] The chapter's largest open question is whether the unlettered-base chemistry at the end is quantitatively significant in vivo or is a laboratory-scale effect. Nobody has measured hypoxanthine content in telomeric DNA as a function of age in human tissue. The method exists. Until that measurement is made, the mechanism stands as a plausible and unquantified contributor, and it is marked open throughout this volume for that reason.

198. Notes to Chapter 15: the end, measured

Quantities worth carrying

[E] Telomere length. Human telomeres are roughly 10 to 15 kilobases at birth in somatic tissue, falling to a few kilobases in aged tissue, with wide variation between individuals, tissues and chromosome arms.

[E] Attrition per division. Fifty to a hundred base pairs per end per division in cultured somatic cells, with the exact value depending on cell type, oxidative conditions and the measurement method.

[E] Ends per cell. Forty-six chromosomes, ninety-two ends, each with an independent history.

The governing variable is the minimum over ninety-two, not the mean.

[E] Overhang length. The 3′ single-strand overhang is on the order of fifty to three hundred nucleotides, generated by resection and processing after replication, and it is the strand that invades to form the t-loop.

[E] Alternative lengthening. A minority of human cancers — a substantial minority in certain sarcomas and in some central nervous system tumors — maintain telomeres by recombination-based mechanisms rather than by telomerase, with characteristic markers including heterogeneous lengths and abundant extrachromosomal telomeric circles.

Methods box: measuring length and its distribution

[F] Terminal restriction fragment analysis. Digest with frequent-cutting enzymes that leave the repeat array intact, separate by gel, hybridize to a telomeric probe. It reports a length distribution for the whole population, needs micrograms of DNA, and is the oldest and most interpretable method.

[VOL p.248] **[F] Quantitative PCR.** Amplify the repeat array relative to a single-copy gene; report a ratio. Cheap, scalable, suitable for epidemiology, and reports only a population mean. Almost every clinical and epidemiological association in the literature uses this method, which is why the literature is about means.

[F] Flow cytometry with in situ hybridization. Hybridize a labeled peptide nucleic acid probe in fixed cells and read fluorescence per cell. Gives cell-level distributions in a population, still not per-chromosome values.

[F] Single telomere length analysis. PCR from a chromosome-specific subtelomeric primer into the repeat array, resolving individual molecules. It is the

method that reports the shortest telomere — the variable that governs — and it is laborious, which is why the field's data are dominated by the methods that do not.

[F] T-circles. Two-dimensional gel electrophoresis or rolling-circle amplification detects extrachromosomal circles, which is the readout for loop resolution as opposed to gradual attrition.

Worked example: distinguishing two histories

[F] Two cell populations have the same mean telomere length, 6 kilobases. Population A reached it by uniform gradual attrition; population B reached it with a wider distribution including a small number of very short ends produced by loop resolution events.

[F] By quantitative PCR the two are indistinguishable, and nearly all published work would report them as equivalent. By single telomere length analysis they are clearly different: B has a tail at the short end. By t-circle assay, B shows circles and A does not. By functional readout, B contains cells with a persistent DNA damage focus at an end and should enter senescence sooner.

[F] The prediction is therefore specific and checkable: in a population matched for mean length, the proportion of cells with a telomere-associated damage focus should predict remaining replicative capacity better than the mean does. The experiment uses established methods and has not been performed as a direct comparison, which is the kind of gap this volume exists to point at.

Problems

[O] 15.1 Derive the distribution of the minimum of ninety-two independent draws from a normal distribution, and show how the minimum's expected value shifts as the mean falls. Compare the shift in the minimum with the shift in the mean over ten divisions.

[O] 15.2 Design a clinical telomere assay that reports the shortest end rather than the mean and that is cheap enough for epidemiology. What would have to be sacrificed?

[VOL p.249] **[O] 15.3** The chapter proposes a loop through p53, mitochondrial biogenesis, cluster assembly and RTEL1. Write it as a feedback system, estimate the gain of each link from the published literature, and identify which link is least constrained by data.

[O] 15.4 Hypoxanthine in telomeric DNA has not been measured as a function of age. Design the measurement: tissue source, isolation of telomeric DNA, quantitation method, controls against oxidation during preparation.

[O] 15.5 For an ex vivo edited cell product, propose a release criterion based on replicative reserve. What would be measured, and what threshold would be defensible?

[O] 15.6 Post-mitotic tissue should show the sulfur arm of the loop without the division arm.

Design the comparison between a mitotic and a post-mitotic tissue that would test this, and say what result would falsify the loop.

Connections

[F] This chapter is Part Four's clearest instance of an unrepresentable quantity, and it closes the Part by connecting back to Part Five in advance: the loop runs through cluster assembly, which is the exclusive mitochondrial function of Chapter 20, and through a helicase whose cofactor is the subject of Chapter 19.

Worked example: why the mean is the wrong statistic, in numbers

[F] Model a cell with ninety-two chromosome ends. Give each a starting length drawn from a distribution with mean 10 kilobases and standard deviation 2 kilobases, and let each lose a random amount per division with mean 75 base pairs and standard deviation 25.

[F] What the mean does. It falls linearly, 75 base pairs per division, with very little variance, because averaging ninety-two independent losses suppresses noise. After fifty divisions the mean has fallen by about 3.75 kilobases, to roughly 6.25.

[F] What the minimum does. The minimum of ninety-two draws from the starting distribution is already well below the mean — roughly two and a half standard deviations below for a sample of that size, so about 5 kilobases at the start. It then falls at the same average rate but with much larger variance, and the end that is shortest at the start is likely to remain among the shortest.

[F] The consequence. The cell reaches a critically short end — the trigger for senescence — far earlier than the mean suggests, and the division at which it does so is strongly influenced by the tail of the starting distribution rather than by its center. Two populations with identical means can therefore have replicative capacities differing by many divisions.

[VOL p.250] **[F] The experimental correlate.** This is exactly what is observed: a single critically short telomere is sufficient to initiate senescence, and the number of cells with a telomere-associated damage focus predicts behavior better than any mean.

[F] The measurement consequence. The methods that dominate the literature — quantitative PCR and flow-based hybridization — report means. The method that reports the governing variable is laborious. The resulting literature is therefore a literature about the wrong statistic, and the corrections needed are not in the analysis but in the assay.

[F] One further consequence, specific to this volume. No sequence record of a genome can carry the quantity at all: it is a property of a population of ends in a cell, updated stochastically, and the record has one symbol per position. That is the sense in which this chapter is an instance of Chapter 8's third class rather than of its first two.

[VOL p.251] Review of Part IV

What Part Four established

[E] What is mutated and what kills are different questions. Mutation in cancer is concentrated in a few genes, several of which are network regulators whose activity can be set chemically as well as genetically. The diseases that kill at scale are cardiovascular and oncologic, and both are diseases of flux, supply and age rather than of a single mistyped letter.

[F] The folding problem's residual is an occupancy problem. Sequence-to-backbone is largely solved. What is not solved, and is not solvable from sequence, is which cofactor is loaded, which cysteines are paired and in which register, which metal occupies a site, and what the redox poise of the compartment is. All four are sulfur chemistry, and all four are measurable with established methods that are not run.

[F] Three modalities in patients act or fail through chemistry their validation cannot report.

An acylated peptide's decisive features are uncoded; a deaminase editor produces a base that reads as a different base and runs its ancestral reaction on RNA; a methylation writer's entire mechanism is sequence-neutral, as is its principal off-target liability.

[E] A governing quantity can be outside the record entirely. The variable that decides whether a cell divides again is the shortest telomere among ninety-two ends, an order statistic that no string with one symbol per position can carry. The structure that manages the gap is a folded recombination intermediate whose characteristic failure deletes without mutating, and the loop closes through the mitochondrion by way of cluster supply.

What Part Four did not establish

[O] It did not quantify the aggregate. The central open question of the Part is what fraction of current clinical-stage agents act or fail through chemistry their validation cannot detect. The survey is feasible from public documents and has not been done.

[O] It did not establish the gain of the telomere loop. Each link is published; the loop as a loop is the claim, and whether it is a driver of aging or a modifier depends on a number nobody has measured.

[O] It did not show that any specific approved therapy has failed for the reasons given here. The argument is structural and predictive, and the predictions are stated per chapter with the assay [VOL p.252] that would test each.

The practical rule the Part produces

[F] Match the instrument to the chemistry. Name the bond the agent makes or breaks; if no sequence change is entailed by that bond, sequencing is not a validation method for it. The four-assay panel of Appendix E — pool composition, cluster supply,

inosine-specific chemistry, compartment redox state — converts a sequence-only package into a state-aware one at a cost that is trivial against a trial.

Questions a reader should be able to answer

[O] R4.1 Name four properties of a working protein that two molecules of identical sequence can differ in, and give the assay for each.

[O] R4.2 Why is a candidate-locus methylation panel the wrong sampling frame for a guide-independent liability?

[O] R4.3 Explain why the mean telomere length is the wrong statistic, and what the right one is.

[O] R4.4 A peptide drug's half-life rises from minutes to days. Which part of the molecule is responsible, and what does a sequence-based identity test establish about it?

[O] R4.5 Give two routes by which a tumor can be functionally deficient in a suppressor whose gene is intact.

Where to go next

[F] Part Five goes underneath all four chapters of this Part and gives the chemistry: the atom, its seven operations, the compartments it runs, and the steps at which it has no substitute. A reader who accepts the diagnosis of Part Four and wants the mechanism should read Part Five in order; a reader who wants the clinical payoff immediately can read Chapter 23 and then return.

7. Sulfur in command

[VOL p.253] **Part V**

Sulfur in Command

[VOL p.254] Six chapters on the element that has no letter.

Sulfur is the sixteenth element, the tenth most abundant in the universe, and roughly a quarter of one percent of the human body by mass. By any accounting of bulk it is a minor constituent. By accounting of control it is not minor at all, and the purpose of this Part is to make that second accounting explicit rather than leave it distributed across a hundred separate literatures.

The case is built in six moves. Chapter 16 places the atom on a map: twelve registers at which an account of matter is kept, seven operations that exhaust what the element does at any of them, and thirteen organelles each keyed to a single element by the chemistry it runs. Chapter 17 gives the chemistry proper — eighteen functional groups, the five active classes the standard table omits, the oxidation ladder that organizes them, and selenium as the element placed where the thiol ladder would overshoot. Chapter 18 walks the three pillars of cellular respiration and finds a sulfur switch on each. Chapter 19 goes inside the genetic machinery: the radical that makes every deoxyribonucleotide, the cluster at the wedge of the strand-separating helicases, and the single position where one element runs three chemistries. Chapter 20 follows the supply: where biological sulfur is mobilized, the transsulfuration junction, and the network of conversations the mitochondrion holds with the rest of the cell. Chapter 21 closes the Part by running the chain backward, from an iron-sulfur mineral precipitated out of sulfidic water to the editing enzymes now used in the clinic, and checking that it closes without a gap.

The claim of the Part is not that sulfur is important. It is that sulfur is the control layer, that the control layer is invisible to a four-letter record, and that the two statements are the same statement seen from opposite ends.

[VOL p.255] **CHAPTER 16**

The Atom and the Map

Abstract. An account of matter is kept at twelve distinct scales, from the fundamental interactions that decide whether a bond forms at all to the objects human intention manufactures. Sulfur has an entry at every one of them, and across all twelve it performs only seven distinct operations. This chapter sets out the twelve registers and the seven operations, keys thirteen organelles to single elements by the chemistry each compartment runs, and places the eighteen sulfur functional groups onto that map. The uneven distribution that results is the first substantive result of Part Five.

199. Why count registers

[F] Most arguments about an element's importance are arguments about frequency: how often it appears, in how many molecules, at what concentration. Frequency is a weak measure, because the most frequent elements are structural and the most consequential ones are often scarce. A better measure is span — at how many distinct levels of organization the element has a named role — and span is what the register count measures.

[F] The twelve registers are not disciplines. They are levels at which matter is accounted for differently: the fundamental interactions; the atom and its electron structure; the molecule; the bulk phases; the molecular clouds that predate the solar system; the minerals of a planet; the three kingdoms of life; the raw stock taken from the ground; the molecules a cell assembles; load-bearing tissue; sensing and signaling tissue; and manufactured matter. An element with an entry in all twelve is an element whose account cannot be confined to one literature.

[F] The seven operations are the complementary reduction. Whatever register it is operating in, sulfur is doing one of seven things: carrying electrons reversibly; forming reversible covalent cross-links; holding metals; transferring acyl groups; carrying methyl groups; tuning molecular recognition; or absorbing oxidative damage. The claim implicit in the list is exhaustiveness, and it is a falsifiable claim: a well-documented sulfur function that fits none of the seven would break it.

[VOL p.256]

200. The seven operations, with their canonical instances

[E] Each operation has a canonical instance in human biochemistry, and naming them here fixes

the vocabulary used for the rest of Part Five.		
operation	**canonical carrier**	**what it decides**
carries electrons	thiol-disulfide couples; glutathione and thioredoxin	the redox tone of each
reversibly	systems	compartment
forms reversible	cystine disulfides in secreted and membrane proteins	tertiary structure, and
cross-links		switchable inactivation
holds metals	cysteine thiolate ligation in iron-sulfur clusters, zinc fingers, molybdenum dithiolene	electron transfer, structure, catalysis
transfers acyl	the thiol of coenzyme A; the lipoyl arm	entry to the citric acid cycle
groups		and all acetylation
carries methyl	the sulfonium of S-adenosylmethionine	every methylation mark in the
groups		cell

tunes recognition	2-thiouridine at anticodon position 34	reading frame fidelity at the ribosome
absorbs oxidative	glutathione, thioredoxin, peroxiredoxin cysteines	survival of an oxidative
damage		episode

Table. The seven operations of sulfur, with the carrier that performs each and the decision it controls.

[F] Two properties of the list deserve comment. First, five of the seven are reversible, which is what distinguishes a control element from a structural one: carbon builds, sulfur switches.

Second, no operation on the list is performed by sulfur alone — each requires a protein scaffold — but in each case the atom at the point of action is sulfur, and substituting it changes the operation. Selenium substituted for sulfur changes the kinetics and the reversibility, which is the subject of Chapter 17; oxygen substituted for sulfur in a thioester destroys the energetics that make the acyl transfer work.

201. Thirteen organelles, keyed to elements

[F] A compartment can be keyed to an element by the chemistry it actually runs rather than

by resemblance or convention.
The lysosome runs proton chemistry at pH 4.5 and keys
to hydrogen. The cytoplasm is the carbon framework. The nucleus holds the nitrogenous

[VOL p.257] bases. The mitochondrion terminates its electron chain on oxygen. The plasma membrane is a phospholipid bilayer and keys to phosphorus. The endoplasmic reticulum forms disulfide bonds and keys to sulfur. The ribosome inserts selenocysteine by reading a stop codon as sense, the one place where the code is rewritten in flight, and keys to selenium.

[F] The remaining six compartments are run by metals that carry no color in this volume’s key: manganese at the Golgi, iron at the peroxisome, magnesium in the chloroplast, potassium in the plant vacuole, calcium at the centrosome, zinc in secretory vesicles. The split is itself a result: the nonmetals build the structures and the metals run the specialized jobs inside them.

[E] Each compartment also has a characteristic set of disease genes — lysosomal storage genes at the lysosome, mitochondrial DNA and nuclear-encoded respiratory genes at the mitochondrion, channel genes at the plasma membrane, and so on — and in two cases the disease gene is itself the handler of the compartment’s assigned element: the Golgi’s manganese pump and the secretory granule’s zinc transporter. That agreement is the kind a map should produce if it is tracking chemistry rather than imposing a scheme.

[O] Eleven of the thirteen do not have that confirmation, and the keying there rests on the chemistry argument alone. The experiment that would test it is stated at the end of Chapter 20: perturb the keyed element in one compartment and measure

whether the failure stays local.

202. Twelve registers, seven operations

[E] An account of what matter is doing is kept at twelve distinct scales of organization, from the four fundamental interactions that decide whether a bond forms at all, through the bulk phases, the molecular clouds that predate the sun, the three kingdoms, the raw stock taken from the ground, the molecules a cell assembles, the tissue that bears load, the tissue that senses, the tissue that thinks, what crosses the gut wall, and what human intention manufactures. Sulfur has an entry at every one of the twelve. There is no rung where it is absent and none where it is idle.

[E] Across all twelve it performs only seven operations. It carries electrons reversibly across nine formal oxidation states, from sulfide at minus two to sulfate at plus six, every one of them reachable at the temperature of a body. It makes the only reversible covalent crosslink between side chains in the canonical twenty amino acids. It holds metals, because a soft ligand binds soft metals hard. It stores and transfers acyl groups through the thioester, which gives up its energy where the corresponding oxygen ester holds on. It carries methyl groups as the sulfonium of S-adenosylmethionine. It tunes recognition, most sharply as 2-[VOL p.258]thiouridine at position thirty-four of a transfer RNA anticodon. And it absorbs oxidative damage, as glutathione, as thioredoxin and as the peroxiredoxins.

[F] Seven operations is a small number for twelve scales, and the smallness is the point. It makes the list a structure rather than an inventory, and it is why the mapping attempted later in this chapter — seven operations onto seven points of therapeutic attack — is possible at all. A set of seven operations that covers twelve scales of matter will also cover one signaling pathway, and the interesting question is which operation lands where.

[F] That claim is checkable inside this document rather than only against the world, because the color convention marks every element mention mechanically. Counting the highlighted instances across all fifty-six pages gives Table A. Sulfur is highlighted 601 times, which is 43.5 per cent of every element mention in the paper and 2.74 times the next most frequent element. The six other keyed elements together account for 780. Of the sulfur instances, 584 are chemical terms drawn from 67 distinct words and 14 are the base letter for thymine, which sits on the sulfur row of the key. **element (color) instances share what it is doing in this chapter** sulfur (yellow) 601 43.5% the subject hydrogen (red) 219 15.9% bonding, adenine, the proton gradient nitrogen (green) 155 11.2% the bases, guanine, nitrogenase phosphorus (purple) 153 11.1% the backbone, oxidative phosphorylation carbon (blue) 138 10.0% the skeleton, cytosine oxygen (orange) 77 5.6% terminal acceptor, inosine selenium (indigo) 38 2.8% GPX4, selenocysteine, the ribosome all seven 1381 100% — Table A. Every colored element mention in this chapter, counted mechanically from the typeset-ting. The convention marks an element and nothing

else, so the count is of element mentions, not of word frequency.

[F] Two things in that table are worth saying plainly. Sulfur outnumbers carbon by nearly four to one in a paper about biochemistry, which is not what any textbook's index would show. And oxygen, which the standard account treats as the element that took over the biosphere, is sixth of seven. The count is not an argument on its own — a paper about sulfur will mention [VOL p.259] sulfur — but the convention was fixed before the content was written and marks elements mechanically wherever they occur, including inside tables and inside words the author did not choose for emphasis. What it measures is how often the chemistry could not be described without naming the atom.

203. The eighteen groups, and where the ladder joins

[E] Eighteen functional groups are built on sulfur in the standard chemical-class table. They do not begin until the fourth register. The first three cannot carry one, because a functional group is a bonding arrangement and those registers concern the atom before it has bonded to anything. The ladder therefore has two halves, and they are joined in the cold molecular cloud, where carbonyl sulfide, carbon monosulfide and hydrogen sulfide are the first sulfur functional groups that ever existed — made before there was a planet for them to be made on.

[F] Two of the eighteen, the carbothioic O-acid and the thionoester, have no established biological role. That is printed rather than padded. A table that found a use for all eighteen would be worth less than one that admits two are laboratory species. Five further classes that do real biological work — sulfenic acids, thiosulfinates, persulfides, sulfoniums and polysulfides — are absent from the source table entirely, and one of those absentees, the sulfonium, turns out in §291 to be the one that gates cell growth.

204. Thirteen organelles, each keyed to one element

[F] Each major organelle can be keyed to a single element by the chemistry it actually runs rather than by resemblance. The lysosome is a hydrogen-ion chamber held near pH 4.5.

The cytoplasm is the carbon framework. The nucleus holds the nitrogenous bases. The mitochondrion ends its electron chain at oxygen. The plasma membrane is a phospholipid bilayer. The endoplasmic reticulum forms disulfide bonds, which is sulfur chemistry. The ribosome inserts selenocysteine by reading a stop codon as sense, which is the one place the genetic code is rewritten in flight, and that makes it the selenium organelle.

[F] The remaining six are run by metals outside the key: manganese at the Golgi, iron at the peroxisome, magnesium in the chloroplast, potassium in the plant vacuole, calcium at the centrosome, zinc in secretory vesicles. The division is itself a result. The nonmetals build the structures; the metals run the specialized jobs inside them. Where a metal holds a cluster, the cluster prints as its sulfur, which is the

convention operating as intended rather than an omission.

[VOL p.260] **[E]** Each organelle is anchored to pathology by its disease genes: GBA1, GLA and HEXA at the lysosome; DMD, MYH7 and ANK1 in the cytoskeleton; TP53, BRCA1/2 and LMNA in the nucleus; MT-TL1, MT-ND4 and POLG in the mitochondrion; CFTR, LDLR and KCNQ1 at the plasma membrane; SERPINA1, WFS1 and ATL1 at the endoplasmic reticulum; RPS19, SBDS and RPS14 at the ribosome; ATP2C1, ATP7B and ATP7A at the Golgi; ABCD1, PEX1 and PEX6 at the peroxisome; ASPM, WDR62 and CEP290 at the centrosome; SLC30A8, STXBP1 and UNC13D in secretory vesicles.

[F] Two of those line up with the element key rather than merely sitting beside it. ATP2C1 encodes the manganese pump of the Golgi and SLC30A8 the zinc transporter of the insulin granule. In both the disease gene is the gene that handles the organelle's assigned metal, which is the agreement a map of this kind should produce if it is tracking real chemistry rather than imposing a scheme.

205. The eighteen groups placed on the organelles

[F] Placing all eighteen groups against the organelle map produces an uneven distribution, set out in Table 1, and the unevenness is the first substantive result of this chapter. The groups concentrate at two organelles: the mitochondrion, which holds the thioester economy and the iron-sulfur clusters, and the endoplasmic reticulum, which holds the disulfide. Those are the two compartments where sulfur is doing structural work and energetic work respectively, and between them they account for more than half the biologically active groups in the table.

 # group formula organelle where it works 1 Thiol R–SH Cytoplasm; cysteine, glutathione, coenzyme A; the mitochondrion redox tone of the whole cell; N-acetylcysteine and captopril 2 Sulfide, thioether R–S–R′ Cytoplasm; methionine's backbone; the methyl cycle nucleus that feeds S-adenosylmethionine 3 Disulfide R–S–S–R′ Endoplasmic insulin's three; antibody architecture; reticulum keratin; the PTEN switch of §290 4 Sulfoxide R–S(=O)–R′ Lysosome (drug alliin; omeprazole, activated by acid and target) shutting the gastric proton pump 5 Sulfone R–SO2–R′ Plasma dapsone; MSM; polysulfone dialysis membrane (drug) membranes

[VOL p.261]

# group formula	organelle where it works
6 Sulfinic acid R–SO2H	Mitochondrion; cysteine sulfinic acid; hypotaurine; the cytoplasm hyperoxidized peroxiredoxin that marks the circadian cycle
7 Sulfonic acid R–SO3H	Plasma taurine; bile salts, without which fat is membrane; not absorbed; detergents secretory vesicles
8 Sulfonate ester R–SO3–R′	Nucleus (as ethyl methanesulfonate, the standard damage) laboratory mutagen; busulfan. The one group whose main job is destruction

9 Thiocyanate R–S–C□N	Peroxisome; rhodanese detoxifying cyanide; secretory lactoperoxidase making hypothiocyanite
10 Isothiocyanate R–N=C=S	Cytoplasm sulforaphane modifying the reactive (sensing) cysteines of KEAP1 and releasing NRF2
11 Thioketone R–C(=S)–R′	Nucleus (drug) azathioprine and 6-mercaptopurine; methimazole and propylthiouracil
12 Thial R–C(=S)–H	Plant vacuole the onion’s lachrymatory factor, syn-propanethial S-oxide
13 Thiocarboxylic acid R–C(=O)–SH	Mitochondrion; ThiS-thiocarboxylate into thiamine; cytoplasm MoaD-thiocarboxylate into molybdopterin

15 Thioester R–C(=O)–S–R MITOCHONDRI acetyl-coenzyme A and the whole acyl ′ **ON economy; the GAPDH intermediate of §229; histone acetylation; ubiquitin transfer**

	R–C(=S)–O–R — no established biological role ′
16 Thionoester	
17 Dithiocarboxylic acid	R–CS2H Cytoplasm (drug) dithiocarbamate fungicides; disulfiram; vulcanization accelerators

18 Dithioate ester R–C(=S)–S–R′ — (industrial) RAFT polymerization chain-transfer agents

— Sulfonium (absent from	R3S+ Nucleus; S-adenosylmethionine: every methyl lysosome mark, and
the eighteen)	the SAMTOR gate on mTORC1 in §291
— Dithiolene (absent) —	Mitochondrion; the molybdenum cofactor; sulfite oxidase peroxisome and xanthine dehydrogenase
— Persulfide (absent)	R–S–SH Mitochondrion how a cysteine desulfurase hands its sulfur to an iron-sulfur cluster

[VOL p.262] **Table 1.** The eighteen sulfur functional groups placed on the organelle map, with three biologically active classes the standard table omits. Two of the eighteen have no established biological role and are printed as such.

[F] Three entries in that table carry the rest of the paper. Group 15, the thioester, is the mitochondrion’s entire currency, and §229 through §233 are an account of what it buys. Group 3, the disulfide, is the switch on PTEN, and §290 is an account of what that costs a clinical trial. The sulfonium, which the standard table omits altogether, gates cell growth, and §291 is an account of where it sits on the Akt fan. A group missing from the reference table turning out to hold the growth decision is the kind of result that follows from asking what a thing is made of rather than what it is called.

[F] Group 8 deserves separate notice because it runs against the direction of everything else here. The sulfonate ester is the only one of the eighteen whose principal use is to damage the molecules of life: ethyl methanesulfonate alkylates guanine and produces G:C to A:T transitions, which is precisely the mutation class that §305’s adenine base editor exists to reverse. The same element supplies both the

standard laboratory mutagen and the chemistry of the enzyme family built to undo its signature lesion.

206. What the uneven distribution means

[F] Placing all eighteen functional groups against the thirteen compartments produces a distribution that is strongly uneven, and the unevenness is informative in three ways.

[F] First, two compartments carry most of the biologically active groups: the mitochondrion, which holds the thioester economy and the iron-sulfur clusters, and the endoplasmic reticulum, which holds the disulfide. Those are the two compartments where sulfur is doing energetic work and structural work respectively. Between them they account for more than half the active groups.

[F] Second, several groups appear only as damage or as drug. The sulfonate ester is in the table because of alkylating agents — the standard laboratory mutagen and one clinical conditioning agent — and its principal biological role is destruction. The sulfone appears mainly as drug chemistry. A table that found a physiological role for every group would be less credible than one that admits two of the eighteen have no established biological role at all.

[F] Third, the compartments with the fewest sulfur groups are the ones keyed to metals. That is what the keying predicts: a compartment whose chemistry is run by manganese or calcium should not also be a center of thiol chemistry, and it is not.

[VOL p.263] ## 207. Objections

[F] **Thirteen compartments keyed to elements is numerology.** It would be, if the keying were assigned by counting. It is assigned by naming the chemistry each compartment runs and asking which element performs it, and the assignment is falsifiable in the way stated at the end of Chapter 20. Two independent confirmations exist already in the disease-gene agreement.

[F] **Seven operations is an arbitrary reduction.** The list is offered as exhaustive and is therefore exposed: one well-documented sulfur function outside the seven breaks it. The candidate most often raised is signaling by hydrogen sulfide as a gasotransmitter, which on inspection operates through persulfidation of protein cysteines and therefore falls under reversible covalent modification rather than constituting an eighth operation.

[F] **The twelve registers mix physical scales with human categories.** They do, deliberately.

The last register is manufactured matter, which exists only because people make things, and it is included because the argument of Part Six is about what people manufacture — drugs, edited cells, engineered proteins — and because sulfur’s entry in that register is large.

208. Consequences

[F] The map does three kinds of work in the chapters that follow.

• **It predicts where failures stay local.** A defect in a compartment-specific chemistry should produce a compartment-specific phenotype unless the compartment is a supplier to others. The mitochondrion is the exception that proves the rule: because cluster assembly is exclusive to it, mitochondrial failures are never local. Chapter 20 develops this.

• **It predicts which therapeutic targets are redundant.** Output distributed across many compartments has many routes; output confined to one has one. Chapter 23 reads the Phase 3 record against that prediction.

• **It gives the volume its filing system.** Every later claim about sulfur can be placed by operation and by compartment, which makes the claims comparable with each other rather than a list of interesting facts.

[O] The open question the map raises is historical rather than mechanistic. If each compartment is keyed to an element, and several compartments were acquired by endosymbiosis or elaborated from the endomembrane system, then the keying is a record of the chemistry available when each compartment was established. Testing that would mean comparing the element keying of compartments across lineages that acquired them at different times, which is a comparative genomics project nobody has run and which could falsify the keying in a single afternoon of analysis if the assignments turned out to be lineage-specific.

[VOL p.264]

209. Notes to Chapter 16: the map, used

Quantities worth carrying

[E] Sulfur in the body. Roughly 0.25 percent by mass, about 140 grams in a 70-kilogram adult, most of it in protein as cysteine and methionine, with the remainder in glutathione, sulfated glycosaminoglycans, sulfolipids and inorganic sulfate.

[E] Glutathione. Intracellular concentrations in the range of 1 to 10 millimolar, making it among the most abundant small molecules in the cell; the ratio of reduced to oxidized forms is held high and differs by compartment, with the endoplasmic reticulum far more oxidizing than the cytosol.

[E] Oxidation states. Sulfur accesses states from minus two to plus six in biological chemistry, which is the structural reason it supports a ladder rather than a pair of states.

[E] Organelle counts. A typical human cell contains on the order of hundreds to a few thousand mitochondria depending on cell type, a single nucleus, one or two centrosomes, and variable numbers of lysosomes, peroxisomes and secretory vesicles. The thirteen-compartment keying is a statement about types, not counts.

[E] Contact sites. A substantial fraction of the mitochondrial surface is in close apposition to the endoplasmic reticulum, and the extent of that contact is a regulated

variable with consequences for calcium transfer and for apoptosis.

Methods box: testing a compartment keying

[F] The keying makes a prediction — perturb the keyed element, see a compartment-local failure — and testing it requires three capabilities.

Compartment-targeted perturbation. Chelators, transporters and sensors can be directed to individual compartments by targeting sequences, so the element's availability can be altered in one place. The control that matters is demonstrating that the perturbation is local, by imaging a compartment-targeted sensor for the same element.

Compartment-resolved readout. The failure must be measured where it occurs: lysosomal pH by ratiometric dyes, endoplasmic reticulum oxidation by targeted redox sensors, mitochondrial membrane potential by potentiometric dyes, Golgi function by glycosylation assays.

A propagation test. The prediction distinguishes the mitochondrion from the rest, so the same perturbation must be applied across compartments and propagation measured each time. The expected pattern is local failure everywhere except at the mitochondrion, where cluster export should carry the failure outward.

[VOL p.265] ### Worked example: why the lysosome keys to hydrogen

[F] The lysosome maintains a lumenal pH near 4.5 against a cytosolic pH near 7.2, a difference of nearly three units and therefore a proton concentration ratio of several hundredfold. The gradient is generated by a vacuolar ATPase that pumps protons at the cost of ATP, and essentially every lysosomal hydrolase has an acidic pH optimum, which means the compartment's entire catalytic repertoire depends on the gradient rather than on the enzymes alone.

[F] That is what it means for a compartment to be keyed to an element: the chemistry the compartment performs is the chemistry of that element, and removing the element's handling removes the compartment's function without touching any of its enzymes. Inhibiting the pump with bafilomycin raises lumenal pH and inactivates the hydrolases in place, which is the experiment that demonstrates the keying for this compartment.

[F] The same test applied to the endoplasmic reticulum would mean disrupting its oxidizing environment and showing that disulfide-dependent folding fails while the chaperones remain intact, which has been done. The test applied to the mitochondrion is the propagation experiment above, and it is the one that has not been done systematically.

Problems

[O] 16.1 For each of the thirteen compartments, name the chemistry that justifies its element assignment and the experiment that would test it. Which assignments are hardest to test, and why?

[O] 16.2 The seven operations are claimed to be exhaustive. Search the literature for a sulfur function that fits none of them and either produce one or report the strongest candidate and why it fails.

[O] 16.3 Six compartments are run by metals with no color in the key. Build a parallel key for the metals and ask whether it predicts anything the element key does not.

[O] 16.4 Place the eighteen functional groups on the compartment map yourself from primary sources, then compare with Table 1 of the chapter. Disagreements locate the places where the assignment required judgment.

[O] 16.5 The two compartments carrying the most groups are the mitochondrion and the endoplasmic reticulum. Construct the argument that this reflects research attention rather than chemistry, and then design the analysis that would distinguish the two explanations.

[O] 16.6 Propose a fourteenth compartment — the nuclear envelope, the cilium, a membrane contact site — and determine whether the keying scheme extends to it or breaks.

[VOL p.266] ## Connections

[F] The map is used in Chapter 18 to locate the three pillars, in Chapter 20 to establish the mitochondrion’s exclusivity, and in Chapters 22 and 23 to sort a signaling fan by compartment and to predict redundancy. It is the volume’s third leg in its most compact form.

Worked example: testing the keying on one compartment

[F] The compartment keying is the volume’s most exposed structural claim, and this example specifies the experiment that would test it on the endoplasmic reticulum, which is keyed to sulfur because it performs oxidative folding and disulfide formation.

[F] The perturbation. Reduce the oxidizing capacity of the compartment specifically, by inhibiting the oxidase that supplies oxidizing equivalents to the folding machinery or by targeting a reductant to the lumen. The control that matters is demonstrating locality: a compartment-targeted redox sensor in the endoplasmic reticulum should shift while the cytosolic sensor does not.

[F] The local readout. Disulfide-dependent folding of a reporter substrate, measured by non-reducing gel or by secretion kinetics. The prediction is impairment proportional to the shift.

[F] The propagation readout. Mitochondrial respiration, nuclear repair capacity, lysosomal degradation and glycosylation, each measured with an established assay. The prediction of the keying is that these stay near baseline, because the endoplasmic reticulum is not an exclusive supplier of anything the other compartments require.

[F] The contrast arm. Run the identical design on the mitochondrion: restrict cluster assembly, show locality of the perturbation with a targeted sensor, and measure the same panel of distant readouts. The prediction is the opposite — repair capacity, lipoylation and several cytosolic activities should fall, because cluster assembly is exclusive.

[F] What each outcome means. If both compartments propagate, the keying's prediction is wrong and the mitochondrion is not special. If neither propagates, the exclusivity of cluster assembly is compensated by a route not currently documented, which would itself be an important finding. If only the mitochondrion propagates, the keying survives its sharpest test and the third leg of the volume stands on an experiment rather than on an argument.

[F] Cost. One cell line, two perturbations with their controls, six readouts. A single well-equipped laboratory could complete it in a few months, and it would settle a claim that this volume has had to mark open throughout Part Five.

[VOL p.267] **CHAPTER 17**

Eighteen Groups, the Oxidation Ladder, and the Silent Seventh

Abstract. Eighteen functional groups are built on sulfur in the standard chemical-class table. Two of them have no established biological role, five classes that do substantial biological work are missing from the table entirely, and the real organizing structure is not a list but an oxidation ladder whose lower half is reversible. This chapter gives the chemistry: the groups, the omissions, the ladder, and the position of selenium as the element placed where the thiol ladder would overshoot.

210. Why sulfur supports so many groups

[E] Sulfur sits below oxygen in group 16 and differs from it in four respects that together explain its chemical range. Its valence shell is one principal quantum number further out, so its electrons are more polarizable and its bonds are longer and weaker. Its electronegativity is substantially lower, close to that of carbon, so a carbon-sulfur bond is nearly nonpolar while a carbon-oxygen bond is strongly polarized. It accesses expanded valence states, giving a series of stable oxidation states from minus two to plus six. And its hydride is a far weaker hydrogen-bond donor than water, so thiols behave very differently from alcohols in a protein environment.

[F] Those four differences are the reason the element can hold nine distinct oxidation states in biological chemistry while oxygen holds essentially two. An atom with many accessible states, interconvertible under physiological conditions, is the natural material for a switch.

Carbon, with a single stable oxidation environment in organic matter and strong directional bonds, is the natural material for a framework. The division of labor between the two is not an accident of availability; it follows from the periodic table.

[E] A second consequence is kinetic. Thiolates are excellent nucleophiles at physiological pH because the thiol's acid dissociation constant sits near or below neutrality in many protein environments, where an alcohol would remain protonated. That is why the catalytic residue of so many enzymes is a cysteine: the chemistry is available at the pH the cell runs at.

[VOL p.268] ## 211. The eighteen, in table order

[E] In the order of the standard table the eighteen are: thiol; sulfide, also called thioether; disulfide; sulfoxide; sulfone; sulfinic acid; sulfonic acid; sulfonate ester; thiocyanate; isothiocyanate; thioketone; thial; thiocarboxylic S-acid; carbothioic O-acid; thiolester; thionoester; dithiocarboxylic acid; and dithiocarboxylic ester.

[F] They do not begin until the fourth register of Chapter 16. The first three registers cannot carry a functional group at all, because a functional group is a bonding arrangement and those registers concern the atom before it has bonded to anything. The ladder therefore has two halves — an atomic half and a molecular half — and they are joined in the cold molecular cloud, which is where the first sulfur-bearing molecules formed and the point Chapter 21 returns to.

[F] Two of the eighteen, the carbothioic O-acid and the thionoester, have no established biological role. That is printed rather than padded. A table that found a use for all eighteen would be worth less than one that admits two are laboratory species.

212. What the standard table omits

[E] Five classes that do real biological work are absent from the source table entirely, and each of them is central to current redox biology.

• **Sulfenic acid.** The first and reversible product of cysteine oxidation, and the actual on-and-off state of many redox switches. It is the intermediate that makes thiol signaling possible, and it is unstable enough that detecting it requires trapping reagents.

• **Thiosulfinate.** The reactive species of allium chemistry, allicin being the familiar example, and a potent thiol-modifying agent.

• **Persulfide.** Generated by hydrogen sulfide signaling and by the desulfurase relay, protective against overoxidation, and the chemical form in which sulfur is trafficked to cluster assembly and to wobble thiolation.

• **Sulfonium.** The positively charged tri-coordinate sulfur of S-adenosylmethionine, which is what makes its methyl group transferable, and the species sensed by the mTORC1 regulator discussed in Chapter 22.

• **Polysulfide.** Chains of catenated sulfur, increasingly implicated in signaling and in sulfur storage, and the species that links biological sulfur chemistry to the mineral forms of Chapter 21.

[VOL p.269] **[F]** The omission of those five from a standard table of functional groups is itself a datum about how the element has been treated. A classification built for synthetic organic chemistry records the groups a chemist installs on purpose; it does not record the species a cell makes transiently and uses as a switch.

213. The oxidation ladder

[E] The organizing structure is not the list but the ladder of oxidation states, and the biologically important part of it runs: sulfide and thiol at the reduced end; persulfide and polysulfide; thioether; sulfenic acid; disulfide; sulfinic acid; sulfonic acid; sulfate at the oxidized end, with sulfoxide and sulfone as the oxidized forms of thioether.

[F] The ladder has a property that matters more than its extent: its lower half is reversible and its upper half is not. Thiol to sulfenic acid to disulfide and back is routine cellular chemistry, performed by the thioredoxin and glutathione systems every second. Oxidation past sulfinic acid is, with one notable exception, terminal — the sulfiredoxin-mediated reduction of hyperoxidized peroxiredoxins is the exception, and it is slow and ATP-dependent.

[F] The reversible-irreversible boundary is therefore the cell's redox fuse. Everything below it is signaling; everything above it is damage. A protein whose regulatory cysteine has been driven to sulfonic acid is not switched off, it is destroyed, and the distinction between a switch and a lesion is a single step on the ladder.

214. Selenium, the silent seventh

[E] Selenium is placed in the human proteome at exactly the positions where a cysteine would be driven past the reversible boundary. The selenol of selenocysteine has a lower acid dissociation constant than a thiol, is more nucleophilic at physiological pH, and — critically — its overoxidized forms are more readily reduced back. In the glutathione peroxidases and the thioredoxin reductases, both of which operate at the point of highest peroxide flux, the catalytic residue is selenocysteine rather than cysteine.

[F] The logic is the volume's clearest instance of chemistry dictating biology: the cell needs a catalytic residue at a position where the ordinary residue would be destroyed, so it uses the element one row down, at the cost of a dedicated insertion machinery, a recoded stop codon, and a trace-element dependency that produces deficiency disease when the supply fails. No cell would pay that price for a marginal improvement.

[VOL p.270] ## 215. The eighteen functional groups

[F] They do not begin until the fourth register. The first three registers cannot carry a functional group, because a functional group is a bonding arrangement and those registers concern the atom before it has bonded to anything. The ladder therefore has two halves, and they are joined in the cold molecular cloud, a point returned to in §22.

[F] Two of the eighteen — the carbothioic O-acid and the thionoester — have no established biological role. That is printed rather than padded. A table that found a use for all eighteen would be worth less than one that admits two are laboratory species.

216. What the table omits

[E] Five further classes that do real biological work are absent from the source table entirely: sulfenic acids, thiosulfinates, persulfides, sulfoniums and polysulfides. The sulfenic acid is the first, reversible step when a cysteine is oxidized, and is the actual on-and-off state for many redox switches. The persulfide is generated by hydrogen sulfide signaling and is largely protective. The S-nitrosothiol, nitric oxide attached to a cysteine, switches caspase-3 off and stabilizes Bcl-2.

[E] The iron–sulfur cluster is excluded from the table by definition, being inorganic rather than a functional group, although it sets how sensitive a cell is to ferroptosis.

[F] The single most important sulfur structure in this account is therefore not one of the eighteen.

And of the omitted classes, two are precisely the ones that connect the table to the mitochondrion: the persulfide, which is the sulfur-donor intermediate that cysteine desulfurase generates on its own active-site cysteine before handing sulfur off to build a cluster; and the sulfonium center of S-adenosylmethionine, which a reduced [4Fe-4S] cluster attacks and cleaves homolytically.

[F] The persulfide is how sulfur is delivered. The sulfonium is how sulfur is spent. Delivery and expenditure are both absent from the standard table, because a chemistry table catalogs bonds at rest and has no row for a bond in transit. Formally the persulfide is the disulfide entry with one substituent replaced by hydrogen, which makes it a special case of entry three rather than a nineteenth class.

[F] One further omitted class deserves naming for what follows. The dithiolene — the two-sulfur ligand that holds molybdenum in molybdopterin — is also absent, and it is the one that carries the argument into §27.

[VOL p.271] 217. Which groups do the work

[E] Partitioned against program d cell death, five of the eighteen are central, two play a minor role, three arise only from drugs or diet, and eight do not take part.

• Thiol. The active site of every caspase, the working part of glutathione, and the redox-switch cysteines on Bax and Bcl-2. Cystine taken into the cell becomes cysteine, which is used to make glutathione; without it, ferroptosis follows.

• Sulfide and thioether. Two thioether bonds hold the heme onto cytochrome c, and the thioether sulfur of methionine 80 binds the heme iron. Both are required before cytochrome c can be released, which makes the initiation of apoptosis a thioether-gated event.

• Disulfide. Bax and Bak dimers can be locked together by disulfide bonds. The same group appears in oxidized glutathione, in glutathionylation of proteins, which switches caspases off, in the cystine imported through SLC7A11, and in the MIA40 disulfide relay that operates alongside the TOM40 import channel.

[F] The MIA40 relay is worth separating out: the mitochondrial protein-import machine runs on disulfide chemistry. Organelle communication and sulfur chemistry are not adjacent subjects at that gate; they are the same subject.

[E] Partitioned instead against supply-chain function — intake, storage, working stock, recycling and disposal — six of the eighteen do the bookkeeping, supported by several of the omitted classes.

[F] The two partitions do not coincide, which indicates the form the enumeration should finally take. It is a matrix rather than a list: eighteen rows against the functional domains they serve.

218. The oxidation ladder

[E] The thiol and its oxidation states — sulfenic acid, then disulfide, then sulfinic acid, then sulfonic acid — account for most redox switching in the cell. The thioether and sulfoxide matter principally through cytochrome c, and the thioester through ubiquitin tagging and lipid metabolism.

[F] The first two steps of the ladder are reversible; the sulfinic and sulfonic acids are the overoxidized end. The ladder is therefore a dimmer and not a toggle, with a graded, recoverable response and a defined point of no return, and the whole of physiological signaling happens on its lower rungs. This is the structure in which the eighteen should be presented.

[F] The reversibility is the operative property and it is not confined to biology. A disulfide is the canonical reversible covalent crosslink in proteins, forming and breaking under redox control, [VOL p.272] which is exactly why it can hold a fold and also release it. In materials, the chalcogenides are the canonical reversible structural switch, moving between amorphous and crystalline states under a heat pulse and stable in either. The same functional role — a bond that can be undone on command — appears in silicon and in protein.

[E] A working instance of the switch: xanthine oxidoreductase exists in two forms. The dehydrogenase hands electrons to NAD□; the oxidase hands them to molecular oxygen and produces superoxide and hydrogen peroxide. The conversion sits at a thermodynamic equilibrium, and disulfide bond formation locks the enzyme in the oxidase form. This has been argued to be a function rather than an artifact.

[F] A reversible sulfur switch decides whether an enzyme produces reducing equivalents or produces reactive oxygen. Few single observations make the control argument more concretely.

219. Selenium, and why it is the silent seventh

[E] Selenocysteine resists overoxidation to the sulfinic and sulfonic dead end and can be rescued where cysteine cannot. Thioredoxin reductase is a selenoprotein; it keeps thioredoxin reduced, and reduced thioredoxin holds the pro-apoptotic kinase ASK1 inactive. When selenium runs short, or under oxidative stress, thioredoxin oxidizes and releases ASK1, which drives apoptosis through the JNK and p38 pathways. Selenoprotein P carries selenium in the blood and is taken up through LRP8; some cancer cells depend on that receptor and undergo ferroptosis when it is lost.

[F] Sulfur does the bulk redox work. Selenium is placed at a few high-stakes sites where cysteine would be permanently knocked out. Too little collapses the defenses; too much is poisonous.

Selenium is, in effect, the irreversibility insurance on sulfur's reversible ladder, and that is the mechanistic reason for its position as the quiet seventh beyond the six core atoms rather than a member of them.

[F] One consequence deserves marking. Thioredoxin stands between the supply of DNA precursors and the decision to die. The same protein that regenerates ribonucleotide reductase after each turnover is the one whose oxidation releases ASK1. If thioredoxin is oxidized, deoxynucleotide synthesis stops and apoptosis is released simultaneously.

220. Which groups do the work

[F] Of the eighteen plus the five omitted classes, six carry nearly all of the biology in this volume, and it is worth saying explicitly which they are and what each is load-bearing for. [VOL p.273] **group load-bearing for chapter** thiol / thiolate catalysis, metal ligation, redox sensing, the radical that makes DNA 18, 19, 22 thioester acyl transfer, the one energy-conserving step of glycolysis, all acetylation 18 disulfide tertiary structure, secreted protein architecture, the PTEN switch 13, 22 persulfide sulfur trafficking to clusters and to wobble thiolation 7, 19, 20 sulfonium methyl transfer, and the sensor that gates mTORC1 18, 22 dithiolene holding molybdenum in two enzymes 24 **Table.** The six sulfur groups that carry the argument, and where each is used.

[F] Two observations follow from the table. The first is that the six are distributed across all seven operations of Chapter 16 — no single group performs more than two — so the element's versatility is not the versatility of one group used many ways but of several groups each specialized. The second is that four of the six are unstable or transient species: persulfides, sulfenic acids, thiyl radicals and the sulfonium's activated methyl all have short lifetimes. Transient species are hard to measure, which is part of why this chemistry is underrepresented in large datasets.

221. Objections

[F] The ladder is a textbook device. It is, and the textbooks that use it do not draw the conclusion drawn here: that the reversible-irreversible boundary is the physical location of the distinction between signaling and damage, and that the position of selenium in the proteome is explained by where that boundary falls.

[F] Selenium is better explained by its catalytic efficiency. The two explanations are the same explanation stated at different depths. Selenocysteine is more efficient because its oxidized forms are more easily recovered, which is the same as saying it sits where cysteine would be destroyed.

[F] Listing omitted classes is a complaint about nomenclature. It would be, if the omitted classes were obscure. They are the sulfenic acid, which is the first step of every thiol redox switch; the persulfide, which is how sulfur moves in the cell; and the sulfonium, which is how every methyl group moves. A nomenclature that omits the three species through which the element does most of its regulatory work is a nomenclature that will produce exactly the blind spot this volume is documenting.

[VOL p.274] ## 222. Tests

[F] Three measurements would convert claims in this chapter into numbers.

• **Map the ladder in vivo, by compartment.** Compartment-targeted redox sensors exist for glutathione and for peroxide. What does not exist is a systematic map of where each compartment sits on the ladder in a normal cell and how far it moves under stress. The measurement is a straightforward imaging study.

• **Measure the fuse.** For a defined set of regulatory cysteines, determine the peroxide exposure at which each crosses from reversible to irreversible oxidation. That threshold is the quantity that decides whether a signal becomes a lesion, and it is known for a handful of proteins and unknown for nearly all.

• **Test the selenium placement rule.** If selenocysteine is used where cysteine would be destroyed, then replacing it with cysteine in a selenoenzyme should produce an enzyme that works initially and inactivates under flux. This experiment has been done for individual enzymes; done systematically across the human selenoproteome it would confirm or break the rule.

223. Consequences

[F] The chemistry in this chapter is what licenses the rest of Part Five. Every later claim — that sulfur gates the citric acid cycle, strings the respiratory chain, makes DNA, holds the reading frame, throws the brake on a survival kinase, and holds the metal in two enzymes at opposite ends of metabolism — is an application of one of the six groups above, operating within the ladder's reversible range.

[F] It also fixes the boundary of the volume's claim. Sulfur is a control element because its chemistry is reversible in the physiological range. Where the chemistry is irreversible — the sulfonate ester as alkylating damage, the sulfonic acid as a

terminal oxidation — the element is not controlling anything. The argument is about a specific window of the ladder, and naming the window is what keeps the argument from becoming a claim that one element explains everything.

224. Notes to Chapter 17: the ladder, measured

Quantities worth carrying

[E] Thiol acidity. A free cysteine's thiol has an acid dissociation constant near 8.3, but in protein environments values from below 4 to above 9 occur. The catalytic cysteines of peroxiredoxins [VOL p.275] and of many thiol enzymes sit well below the free-amino-acid value, which is why they are reactive at physiological pH.

[E] Bond energies. The sulfur-sulfur bond is weaker than a carbon-carbon bond and far more readily exchanged, which is what makes disulfide exchange a usable biological reaction rather than a permanent fixation.

[E] Electronegativity. Sulfur at about 2.58 on the Pauling scale sits close to carbon at 2.55 and far from oxygen at 3.44, which is why a carbon-sulfur bond is nearly nonpolar and a thioester is energetically unlike an ester.

[E] Selenium's advantage. The selenol of selenocysteine has an acid dissociation constant near

5.2, so it is ionized at physiological pH, more nucleophilic than a thiol, and its overoxidized forms are more readily reduced.

[E] Peroxiredoxin hyperoxidation. The sulfinic acid form of a peroxiredoxin catalytic cysteine can be reduced by sulfiredoxin at the cost of ATP, slowly, which is the exception that proves the irreversibility of the upper ladder. The cycle of hyperoxidation and recovery has a period that tracks the circadian cycle in several systems.

Methods box: locating a protein on the ladder

[F] Trapping the sulfenic acid. Dimedone and its derivatives react specifically with sulfenic acids and are the standard trapping reagents; the adduct is detected by mass spectrometry or by antibody. Because the species is short-lived, trapping must be done in situ and quickly.

[F] Persulfide detection. Persulfides are distinguished from thiols by differential alkylation protocols that exploit the different reactivity of the extra sulfur, or by tag-switch methods. The field's measurements have been revised more than once as methods improved, so quantitative claims should be read with the method in mind.

[F] Quantifying the redox couple. The glutathione couple's potential depends on both the ratio of reduced to oxidized forms and the absolute concentration, so reporting a ratio alone is insufficient. Genetically encoded sensors report the potential directly and by compartment, which is why they have displaced bulk measurements for this purpose.

[F] Distinguishing switch from damage. The practical test is reversibility: apply an oxidative load, remove it, and ask whether activity returns. A protein that recovers was switched; one that does not was oxidized past the fuse.

[VOL p.276] **Worked example: a redox switch, traced**

[F] Consider a peroxiredoxin under a rising peroxide load. At low flux it cycles: the catalytic cysteine is oxidized to a sulfenic acid, resolves with a second cysteine to a disulfide, and is reduced back by thioredoxin at the cost of NADPH. The enzyme is a catalyst and the sulfur atom is a switch cycling several times per second.

[F] As flux rises, a fraction of the sulfenic acid is oxidized again before it can resolve, giving the sulfinic acid. The enzyme is now inactive as a peroxidase. Two things follow. First, peroxide accumulates locally, because the scavenger has been removed, which allows peroxide to act as a signal rather than being destroyed — the floodgate model. Second, the inactivated enzyme accumulates as a marker of the episode, and it can be recovered only slowly by sulfiredoxin.

[F] The example shows the chapter's claim concretely: the same protein, the same cysteine, the same chemistry, with the position on the ladder deciding whether the system is scavenging, signaling, or damaged. No sequence-level measurement distinguishes the three states, and all three can occur within one minute.

Problems

[O] 17.1 Draw the ladder with midpoint potentials where known and mark the reversible and irreversible segments. Identify the step at which recovery becomes ATP-dependent.

[O] 17.2 For a protein of your choice with a known regulatory cysteine, find or estimate the peroxide exposure at which it crosses from reversible to irreversible oxidation, and compare with physiological peroxide concentrations.

[O] 17.3 Five classes are missing from the standard table. Write the table that would include them, with structures, and say why each was omitted from the synthetic-chemistry version.

[O] 17.4 Selenocysteine is used where cysteine would overshoot. Identify all human selenoproteins and test the rule against them: in how many is the selenocysteine at a position of high oxidative flux?

[O] 17.5 Construct the argument that the ladder is a continuum rather than a set of discrete states, and determine whether any argument in the volume depends on discreteness.

[O] 17.6 Design an experiment to measure, in living cells, the fraction of the proteome that is reversibly oxidized at a given moment, with the controls needed to rule out oxidation during preparation.

[VOL p.277] **Connections**

[F] The ladder licenses the claims of Chapters 18 through 22: the thioester of glycolysis, the cluster ligation of respiration, the thiyl radical of nucleotide reduction, the persulfide relay of cluster assembly, and the disulfide switch at the signaling brake all sit within the reversible window named here.

Worked example: locating one protein's fuse

[F] Take a regulatory protein with a single reactive cysteine and determine where its fuse sits — the peroxide exposure at which the cysteine crosses from reversible oxidation to irreversible. The procedure is four steps and uses standard reagents.

[F] Step one: establish the baseline state. Block free thiols in a lysate prepared under argon with a chelator present, then label reversibly oxidized cysteines after reduction. The ratio gives the resting oxidation fraction. A protein with a resting fraction near zero is either unreactive or well protected; near fifty percent, it is poised as a switch.

[F] Step two: titrate. Expose cells to a graded series of peroxide concentrations, each for a fixed interval, and repeat the measurement. The reversibly oxidized fraction should rise and then plateau.

[F] Step three: find where recovery fails. At each exposure, wash out and allow recovery, then measure again. At low exposures the protein returns to baseline within minutes. At some exposure it does not, and the fraction that fails to recover is the fraction driven past the fuse — to sulfinic or sulfonic acid — which can be confirmed by mass shift.

[F] Step four: relate the fuse to physiology. Compare the exposure at which recovery fails with peroxide concentrations measured in the relevant compartment under physiological stimulation, using a targeted sensor. If the physiological range sits well below the fuse, the protein is a switch under normal conditions and a casualty only under pathology. If the ranges overlap, the protein is a casualty routinely, and its loss is part of normal signaling rather than an accident.

[F] What the result decides. Whether a given oxidation event in a dataset should be read as regulation or as damage — a distinction made constantly in the redox literature and almost always by inference rather than by measurement. The experiment converts a vocabulary choice into a number.

[F] Why it belongs in this chapter. The fuse is the ladder's load-bearing feature. Every claim in Part Five about sulfur as a control element depends on the chemistry staying below it, and the claim is only as good as the measurement of where it sits.

[VOL p.278] **CHAPTER 18**

The Mitochondrion: Three Pillars Strung on Sulfur

Abstract. The three pillars of cellular respiration are glycolysis, the citric acid cycle and oxidative phosphorylation, and each of them has a sulfur switch on it. The one step of glycolysis that conserves energy runs through a thioester on a catalytic

cysteine. Both dehydrogenase complexes that feed and turn the citric acid cycle run on a lipoyl arm and hand their product to coenzyme A. Every electron that moves down the respiratory chain moves through an iron held by cysteine sulfur. This chapter walks the three, then takes the two currencies the mitochondrion exports — acetyl groups and methyl groups — and shows that both are carried on sulfur.

225. Glycolysis: a thioester at the one step that conserves energy

[E] Glycolysis has ten steps and one of them conserves energy as a high-energy intermediate rather than consuming or merely rearranging. Glyceraldehyde-3-phosphate dehydrogenase oxidizes the aldehyde of its substrate and captures the oxidation energy by forming a covalent thioester with an active-site cysteine, then transfers the acyl group to inorganic phosphate to give 1,3-bisphosphoglycerate. The next enzyme hands that phosphate to ADP.

[F] The chemistry is worth stating precisely because the energetics depend on the element. A thioester has a much higher free energy of hydrolysis than an ordinary ester, because the carbon-sulfur bond is long and nearly nonpolar and the resonance stabilization available to an oxygen ester is largely absent. That difference is what makes the intermediate capable of driving a phosphorylation. Replace the cysteine with a serine and the reaction either fails or becomes thermodynamically useless.

[E] The same cysteine is a well-characterized redox sensor. Oxidation of it inactivates the enzyme, which blocks the lower half of glycolysis and redirects carbon into the pentose phosphate pathway, where NADPH is made to deal with the oxidative episode. The switch is reversible and operates on a timescale of seconds.

[F] So the main carbon highway of the cell has a sulfur switch at its one energy-conserving step, and the switch is wired to the cell’s oxidative state. A cell under oxidative stress automatically reroutes its carbon toward reducing power, and the decision is made by the oxidation state of a single sulfur atom.

[VOL p.279] ## 226. The citric acid cycle: lipoate, coenzyme A, and an iron-sulfur valve

[E] Entry to the cycle is through pyruvate dehydrogenase, and the first turn’s rate-limiting oxidative decarboxylation is performed by the 2-oxoglutarate dehydrogenase complex. Both are multi-enzyme assemblies of the same architecture, and both depend on lipoate, a cofactor whose business end is a dithiolane ring — two sulfur atoms on a short chain — attached as an amide to a lysine, forming a swinging arm that carries the reaction intermediate between active sites.

[E] Both complexes hand their product to coenzyme A as a thioester: acetyl-coenzyme A from pyruvate, succinyl-coenzyme A from 2-oxoglutarate. The thiol of coenzyme A is the acceptor in each case, and the thioester is again what makes the product energetically useful.

[E] Within the cycle, aconitase carries a [4Fe-4S] cluster that participates directly in catalysis, coordinating the substrate's hydroxyl through the one iron that lacks a cysteine ligand. The cluster is unusually oxygen-sensitive, and its loss converts the enzyme into an RNA-binding protein that regulates iron homeostasis.

[F] That conversion is a second instance of the volume's recurring pattern: one polypeptide, two functions, the switch between them made by the presence or absence of a sulfur-ligated cluster, with no change in sequence. An assay that reports the gene reports one protein; the cell has two.

227. Oxidative phosphorylation: the chain is strung on iron held by sulfur

[E] The respiratory chain moves electrons from NADH and succinate to oxygen through a series of carriers, and the great majority of the intermediate electron-transfer steps occur at iron-sulfur clusters. Complex I alone carries eight of them in a chain that spans the hydrophilic arm; complex II carries three; complex III carries the Rieske cluster, whose two histidine ligands give it the potential it needs. In every one of them the iron is held by cysteine sulfur, except at the deliberately modified sites where the altered ligation sets a different redox potential.

[F] Stated plainly: every electron that moves in oxidative phosphorylation moves through an iron held by sulfur. The element does not carry the electrons itself; it holds the atom that does, at the potential required, in the position required. That is the third operation of Chapter 16, and the respiratory chain is its largest single application in the cell.

[E] Cluster loss from the chain is both a consequence and a cause of oxidative damage, and the assembly machinery that replaces lost clusters is mitochondrial, which is the subject of [VOL p.280] Chapter 20.

228. The two currencies the mitochondrion exports

[F] Two signals leave the mitochondrion and change what the nucleus does, and both are carried on sulfur.

[E] The first is acetylation. Acetyl-coenzyme A made in the matrix is exported as citrate and reconverted in the cytosol by ATP-citrate lyase, and it is the sole donor for histone acetylation. Histone acetylation state tracks acetyl-coenzyme A availability, which tracks mitochondrial carbon flux. The thiol of coenzyme A is the carrier at every step.

[E] The second is methylation. S-adenosylmethionine is the methyl donor for essentially every methylation in the cell — DNA, histones, RNA caps, small molecules — and its methyl group is held on a positively charged sulfonium center, which is what makes it transferable.

Its supply depends on the methionine cycle, which depends on one-carbon units from folate metabolism, a substantial part of which runs in the mitochondrion.

[F] The consequence is that the epigenome's two principal marks are both written from substrates whose availability is set by mitochondrial metabolism, and both are carried on a sulfur atom. The usual framing has signaling pathways instructing the nucleus; this one has metabolism supplying it. Both are true, and only one of them is visible in a sequence record.

229. Glycolysis: a thioester at the one step that conserves energy

[E] Glycolysis has ten steps and only one of them conserves energy in a chemical bond before the payoff phase. Glyceraldehyde-3-phosphate dehydrogenase oxidizes its substrate and traps the released energy as a high-energy acyl intermediate on its own catalytic cysteine — residue 152 in the human enzyme. The intermediate is a thioester. Phosphate then attacks it to give 1,3-bisphosphoglycerate, and that phosphate is what later becomes ATP.

[F] The single energy-conserving step of the main carbon highway runs through a sulfur atom, and it runs through one that is unusually exposed. That cysteine is among the most oxidation-sensitive residues in the cell. When it is oxidized the enzyme stops, glycolytic flux backs up, and carbon is rerouted into the pentose phosphate pathway — which generates NADPH, which reduces glutathione, which repairs the oxidation. The switch and the repair are the same chemistry.

[F] That matters for the fan mapped in Part III. Akt drives glycolysis through two of its arrows, phosphofructokinase-2 and the GLUT4 vesicle, and both end in balloons labeled glucose [VOL p.281] uptake and glucose import. The pathway Akt accelerates has a sulfur switch at its only energy-conserving step, so the growth signal's effect on metabolism is gated by a redox state the growth signal does not control. A cell with an oxidized GAPDH cysteine does not raise glycolytic flux however hard Akt pushes.

[O] Whether that gate contributes to the clinical pattern in §302 — Akt inhibition slowing growth without lengthening survival — is not established. It is a reason to measure the redox state of the glycolytic enzymes in tumors that progress on a hub inhibitor, and that measurement has not been reported.

230. The citric acid cycle: lipoate, coenzyme A, and an iron-sulfur valve

[E] The cycle is entered through pyruvate dehydrogenase, a complex whose swinging arm is lipoic acid — a dithiolane carrying two sulfur atoms that are reduced and reoxidized on every turn. The arm accepts the acetyl group and hands it to coenzyme A, and the product that enters the cycle, acetyl-coenzyme A, is a thioester. The same architecture repeats inside the cycle at alpha-ketoglutarate dehydrogenase, which also carries lipoate and also delivers a thioester, succinyl-coenzyme A.

[E] The cycle's classic regulated step is aconitase, which carries a 4Fe-4S cluster in which one iron is not held by a cysteine and is therefore exposed. Oxidation converts

the cluster from 4Fe-4S to 3Fe-4S, the enzyme stops, and in the cytosolic form the same protein becomes iron regulatory protein 1 and switches from metabolism to iron-responsive translation control. Succinate dehydrogenase, which is simultaneously a cycle enzyme and Complex II of the respiratory chain, carries three further iron-sulfur clusters.

[F] Both entry points to the cycle run on lipoate and deliver thioesters, and the cycle's regulated valve is an iron-sulfur cluster that doubles as a sensor. Three of the seven operations — acyl transfer, metal holding, reversible electron carriage — are therefore all discharged inside one metabolic cycle, by the same element, in three different arrangements. That is the densest concentration of sulfur operations anywhere in the cell, and it is why the mitochondrion is the organelle this chapter treats as the center of the chemistry even though the key assigns it to oxygen.

[F] The assignment is not in conflict. Oxygen is where the mitochondrion's electrons end; sulfur is what carries them there and what holds the carbon in the meantime. An element key naming the terminal acceptor and a chemistry running the transfer are two different accounts of one organelle, and both are correct.

[VOL p.282] 231. Oxidative phosphorylation: the chain is strung on iron held by sulfur

[E] Complex I carries eight iron-sulfur clusters and is the longest electron-transfer wire in biology. Complex II carries three. Complex III carries the Rieske 2Fe-2S center, whose unusually high potential is what makes the Q cycle work. Every one of those clusters is held to its protein by cysteine thiolates, except the Rieske, which is held by two cysteines and two histidines — and that substitution is precisely what tunes its potential.

[F] Essentially every electron that moves in respiration moves through an iron held by a sulfur.

The chain's terminus is oxygen and its currency is a phosphate gradient, but its conduction is a sulfur phenomenon from end to end. Stated against the register ladder: the operation called holding metals is not one of sulfur's seven jobs among others here — at the inner membrane it is the job, repeated a dozen times in series.

[E] The dependency runs one layer deeper. Those clusters are not spontaneous. They are assembled by the ISC machinery, in which a cysteine desulfurase abstracts sulfur from free cysteine, carries it as a persulfide on its own active-site cysteine, and hands it to a scaffold protein. The persulfide — one of the classes the standard eighteen-group table omits — is the delivery mechanism for the entire respiratory chain.

[F] That closes a loop worth stating plainly. The mitochondrion's capacity to make ATP depends on clusters that depend on a persulfide that depends on free cysteine, and free cysteine is supplied by the transsulfuration pathway or imported as cystine through SLC7A11. Respiration is downstream of the cysteine supply, which is the

same supply that §304 shows governs whether an engineered cell survives after infusion.

232. The twelve conversations

[F] The mitochondrion is usually drawn as a power plant, which makes it sound like a terminal node. It is not. It holds a distinct, named, physically implemented conversation with each of the twelve other organelles on the map, and Table 2 sets out what each one carries. The conversations are not metaphors: most are membrane contact sites with identified tether proteins, and the rest are vesicular or metabolite traffic with identified carriers.

[VOL p.283]

Ion and metabolite Sulfate is stored in the The one compartment in the storage; functional vacuole and mobilized on set that stores sulfur as sulfate counterpart of the demand — animals have no equivalent lysosome [VOL p.284] **Table 2.** The twelve conversations the mitochondrion holds with the rest of the cell, the physical connection that carries each, and the sulfur chemistry in it.

[F] Two entries in that table are worth separating from the rest. The conversation with the endoplasmic reticulum is where apoptosis is committed, and it is a conversation between the oxygen organelle and the sulfur organelle conducted across a calcium channel. Three of the twenty-seven Akt arrows — BAD, caspase-9 and XIAP — all land on the mitochondrial side of exactly that junction, which is why §303 finds it the least redundant balloon in the fan.

[F] And the conversation with the plant vacuole is the only one in the table in which sulfur is stored rather than used. A plant holds sulfate in the vacuole and draws it down. An animal has no such depot: the element is held in working molecules or it is not held at all, which is why a shortage announces itself as work not getting done rather than as a level that has fallen, and why no clinical assay for sulfur status exists.

233. Acetylation and methylation: the two currencies the mitochondrion exports

[E] Histone acetyltransferases do not make acetyl groups. They transfer them from acetyl-coenzyme A, and the nuclear pool of acetyl-coenzyme A is set by mitochondrial output — citrate exported from the cycle and cleaved back to acetyl-coenzyme A by ATP-citrate lyase. Histone and DNA methyltransferases do not make methyl groups either. They transfer them from S-adenosylmethionine, made from methionine and ATP, and the ratio of S-adenosylmethionine to S-adenosylhomocysteine decides whether a methyl mark is written at all.

[F] Acetyl-coenzyme A is a thioester. S-adenosylmethionine is a sulfonium. The two molecules that write every acetyl and every methyl mark in the genome are both sulfur compounds, and both are metered by the mitochondrion. The epigenome is not merely influenced by metabolism; it is inscribed using two sulfur carriers whose abundance the mitochondrion sets.

[F] That is the cleanest statement of the paper's central chemistry, and it reframes what epigenetic editing is doing. §306 maps CRISPRa, CRISPRi and dCas9-TET1 across the Akt fan. Every one of those tools is a targeting device bolted onto an enzyme that still has to be supplied with a sulfur-borne group by the mitochondrion. An epigenetic editor directed at a silenced promoter cannot write a mark the cell's sulfonium pool will not pay for.

[H] It follows, and is testable, that the efficiency of targeted epigenetic editing should track the S-adenosylmethionine to S-adenosylhomocysteine ratio and the acetyl-coenzyme A pool in the [VOL p.285] cells being edited. If so, methionine availability in the culture medium is a determinant of editing efficiency, and a reported failure to reactivate a promoter may be a supply failure rather than a targeting failure. This is stated as a hypothesis because the experiment has not been reported.

[E] The demethylation side carries the same dependency from the opposite direction. The TET enzymes and the Jumonji demethylases are alpha-ketoglutarate-dependent dioxygenases, and succinate and fumarate — both mitochondrial cycle intermediates, both products of reactions that passed through a thioester — inhibit them competitively. The mitochondrion writes marks through sulfur carriers and erases them through cycle intermediates, so it holds both ends of the epigenetic conversation.

234. The three pillars, summarized

pillar the sulfur species the step it controls consequence of losing it glycolysis thioester on the catalytic cysteine of GAPDH the one energy-conserving step flux reroutes to the pentose phosphate pathway citric acid cycle lipoyl dithiolane; coenzyme A thiol; aconitase cluster entry, the rate-limiting turn, and the isomerization pyruvate cannot enter; the cycle stalls; iron regulation switches oxidative phosphorylation cysteine-ligated iron-sulfur clusters every intermediate electron transfer the chain cannot conduct **Table.** One element, three pillars, three different chemistries.

[F] The table is the chapter's compression. Three different sulfur chemistries — a thioester, a dithiolane arm with a thiol acceptor, and thiolate ligation of metal — perform three different functions at the three stages of respiration. This is not one mechanism recurring; it is one element supplying three mechanisms, which is the distinction between a theme and a coincidence.

235. Objections

[F] Every cofactor could be made to look central this way. Try it with another element and the attempt fails at the second pillar. Magnesium is essential to glycolysis as the counter-ion for every phosphate transfer, and plays no comparable role in the respiratory chain's electron transfers. Iron is central to the chain and absent from glycolysis. Sulfur is the element that appears at the decisive step of all three, in three different chemical forms.

[VOL p.286] **[F] These are textbook facts.** They are, and each is taught in the chapter where it occurs: the GAPDH thioester in glycolysis, lipoate in the cycle, clusters in the chain. What is not taught is the three together as a single statement about one element, and it is the single statement that generates the predictions of Part Six.

[F] The export argument proves only correlation. The claim that acetylation and methylation track mitochondrial flux is supported by direct experiment: manipulating acetyl-coenzyme A availability changes histone acetylation, and manipulating methionine availability changes histone and DNA methylation. The dependency is demonstrated, not inferred.

236. Tests

• **Thioester occupancy as a flux readout.** The covalent intermediate at GAPDH is measurable by mass spectrometry. Its steady-state occupancy should track glycolytic flux and should fall sharply before any change in metabolite concentrations is detectable under oxidative stress.

• **Lipoate status in disease tissue.** Lipoylation of the two dehydrogenase complexes depends on the same iron-sulfur-dependent machinery as cluster assembly. Measuring lipoylation and cluster content together across tumor and normal tissue would test whether the two fail together, as the shared-supply model requires.

• **Acetyl and methyl budgets in parallel.** Measure acetyl-coenzyme A and S-adenosylmethionine in the same cells across a respiratory perturbation, with histone acetylation and methylation quantified alongside. The prediction is that the two marks move in opposite directions under some perturbations and together under others, in a pattern set by where the carbon goes.

237. Consequences

[F] The chapter's result for the volume's third leg is that the mitochondrion is not simply the cell's power plant but its chemical supplier: it exports the acyl currency, supports the methyl currency, and, as Chapter 20 shows, monopolizes the assembly of the clusters on which its own chain and several nuclear enzymes depend. A compartment that supplies the rest of the cell with irreplaceable chemistry is a compartment whose failures cannot stay local, and that single structural fact is what the clinical argument of Part Six rests on.

[O] The open question is quantitative and is the same one that recurs through Part Five: what fraction of the variance in histone acetylation and DNA methylation across

tissues is accounted for by substrate availability rather than by enzyme expression? The experiment requires measuring substrate pools and marks in the same samples, which is now routine, and it has not been done at scale in human tissue.

[VOL p.287]

238. Notes to Chapter 18: respiration, measured

Quantities worth carrying

[E] Glycolytic yield. Two ATP net per glucose, with the only substrate-level phosphorylation of the pathway's payoff phase enabled by the thioester intermediate at glyceraldehyde-3-phosphate dehydrogenase.

[E] Citric acid cycle yield. Per acetyl group: three NADH, one reduced flavin, one GTP or ATP. Both entry points to the cycle's oxidative decarboxylations depend on lipoate.

[E] Chain yield. Oxidative phosphorylation produces the great majority of cellular ATP in aerobic tissue, with commonly cited values near 30 to 32 ATP per glucose depending on shuttle usage and proton leak.

[E] Cluster count. Complex I carries eight iron-sulfur clusters; complex II three; complex III one Rieske cluster. Together they constitute the largest concentration of cluster chemistry in the cell.

[E] Acetyl-coenzyme A concentrations. Nuclear and cytosolic acetyl-coenzyme A concentrations are in the low micromolar range and fluctuate with nutrient state; histone acetyltransferases have Michaelis constants in that range, which is what makes acetylation substrate-sensitive rather than saturated.

[E] Methylation index. The ratio of S-adenosylmethionine to S-adenosylhomocysteine is the standard index of methylation capacity, and many methyltransferases are product-inhibited by the homocysteine form, which couples the whole methylation economy to one ratio.

Methods box: measuring flux rather than level

[F] Extracellular flux analysis. Oxygen consumption and extracellular acidification measured in real time give respiration and glycolysis as rates, with inhibitor injections resolving basal respiration, ATP-linked respiration, proton leak and maximal capacity. It is the standard first measurement and reports the system, not the enzymes.

[F] Stable isotope tracing. Labeled glucose, glutamine or fatty acid followed into cycle intermediates by mass spectrometry reports which substrate is feeding which pathway, which is the only way to distinguish a cell that is respiring from a cell that is respiring on a different fuel.

[F] Enzyme-level readouts. Aconitase activity as a cluster proxy; pyruvate dehydrogenase phosphorylation state as a gate readout; lipoylation status by immunoblot, which reports the output of the same sulfur relay that serves cluster assembly.

[VOL p.288] **[F] Acetyl and methyl budgets.** Both currencies are measurable by targeted mass spectrometry, and both should be reported alongside the marks they write — histone acetylation and methylation by immunoblot or by mass spectrometry of histone peptides — because the point of the measurement is the relationship between substrate and mark.

Worked example: a redox switch rerouting carbon

[F] Apply an oxidative load to a cell and follow the consequences at the glycolytic dehydrogenase. The catalytic cysteine is oxidized, the enzyme loses activity, and flux through the lower half of glycolysis falls. Upstream intermediates accumulate, and the accumulated glucose- 6-phosphate is available to the pentose phosphate pathway, which produces NADPH — the reducing power needed to restore the thiol pools and to run the peroxiredoxin cycle.

[F] The circuit is self-correcting and it is implemented in chemistry rather than in signaling: no transcription, no kinase cascade, and a response time set by the oxidation rate of one cysteine. When the load clears, the enzyme is reduced back and flux returns.

[F] The example is worth running in full because it demonstrates the volume's general proposition in a system everyone knows. The regulation of the cell's central carbon pathway at its decisive step is performed by the oxidation state of a sulfur atom, is invisible in any sequence or transcript measurement, and is fully reversible on a timescale shorter than any transcriptional response.

Problems

[O] 18.1 Compute the fraction of the respiratory chain's electron-transfer steps that occur at iron-sulfur clusters, and compare with the fraction that occur at hemes and at flavins.

[O] 18.2 Design an experiment that distinguishes loss of lipoylation from loss of the dehydrogenase proteins themselves, and say what the distinction would mean clinically.

[O] 18.3 Both exported currencies depend on mitochondrial metabolism. Design a perturbation that raises one and lowers the other, and predict the consequences for histone marks.

[O] 18.4 The chapter claims no other element appears at the decisive step of all three pillars. Test it: for magnesium, iron and zinc, list the role at each pillar and judge whether the claim survives.

[O] 18.5 Estimate the turnover number required of the glycolytic dehydrogenase to sustain a dividing cell's glycolytic flux, and ask how much oxidative inactivation that flux can tolerate.

[O] 18.6 Aconitase switches function on cluster loss. Find two more proteins that change function rather than merely losing it when a cofactor is lost, and ask what they have in common.

[VOL p.289] **Connections**

[F] This chapter supplies the energetic half of Part Five's case; Chapter 19 supplies the genetic half, and Chapter 20 joins them by showing that one relay feeds both. The exported currencies return in Chapter 22, where the methyl economy is sensed directly by a growth-signaling regulator.

Worked example: following one acetyl group from glucose to a histone

[F] Trace a single acetyl group through the pathway and note where sulfur carries it.

[F] Glucose to pyruvate. Ten steps, with the one energy-conserving step running through a thioester on the catalytic cysteine of glyceraldehyde-3-phosphate dehydrogenase. Sulfur carries the acyl group here for the first time, long enough to transfer the oxidation energy to phosphate.

[F] Pyruvate to acetyl-coenzyme A. The pyruvate dehydrogenase complex decarboxylates pyruvate, carries the resulting acetyl group on the lipoyl arm — a dithiolane, two sulfurs — and transfers it to the thiol of coenzyme A as a thioester. Sulfur carries the acyl group twice more, and the product leaves the complex attached to a sulfur atom.

[F] Matrix to cytosol. Acetyl-coenzyme A does not cross the inner membrane. The acetyl group is condensed with oxaloacetate to citrate, exported, and cleaved back to acetyl-coenzyme A in the cytosol by ATP-citrate lyase — re-attached, again, to a coenzyme A thiol.

[F] Cytosol to chromatin. A histone acetyltransferase transfers the acetyl group from the thioester to a lysine side chain, where it neutralizes a positive charge and loosens the histone's grip on DNA. The mark is written.

[F] Count the transfers. The acetyl group was attached to a sulfur atom at four separate points on its route from glucose to chromatin, and at no point was it carried by anything else. The epigenetic mark that opens a gene arrives on a sulfur carrier.

[F] The measurable consequence. Because the acetyltransferases operate near their Michaelis constants for acetyl-coenzyme A, the extent of histone acetylation tracks the concentration of the carrier, which tracks mitochondrial carbon flux. Acetylation is therefore a readout of metabolic state as well as a regulatory instruction, and the two cannot be separated by any measurement of the histone alone.

[F] The claim this supports. Chromatin marks are usually described as instructions written by signaling pathways. They are also, and simultaneously, reports of substrate availability from a compartment. Chapter 20 follows the same logic for the methyl economy, where the carrier is a sulfonium.

[VOL p.290] **CHAPTER 19**

Sulfur Inside the Genetic Machinery

Abstract. The machinery that makes and reads the genome is built on sulfur at three decisive points. The enzyme that converts ribonucleotides into deoxyribonucleotides does so with a transient radical on a cysteine, which is the chemical event that separates a DNA world from an RNA world. The helicases that open the double helix for repair and for replication hold their wedge with an iron-sulfur cluster. And at one position in the anticodon, one element runs three different chemistries. This chapter takes the three in order and draws the conclusion that the genome's manufacture and maintenance are sulfur-dependent at steps that have no alternative route.

239. The enzyme that makes DNA

[E] Ribonucleotide reductase performs the only de novo route to deoxyribonucleotides in all organisms. It removes the 2′ hydroxyl of a ribonucleotide and replaces it with hydrogen, and the chemistry is difficult: the carbon being modified is unactivated, and the reaction requires generating a radical.

[E] The mechanism, worked out over decades, runs through a transient thiyl radical on an active-site cysteine. The radical abstracts the 3′ hydrogen from the substrate, which initiates loss of the 2′ hydroxyl as water; a pair of further cysteines supplies the two electrons and two protons that complete the reduction, becoming a disulfide in the process; and that disulfide is then reduced back by thioredoxin or glutaredoxin, at the cost of NADPH, to reset the enzyme.

[F] Count the sulfur atoms involved in one turnover: one that becomes the radical, two that become the disulfide, and two more in the thioredoxin that reduces it back. Five sulfur atoms per deoxyribonucleotide made, and the first of them does chemistry no other biological element performs at that position.

[F] The consequence for the arc of Chapter 3 is direct. The transition from an RNA world to a DNA world required exactly this reaction, and the reaction is a sulfur radical chemistry. Class III ribonucleotide reductases, which operate anaerobically and use a glycyl radical, still require a cysteine in the catalytic step, and the class distribution across the tree is consistent with the oxygen history of the planet. Whatever else happened at that transition, the element [VOL p.291] that made it possible was sulfur.

240. Sulfur removes an oxygen to make DNA

[F] Stated at the level of atoms, the reaction is a trade between two of this volume's colored elements: a sulfur radical removes an oxygen. The product is a molecule that is chemically duller, less reactive at the 2′ position, incapable of the base-catalyzed self-cleavage that limits RNA's lifetime, and therefore suitable for archiving.

[E] The stability difference is large. RNA is hydrolyzed orders of magnitude faster than DNA at physiological pH, because the 2′ hydroxyl attacks the adjacent phosphodiester. Removing it converts a molecule with a half-life of hours or days into one with a half-life measured in much longer intervals.

[F] So the archival property of the genome — the property on which the entire concept of genetic inheritance rests — is conferred by a single atom's removal, performed by a single element's radical chemistry, consuming reducing power supplied by another sulfur system.

The genome is archival because of sulfur.

241. The cluster at the wedge

[E] A distinct family of superfamily 2 helicases carries a [4Fe-4S] cluster in a domain inserted near the ATPase core: XPD, which opens the helix during nucleotide excision repair; FANCJ, which works on interstrand crosslinks and G-quadruplexes; RTEL1, which dismantles the telomeric t-loop; and DDX11, which functions in sister chromatid cohesion. In each, the cluster sits at the point where the two strands are separated and contributes to the wedge that splits them.

[E] Mutations in these enzymes cause distinct human diseases: xeroderma pigmentosum, trichothiodystrophy and Cockayne syndrome for XPD; Fanconi anemia and breast cancer pre-disposition for FANCJ; Hoyeraal-Hreidarsson syndrome and telomere disease for RTEL1; Warsaw breakage syndrome for DDX11. The clinical spectrum is varied; the chemistry at the wedge is the same.

[F] Two implications follow. The first is that cluster supply is a determinant of genome maintenance capacity: a cell that cannot assemble clusters cannot load these enzymes, and the phenotype will be a repair deficiency with no mutation in any repair gene. The second is that oxidative conditions, which degrade clusters, impair the repair machinery at the moment it is most needed — an architecture that looks like a design flaw and is better read as a coupling between damage and the cell's decision to stop dividing.

[VOL p.292] ## 242. One element, three chemistries, one position

[F] The anticodon's position 34 was treated in Chapter 7 from the standpoint of recognition. Here it is worth restating as a chemical fact about the element. At that one position in different transfer RNAs, sulfur appears in three distinct forms.

• **As a thiocarbonyl**, replacing the 2-oxygen of uridine to give 2-thiouridine, which restricts wobble and stabilizes the codon-anticodon pair.

• **As a methylthio group**, installed on the adjacent position 37 of certain transfer RNAs by a radical SAM enzyme that carries two iron-sulfur clusters and uses S-adenosylmethionine both as a radical source and as the methyl donor.

• **As the persulfide relay** that delivers it, where the sulfur travels as a protein-bound persulfide from the desulfurase through carrier proteins to the installing enzyme.

[F] Three chemistries, one element, one position, all of them invisible in a sequence record, all of them required for accurate translation. The radical SAM enzyme in the second case is a particularly compact example of the volume's whole thesis: an

enzyme that holds iron with sulfur, uses a sulfonium as its radical source, and installs a sulfur-containing group — three of the seven operations of Chapter 16 in a single active site.

243. The enzyme that makes DNA

[E] Every deoxyribonucleotide in the body is made by ribonucleotide reductase, which removes the hydroxyl at the 2′ position of the sugar. There is no alternative route and no salvage pathway that bypasses it.

[E] In every class of the enzyme, aerobic or anaerobic, the actual bond-breaking step — pulling the 3′ hydrogen off the ribose to set up loss of the 2′ hydroxyl — is performed by a transient cysteine thiyl radical in the catalytic subunit. In the diiron, tyrosyl-radical version used by humans, that thiyl radical is generated by long-range electron and proton transfer from a diiron-oxo center which first parks the radical on a tyrosine and then relays it roughly thirty-five ångströms through the protein to the active-site cysteine.

[E] After turnover, two active-site cysteines are left as a disulfide, which must be reduced back to two thiols by thioredoxin or glutaredoxin — another cysteine-based redox couple, ultimately paid for by NADPH — before the enzyme can run again.

[F] The sulfur groups doing the work are therefore three: thiol and thiolate, thiyl radical, and disulfide. This is organic sulfur redox chemistry; it is not an inorganic cluster and it is not the electron transport chain.

[VOL p.293] ## 244. Sulfur removes an oxygen to make DNA

[E] RNA is unstable because of a single chemical group: the 2′ hydroxyl attached to the ribose ring. To build a durable blueprint, that oxygen must be stripped away and ribose converted to deoxyribose.

[F] Ribonucleotide reductase is the bridge at which that becomes possible, and the transaction is an exchange between sulfur and oxygen. The thiyl radical takes the 3′ hydrogen; the 2′ hydroxyl departs as water. DNA exists because sulfur chemistry deleted an oxygen atom from RNA.

[F] This is the join between the first part of the thesis and the second, and it falls exactly on the middle member of the nucleotide triad. The base is the digital code and the phosphate is the engine, but the structural bridge — the sugar — is the member that sulfur chemistry creates.

[F] Two enzymes were required for the transition from an RNA world to a DNA world: the reductase, which makes the deoxy sugar, and reverse transcriptase, which copies RNA into DNA. They do not share a fold, a mechanism or a common ancestral gene; they are independent inventions that both had to exist before a DNA-based genome was viable. The defensible statement is two independent inventions at one transition, both dependent on the sulfur and iron economy.

[O] The reductase of the aerobic class depends on a ferritin-like diiron center, and iron loading of that center runs through the same mitochondrial iron–sulfur machinery that builds the clusters. Whether the enzyme should therefore be described as doubly dependent on that machinery — once through the thiol pair and again through cofactor assembly — is open, and worth settling, because it bears on how tightly the supply argument can be drawn.

245. One group, two chemistries

[E] The thiol is entry one of the eighteen. It is the cysteine side chain that becomes the thiyl radical abstracting the ribose 3′ hydrogen. The same group in its deprotonated form, the thiolate, is what ligates iron in an iron–sulfur cluster: each cysteine in the cluster-binding motif donates its thiolate sulfur as one of the four ligands around an iron atom. Clusters are typically coordinated by four amino-acid side chains, usually cysteine thiolates, though histidine and aspartate also occur.

[F] One functional group is therefore doing double duty: radical chemistry in the enzyme active site, and metal ligation in every cluster-dependent step. Entry one spans both halves of this account. The thiol is not one of eighteen equals; the remaining seventeen are its oxidation [VOL p.294] products, its esters, or its exotica.

[E] None of the other sixteen appears in reductase catalysis or in cluster biogenesis as far as established mechanism goes.

246. One element, three chemistries, one position

[F] A pattern runs through the proteins that handle DNA directly: the same element in three different chemistries, at the same functional position.

• Thioether, no metal. In RAD51, methionine 278 presents a neutral sulfur face-on against an unpaired base at 3.66 ångströms.

• Thiolate with one metal. In the helicase loader DnaI, the N-terminal domain is a zinc-binding fold sitting in the helicase-interaction region rather than the DNA-binding region. The sulfur there is doing coordination chemistry rather than base chemistry: different job, same element, same machine.

• Thiolate with a four-metal cluster. XPD, FANCJ, RTEL1 and DDX11 each carry a conserved iron–sulfur cluster within the helicase domain, positioned at the point where the two strands part — the wedge. Remove the cluster and helicase activity dies while the ATPase survives.

[F] In the archetypal DNA-opening helicase the strand-separation device is built on sulfur: four cysteine thiolates plus inorganic sulfide, holding an iron core, positioned exactly where the duplex splits. The dissociation between lost helicase activity and surviving ATPase is the cleanest available evidence that the cluster performs mechanical work rather than structural stabilization.

[F] The escalation across the three cases — no metal, one metal, four-metal cluster, with the element and the functional position held constant — is the shape of the

whole

247. Why these steps have no alternative route

[F] The chapter's claim is stronger than "sulfur participates." It is that at three steps there is no alternative chemistry available to the cell, and the three are listed with what would have to be true for an alternative to exist.

• **Making deoxyribonucleotides.** Every organism uses a ribonucleotide reductase, and every class of the enzyme uses a cysteine in the catalytic step. No alternative de novo route to deoxyribonucleotides is known. An alternative would require a different way of activating an unactivated carbon, which is chemistry no other biological element performs at that position.

• **Opening the helix in repair.** The cluster helicases could in principle be replaced by cluster-free helicases, and the cell does have those. What it does not have is a cluster-free version of [VOL p.295] these particular enzymes, and the human diseases show what their absence costs.

• **Thiolating the wobble base.** The modification is installed from cysteine sulfur by a dedicated relay. No other element substitutes: the chemistry of a 2-thiocarbonyl is what produces the pairing restriction, and an oxygen in that position gives ordinary uridine.

[F] An element that is merely common can be replaced in any given instance. An element that is at an irreplaceable step is a dependency, and dependencies are where a system can be broken — which is the therapeutic argument of Chapter 23 and the inherited-disease argument of Chapter 24.

248. What the clinic already shows

[E] Three classes of clinical fact support the chapter without any new experiment.

[E] Ribonucleotide reductase is a validated oncology target: hydroxyurea, in use for decades, inactivates the tyrosyl radical that generates the thiyl radical, and gemcitabine's diphosphate inhibits the enzyme. Both drugs work by starving cells of deoxyribonucleotides, which is a supply-line intervention in the sense of Chapter 4.

[E] The cluster helicases produce a set of inherited diseases whose severity tracks the specific function lost, and in at least one case — RTEL1 — the phenotype includes telomere failure, connecting this chapter directly to Chapter 15.

[E] Defects in the sulfur relay that serves wobble thiolation produce mitochondrial disease, and defects in the shared upstream desulfurase produce a severe multisystem disorder, which is the clearest clinical demonstration that cluster assembly and translational accuracy draw on one supply.

249. Tests

• **Deplete the relay, measure both outputs.** A graded knockdown of the cysteine desulfurase, with cluster occupancy and wobble thiolation measured in parallel,

would establish the order in which the cell sacrifices them. The experiment is one cell line and two assays.

• **Cluster occupancy of repair helicases under oxidative load.** Measure the cluster content of XPD-family enzymes across an oxidative titration and relate it to repair capacity measured functionally. The prediction is that repair capacity falls with cluster occupancy before any change in enzyme abundance.

• **Thiolation as a function of cysteine supply in primary human cells.** Chapter 7's test restated here because it is the cheapest decisive experiment in Part Five.

[VOL p.296] ## 250. Consequences

[F] The genome is made by sulfur chemistry, opened by sulfur-ligated clusters, and read with the help of sulfur-modified bases. None of those three facts appears in any sequence record, and all three are required for a sequence record to exist at all.

[F] That is the sharpest form of the volume's argument. The instrument that the field treats as the complete description of genetic material is produced by chemistry the instrument cannot describe. Chapter 21 follows the same element backward in time to the mineral it came from, and Chapter 20 follows it sideways into the compartment that supplies it.

251. Notes to Chapter 19: the machinery, measured

Quantities worth carrying

[E] Ribonucleotide reductase classes. Three classes, distinguished by how the radical is generated: class I uses a metal center and oxygen, class II a cobalamin cofactor, class III a glycyl radical generated by a radical SAM activase under anaerobic conditions. All three use a cysteine in the catalytic step.

[E] Allosteric control. The enzyme carries two allosteric sites, one setting overall activity through ATP and dATP and one setting substrate specificity. The arrangement is what balances the four deoxyribonucleotide pools, and its failure produces the pool imbalance that raises mutation rates.

[E] Cluster helicases. XPD, FANCJ, RTEL1 and DDX11 each carry a [4Fe-4S] cluster in an inserted domain. Mutations that disrupt cluster ligation produce disease, and the diseases differ because the enzymes' substrates differ.

[E] Hydrogen abstraction. The thiyl radical abstracts the 3′ hydrogen of the substrate, which is a high-energy step; the reaction's feasibility depends on the radical's reactivity and on precise positioning, which is why the enzyme's active site is one of the most carefully studied in biochemistry.

[E] Reducing cost. Each turnover leaves an active-site disulfide that must be reduced by thioredoxin or glutaredoxin, which in turn is reduced at the cost of NADPH. Making DNA is therefore a continuous drain on reducing power, not just on nucleotides.

Methods box: catching a radical and counting a cluster

[F] Radical detection. Electron paramagnetic resonance detects the enzyme's stable radical and, with rapid freeze-quench, transient species. The thiyl radical itself is short-lived and is [VOL p.297] usually inferred from mechanism-based inhibitors and isotope effects rather than observed directly.

[F] Mechanism-based inhibitors. Substrate analogs that generate a trapped intermediate have been central to establishing the mechanism; gemcitabine diphosphate acts this way clinically, which makes the drug a pharmacological confirmation of the chemistry.

[F] Cluster occupancy in helicases. Purified enzyme gives spectroscopic occupancy; in cells, the relevant measurement is functional — helicase-dependent repair capacity — because direct cluster measurement in a low-abundance nuclear protein is impractical.

[F] Repair capacity assays. Host-cell reactivation, comet assays and unscheduled DNA synthesis each report repair capacity with different sensitivities. For the prediction that repair falls with cluster supply, the assay must be run alongside a cluster-status proxy such as aconitase activity.

Worked example: tracing five sulfur atoms through one turnover

[F] Follow the atoms for a single deoxyribonucleotide. The catalytic cysteine's sulfur becomes a thiyl radical and abstracts a hydrogen: one atom. Two further cysteines donate the electrons and protons that remove the 2′ hydroxyl as water and become a disulfide: two more.

Thioredoxin reduces that disulfide using its own pair of cysteines: two more. Thioredoxin reductase then restores thioredoxin, using NADPH and — in the human enzyme — a selenocysteine at its active site.

[F] So one deoxyribonucleotide costs the participation of five sulfur atoms and, in the final step, one selenium atom. Multiply by the number of nucleotides in a human genome and the sulfur-mediated turnover involved in copying it once becomes a quantity worth noticing, even though no sulfur atom is consumed: all of them cycle.

[F] The example also shows why the volume insists on the distinction between a catalyst and a substrate. Sulfur is never consumed in this chemistry. It is the medium in which the chemistry happens, which is precisely why it leaves no trace in the product and no symbol in the record.

Problems

[O] 19.1 Compute the NADPH cost of one genome duplication attributable to ribonucleotide reductase alone, and compare with the pentose phosphate pathway's capacity.

[O] 19.2 The chapter claims there is no alternative de novo route to deoxyribonucleotides. Search for counterexamples across the tree of life and report

what you find.

[VOL p.298] **[O] 19.3** For one cluster helicase, design an experiment separating loss of cluster from loss of ATPase activity, and say which human disease alleles would be predicted to fall in each category.

[O] 19.4 The allosteric specificity site balances four pools. Model the system and determine how sensitive pool balance is to the site's affinity constants.

[O] 19.5 Radical SAM enzymes use a cluster to cleave S-adenosylmethionine. List the radical SAM enzymes operating on transfer RNA and ask how many of the volume's seven operations are represented in each.

[O] 19.6 Gemcitabine and hydroxyurea both target the same enzyme by different mechanisms.

Predict how their resistance profiles should differ, given the chemistry, and check against the clinical literature.

Connections

[F] The chemistry here is the third link of the chain in Chapter 21 and the mechanistic basis of the supply argument in Chapter 4. The cluster helicases connect forward to Chapter 15, where one of them dismantles the telomeric loop, and to Chapter 20, where their cofactor's supply is shown to be mitochondrial and exclusive.

Worked example: hydroxyurea, read as chemistry

[F] Hydroxyurea has been in clinical use for decades, in sickle cell disease and in myeloprolifera-tive disorders. Read through this chapter's mechanism, what it does and what it costs become a single account.

[F] The target. The radical-generating subunit of ribonucleotide reductase. The drug quenches the stable tyrosyl radical that is used to generate the transient thiyl radical at the catalytic site. Without it, the enzyme cannot initiate hydrogen abstraction.

[F] The immediate consequence. Deoxyribonucleotide supply falls. Replication forks slow and stall, and in a proliferating population this produces the cytoreduction the drug is given for.

[F] The second consequence, in sickle cell disease. Fetal hemoglobin induction, which is the therapeutically important effect in that indication and is not a straightforward consequence of nucleotide depletion. The mechanism involves stress signaling and nitric oxide chemistry, which is a reminder that a drug acting on a supply line has effects beyond the supply line.

[F] What the sequence record shows. Nothing, during treatment. The genome is unchanged.

The cell's behavior changes because its pools changed.

[F] The chemistry the volume adds. The enzyme's turnover leaves an active-site disulfide that must be reduced back by thioredoxin or glutaredoxin, at the cost of NADPH. So the enzyme [VOL p.299] is a continuous drain on reducing power as well as on substrate, and a cell inhibited at this step is spared that drain. Whether the spared reducing power contributes to the drug's effects is, as far as this volume can establish, unexamined.

[F] The test that follows. Measure NADPH and glutathione redox state in treated and untreated cells at matched proliferation rates. If inhibiting the enzyme measurably spares reducing power, then some of the drug's effects are redox effects rather than nucleotide effects, and the distinction matters for combination strategies.

[F] Why this is the right example for this chapter. It shows a sulfur-dependent step being exploited therapeutically for sixty years without the sulfur chemistry being the frame in which the drug is discussed — which is the volume's complaint about the field, stated with a drug that works.

[VOL p.300] **CHAPTER 20**

The Mitochondrial Sulfur Economy and the Organelle Network

Abstract. Biological sulfur is mobilized at a small number of points, and one of them is exclusive to the mitochondrion. The initial step of iron-sulfur cluster assembly happens in the matrix and nowhere else, which makes the mitochondrion the sole supplier of a cofactor that nuclear enzymes, cytosolic enzymes and the respiratory chain all require. Around that supply sits the transsulfuration junction, which converts methionine sulfur into cysteine sulfur and sets the budget for glutathione, taurine and everything downstream. This chapter sets out the economy and then the network it serves: thirteen compartments, twelve conversations, and one supplier that cannot be bypassed.

252. Where biological sulfur is mobilized

[E] Sulfur enters human metabolism as methionine and cysteine from protein, as inorganic sulfate, and as hydrogen sulfide produced endogenously by three enzymes. From there it moves through a small number of hubs.

• **The methionine cycle** converts methionine to S-adenosylmethionine, which donates its methyl group and becomes S-adenosylhomocysteine, hydrolyzed to homocysteine.

Homocysteine is either remethylated back to methionine, which conserves the sulfur, or committed down transsulfuration, which spends it.

• **The transsulfuration junction** commits homocysteine to cystathionine by cystathionine beta-synthase, and cystathionine to cysteine by cystathionine

gamma-lyase. This is the only route by which methionine sulfur becomes cysteine sulfur in human cells, and both enzymes also produce hydrogen sulfide as a side activity.

• **The desulfurase relay** abstracts sulfur from cysteine as a protein-bound persulfide and delivers it to cluster assembly, to wobble thiolation, to molybdenum cofactor synthesis, to biotin and to lipoate. One enzyme, several destinations.

• **The sulfur oxidation pathway** disposes of excess, running cysteine through sulfinate to sulfite and then to sulfate by sulfite oxidase, an enzyme carrying the molybdenum cofactor that Chapter 24 takes apart.

[VOL p.301] **[F]** The architecture is a single input stream feeding several irreplaceable outputs, with one disposal route. A system of that shape has a characteristic failure mode: competition. When supply is restricted, the outputs compete, and the order in which they are sacrificed is a property of the cell that nobody has measured directly.

253. The exclusivity that matters

[E] Iron-sulfur cluster biogenesis in eukaryotes has two systems. The mitochondrial system builds the initial cluster on a scaffold protein in the matrix, using iron delivered by frataxin-associated machinery and sulfur delivered as persulfide by the mitochondrial desulfurase. The cytosolic system cannot start from scratch: it requires a sulfur-containing species exported from the mitochondrion by a dedicated inner-membrane transporter.

[F] The consequence is structural and it is the pivot of the volume’s third leg. Cluster assembly is mitochondrial and exclusive. Every cytosolic and nuclear enzyme that needs a cluster — including the repair helicases of Chapter 19, DNA primase, several glycosylases and the cytosolic aconitase — depends on an organelle it is not in. A failure of mitochondrial mass or of the export step therefore propagates to the nucleus, and the propagation has nothing to do with mitochondrial DNA.

[E] Friedreich ataxia is the clinical demonstration: a defect in frataxin, a protein of the mitochondrial assembly machinery, produces a disease whose features include loss of cluster-dependent enzymes in several compartments.

254. The transsulfuration junction as a budget

[F] Transsulfuration is the point at which the cell decides between conserving methionine sulfur and spending it. The decision is made by the availability of substrates and by allosteric control: S-adenosylmethionine activates cystathionine beta-synthase, which is to say that a replete methyl economy licenses spending sulfur downstream.

[E] Downstream of the junction sit glutathione, the cell’s principal thiol buffer, and taurine, without which bile salts do not form and fat is not absorbed. Both are quantitatively large sinks. Glutathione concentrations in the millimolar range make it one of the most abundant small molecules in the cell, and its synthesis is limited by

cysteine availability.

[F] So one junction sets the budget for the antioxidant buffer, for bile physiology, for cluster assembly, for the wobble modification and for the molybdenum cofactor. The methionine restriction literature — which reports lifespan extension in several model organisms — is [VOL p.302] best read in that frame: restricting the input to a junction with multiple competing outputs changes the allocation among them, and which output benefits is a question about the ordering nobody has established.

255. Thirteen compartments, twelve conversations

[F] The mitochondrion holds a distinct, named relationship with each of the twelve other compartments of the keying in Chapter 16, and the set of twelve is the volume's third leg stated concretely. The material that follows gives them in full; three deserve preview because they carry argument later.

• **With the nucleus**, the conversation is metabolic: acetyl groups and methyl groups set the substrate availability for histone and DNA marks, and cluster export sets the functional capacity of repair enzymes. Signals run both ways, and one direction is invisible to transcriptomics.

• **With the endoplasmic reticulum**, the conversation is structural and runs on calcium at contact sites, with consequences for apoptosis that Chapter 22 uses: the proximity determines how much calcium a stressed cell transfers, and the transfer decides whether it dies.

• **With the lysosome**, the conversation is about turnover: damaged mitochondria are degraded by a dedicated autophagic route, and lysosomal failure therefore produces mitochondrial accumulation, which is the mechanistic link between two disease classes usually taught apart.

256. Where biological sulfur is mobilized

[E] Sulfur destined for cofactors does not circulate free. It is mobilized by cysteine desulfurase, which abstracts the sulfur atom from cysteine and holds it as a persulfide on its own active-site cysteine, then transfers it — still bound — to a scaffold protein where it is combined with iron and assembled into a cluster. What is genuinely mitochondrial is this biogenesis pathway and its export.

[F] A point of precision that the account depends on: the reductase itself is not a mitochondrial enzyme. In eukaryotes it is cytosolic, feeding deoxynucleotides to nuclear replication, while mitochondrial DNA draws its precursors largely from local salvage kinases. The defensible claim is that mitochondrial iron–sulfur biogenesis is an upstream hub on which both oxidative phosphorylation and certain genome-maintenance enzymes depend — they draw sulfur from the same well. The claim that reductase chemistry runs through oxidative phosphorylation is not correct, and the distinction must be kept sharp.

[VOL p.303] 257. The transsulfuration junction

[E] Methionine is converted to S-adenosylmethionine, which donates its methyl group and becomes homocysteine. Homocysteine may be remethylated or committed irreversibly to transsulfuration, where cystathionine β-synthase condenses it with serine and cystathionine γ-lyase cleaves the product to yield cysteine. Cysteine is used in the synthesis of glutathione, taurine and hydrogen sulfide.

[E] Deficiencies in cystathionine β-synthase trap sulfur upstream or downstream and severely alter both taurine levels and glutathione production. Defects in methylenetetrahydrofolate reductase alter the methylation cycle, pulling raw material away from transsulfuration and diminishing the cysteine pool available for both.

[F] One junction therefore sets five outputs: the methyl groups for nucleotide construction, the methyl groups for the epigenetic program, glutathione, taurine, and hydrogen sulfide signaling. These are not five systems that interact. They are five withdrawals from one account, and two named human gene variants demonstrate the coupling.

[F] The last of the five closes a loop. Hydrogen sulfide signaling produces persulfides, and the persulfide is the species the desulfurase uses to build clusters. One pathway feeds both the antioxidant pool and the cluster factory.

258. The communication network

[F] The third part of this account is the communication network between the mitochondrion and the twelve other organelles of the cell, which is the key to human disease and human health.

[E] The mitochondrion is not a passive furnace producing ATP. It is a command center that continuously samples the energetic, redox and atomic environment of the cell. Physical tethering between the mitochondrion and the other organelles — the endoplasmic reticulum through the mitochondria-associated membranes, and the lysosomes, peroxisomes and nucleus through their own contact sites — creates direct channels for lipid transport, calcium signaling and metabolic data transfer. When this structural communication breaks down the cell loses homeostatic balance.

[F] The mitochondrion is, among other things, a sulfur sensor, and the environment it samples includes the atomic one. That places sulfur inside the third part of the account and not only the second.

[E] Each major organelle can be keyed to a single element by the chemistry it actually runs. The lysosome is a hydrogen-ion chamber held near pH 4.5. The cytoplasm is the carbon frame[VOL p.304]work. The nucleus holds the nitrogenous bases. The mitochondrion ends its electron chain at oxygen. The plasma membrane is a phospholipid bilayer. The endoplasmic reticulum forms disulfide bonds, which is sulfur chemistry. The ribosome inserts selenocysteine by reading a stop codon as sense, which is the one place the genetic code is rewritten in flight, and that makes it the selenium organelle. The remaining six are run by metals outside the key:

manganese at the Golgi, iron at the peroxisome, magnesium in the chloroplast, potassium in the plant vacuole, calcium at the centrosome, zinc in secretory vesicles.

[F] Sulfur chemistry concentrates in two of these compartments: thioesters dominate the mitochondrial acyl economy, and disulfides act as structural switches in the reticulum. The division follows from the ambient redox state. The reticulum lumen is the oxidizing compartment, which is the precondition for forming a disulfide; the matrix is reducing, which is the precondition for keeping a thioester live. Neither operation could run in the other's compartment.

[F] It follows that the central tether of the organelle network — the junction between mitochondrion and reticulum — is the contact between the oxygen organelle and the sulfur organelle. It is usually described in terms of lipid transfer and calcium flux. Those are the cargo.

259. One supplier, both ends

[E] The same cysteine desulfurase generates the persulfide that builds the iron–sulfur clusters and the persulfide that is installed as 2-thiouridine at anticodon position 34. The thiolation of that wobble base is performed in human mitochondria by TRMU, and in the cytosol by CTU1 and CTU2 operating with the ubiquitin-like sulfur carrier URM1. Loss of these activities causes defective translation and recognized human disease.

[F] The oldest cofactor and the reading frame draw on the same sulfur donor. That is what makes the chain a circuit rather than a line.

[F] The structural effect of the thiolation is specific. Sulfur is larger than oxygen and a poorer hydrogen-bond acceptor; substituting it at the 2 position rigidifies the ribose pucker and sharpens the pairing preference of the wobble base. Decoding accuracy at the third codon position is set, in part, by the presence of a single sulfur atom — which is the same physics as the angular constraint the sugar imposes on base stacking, described in §30.

[O] If one enzyme supplies two destinations and its capacity is finite, the destinations compete, and there is a priority order between genome maintenance and decoding accuracy. That order is a physical quantity and has not been measured.

260. One supplier, both ends

[F] The single most consequential fact in this chapter is that one enzyme family supplies both ends of the genetic process. The mitochondrial cysteine desulfurase delivers sulfur to cluster assembly, which supplies the respiratory chain and the repair helicases, and to wobble

thiolation, which supplies translational accuracy.
Energy production and reading-frame
fidelity draw on one supply.

[VOL p.316] **[F]** Three predictions follow from the shared supply, and they are the chapter’s main experimental content.

• **Coordinated failure.** Perturbing the relay should produce respiratory deficiency and frameshifting together, with a reproducible ratio. If they can be separated by a perturbation of the shared enzyme, the model is wrong.

• **A priority order.** Under graded restriction the cell should sacrifice one output before the other, and the order should be the same across cell types if it is chemically determined and different if it is regulated. Either answer is informative; nobody has looked.

• **Compartment-local failure elsewhere.** For the twelve other compartments, perturbing the keyed element should produce a phenotype confined to that

compartment, because none of them is an exclusive supplier. The mitochondrion should be the only compartment whose perturbation propagates. That contrast is the test of the entire keying scheme, and it is runnable with existing tools in one well-designed study.

261. Objections

[F] Compartment keying is a presentation device. It would be, except that it makes the prediction above, which could fail. If perturbing the endoplasmic reticulum's disulfide chemistry produced a nuclear phenotype as severe as its local one, or if mitochondrial cluster failure turned out to be compensable by a cytosolic route, the scheme would be in trouble.

[F] Transsulfuration is well studied and the budget framing adds nothing. The framing adds a specific question: what is the order in which the junction's outputs are sacrificed? That question is not in the literature, and it is the question that would make methionine restriction interpretable rather than merely reproducible.

[F] The twelve conversations are a list, not a mechanism. Each is a mechanism, and most are separately documented. What is new here is treating them as one object — a supply and signaling network with a single node that cannot be bypassed — and drawing the therapeutic consequence that Chapter 23 tests against the trial record.

262. Consequences

[F] For disease biology, the conclusion is that mitochondrial dysfunction should not be modeled as an energy deficit alone. It is simultaneously a cofactor supply deficit, and the two have different time courses and different downstream signatures. A cell with reduced ATP and intact clusters is in a different state from a cell with adequate ATP and failing cluster export, and current assays do not distinguish them.

[VOL p.317] **[F]** For therapeutic strategy, the conclusion is where to intervene. A supply line with one exclusive supplier has a single point of failure, and the agents that would act on it — cysteine availability, hydrogen sulfide donors, frataxin replacement strategies — act on a quantity that no sequence-based diagnostic reports.

[O] The chapter's open question is the one named above and worth stating in isolation because it is answerable: when sulfur is scarce, what does the cell give up first — respiration or the reading frame? The answer would tell us which of the two the cell treats as more urgent, and by extension which failure it is built to tolerate. Nothing in the literature settles it, and a single graded-restriction experiment with two established readouts would.

263. Notes to Chapter 20: the economy, measured

Quantities worth carrying

[E] Methionine flux. Dietary methionine is partitioned between protein synthesis and the methionine cycle; within the cycle, the partition between remethylation and transsulfuration determines whether sulfur is conserved or spent. Both branches are regulated by one-carbon availability and by the methylation index.

[E] Glutathione turnover. Hepatic glutathione turns over on a timescale of hours, which makes cysteine supply a continuous requirement rather than a buffered one, and explains why cysteine availability is limiting for glutathione synthesis under stress.

[E] Taurine. One of the most abundant free amino acids in many mammalian tissues, made from cysteine, and required for bile salt conjugation. It is a large and often overlooked sink on the same sulfur budget.

[E] Cluster export. The cytosolic cluster assembly system depends on a sulfur-containing species exported from the mitochondrial matrix by a dedicated inner-membrane transporter; disruption of the exporter produces cytosolic cluster deficiency with intact mitochondrial assembly, which is the experiment that establishes the directionality.

[E] Contact site extent. Mitochondria-endoplasmic reticulum contacts cover a measurable fraction of the mitochondrial surface and the fraction changes with stress, nutrient state and apoptotic signaling.

Methods box: watching a shared supply

[F] Tracing sulfur. Stable-isotope-labeled methionine or cysteine, followed by mass spectrometry into glutathione, taurine, protein and the modified nucleosides, reports the partition [VOL p.318] among the junction's outputs. This is the measurement that would answer the chapter's open question, and the reason it is rare is that the outputs are measured in different laboratories by different methods.

[F] Cluster status. Aconitase activity ratio for the mitochondrial pool; the activity of a cytosolic cluster enzyme for the exported pool. Measuring both distinguishes an assembly defect from an export defect.

[F] Wobble thiolation. Thiol-specific gel retardation or mass spectrometry, as in the notes to Chapter 7.

[F] Contact sites. Proximity ligation, split-fluorophore reporters and electron microscopy all report contact extent; the first two are quantitative in live cells and the third is the reference method.

Worked example: a graded restriction experiment

[F] The experiment the chapter calls for can be specified exactly. Take a human cell line. Restrict cysteine availability in graded steps, using a defined medium and a transport inhibitor to achieve intermediate states. At each step measure four outputs: glutathione concentration, mitochondrial aconitase activity as a cluster proxy, wobble thiolation extent, and frameshifting frequency by dual reporter.

[F] Three outcomes are possible and each is informative. If glutathione falls first and the others follow in a fixed order, the cell has a priority ordering and the ordering is the result. If all fall proportionally, the outputs share a pool without regulation, which is itself a finding — it would mean the cell has no mechanism for protecting one function over another. If the ordering differs between cell types, the priority is regulated rather than chemical, and the regulator becomes the next target of study.

[F] Nothing in the experiment is technically difficult. Its absence from the literature is a consequence of the outputs belonging to four different fields.

Problems

[O] 20.1 Draw the sulfur economy as a flux diagram with one input and five outputs, and identify which outputs are buffered and which are not.

[O] 20.2 Methionine restriction extends lifespan in several model organisms. Reinterpret that result in terms of the junction's allocation, and design the experiment that would distinguish allocation effects from a general reduction in protein synthesis.

[O] 20.3 For each of the twelve conversations, name the measurable quantity that would report its state, and rank the twelve by how well characterized that quantity is.

[VOL p.319] **[O] 20.4** Cluster assembly is mitochondrial and exclusive. Construct the strongest argument that this is an evolutionary accident rather than a design constraint, and state what evidence would distinguish the two.

[O] 20.5 Design the propagation experiment that tests the compartment keying of Chapter 16 across all thirteen compartments, with controls for perturbation locality, and estimate its cost.

[O] 20.6 Hydrogen sulfide is produced by the transsulfuration enzymes as a side activity. Estimate its flux relative to the flux of sulfur into glutathione, and ask whether a signaling role is plausible at that flux.

Connections

[F] The exclusivity established here is what makes the mitochondrion the exception in the compartment map, and it is the mechanism behind the loop of Chapter 15. The junction's competition is the open question that recurs in Chapters 7, 19 and 24, each of which draws on the same supply.

Worked example: what methionine restriction actually restricts

[F] Methionine restriction extends lifespan in several model organisms and is being investigated in human metabolic disease. Read through the junction of this chapter, the intervention has a specific meaning that the phrase "restriction" conceals.

[F] What is restricted. The input to the methionine cycle, and therefore the supply of S-adenosylmethionine and, downstream of the transsulfuration junction, of cysteine.

[F] What competes for the restricted supply. Protein synthesis, which needs methionine as a residue and as the initiator. Methylation, which needs the sulfonium. Glutathione synthesis, which needs cysteine. Taurine. Cluster assembly, wobble thiolation and cofactor biosynthesis, all of which need the desulfurase's sulfur, which comes from cysteine.

[F] What is actually being manipulated. The allocation among those outputs, not a single quantity. Two cells under the same restriction can end up in different states depending on which outputs their regulation protects, which is why the intervention's effects differ by tissue and by organism.

[F] The experiment that would make it interpretable. Trace labeled methionine under graded restriction and measure where the label goes: into protein, into methyl marks, into glutathione, into taurine, into cluster-dependent enzymes and into wobble thiolation. Report [VOL p.320] the allocation, not the phenotype. The phenotype is what everyone measures; the allocation is what would explain it.

[F] A prediction worth recording. If lifespan extension under methionine restriction is mediated by reduced methylation capacity, it should be mimicked by inhibiting methyl transfer directly and should not require cysteine limitation. If it is mediated by the sulfur arm, the reverse. The two are separable with existing reagents, and the volume's expectation — stated so it can be wrong — is that the sulfur arm carries more of the effect than the literature's focus on methylation suggests.

[F] Why this belongs in this chapter. Because it is the clearest case where an intervention is named for its input while acting on an allocation, and because the allocation is exactly what the junction of this chapter controls.

[VOL p.321] **CHAPTER 21**

The Chain from the Mineral to the Editor

Abstract. The chain runs from a mineral precipitated out of sulfidic water to the enzymes now used to edit human genomes, and it closes without a gap. An iron-sulfur mineral has the cubane geometry of the cluster at the center of the respiratory chain. Hydrogen sulfide reached the first nucleotides before water chemistry did, and a thiophosphate backbone preceded the phosphodiester one. A thiyl radical converted ribonucleotides into deoxyribonucleotides and made a DNA world possible. Every editing enzyme that writes rather than cuts runs on sulfur chemistry. This chapter states the chain link by link and then asks what would break it.

264. Why run the chain at all

[F] A claim that an element is central can be made by accumulation — listing places it appears — or by continuity, showing an unbroken sequence from the earliest chemistry to the latest technology in which each step depends on the one before.

Accumulation is weak evidence; continuity is stronger, because a single missing link breaks it and every link is separately checkable.

[F] The chain here has seven links. Each is stated as a claim with its evidence class, and the chapter closes by naming what would have to be found for the chain to fail.

265. Link one: the mineral

[E] The Archean ocean was anoxic and, in large regions and periods, sulfidic. Iron delivered by hydrothermal circulation and sulfide produced by sulfate reduction precipitated iron sulfide minerals, among them mackinawite and greigite. Greigite's structure contains an Fe4S4 cubane unit.

[F] That unit is the geometry of the [4Fe-4S] cluster found in ferredoxins, in the respiratory chain, in the repair helicases of Chapter 19 and in radical SAM enzymes. A protein cluster is, in the structural sense, a mineral fragment held by four cysteine thiolates.

[E] The mineral-first interpretation of early metabolism is an established position in origins research, with laboratory support for sulfide-mineral-catalyzed carbon fixation chemistry. It is also contested in its stronger forms, and the volume takes only the weak form: that the [VOL p.322] geometry is the same and that the cluster did not have to be invented, only captured.

266. Link two: sulfide before water chemistry

[E] Hydrogen sulfide was abundant in the prebiotic environment and is a better nucleophile than water at comparable pH. In prebiotic syntheses relevant to nucleotide formation, sulfide and related sulfur species participate in several steps, and thiophosphate has been proposed and demonstrated as a prebiotically plausible phosphorylating agent.

[F] The implication for the volume's first leg is that the nucleotide's own origin involves sulfur chemistry before the phosphodiester backbone exists. The record the field now reads is written in phosphate; the chemistry that assembled its first monomers was not.

[O] How much of the prebiotic route ran through sulfur rather than through phosphate is an open question in a contested field. The volume's claim is only that the sulfur route is plausible, demonstrated in parts, and consistent with the mineral evidence.

267. Link three: the radical that made DNA

[E] Ribonucleotide reductase, treated in Chapter 19, is the only de novo route to deoxyribonucleotides and runs through a thiyl radical. The three classes of the enzyme map onto different oxygen regimes, and their distribution across the tree of life is consistent with the enzyme predating the oxygenation of the atmosphere.

[F] This is the chain's load-bearing link. Without it there is no DNA genome; with it, the archival molecule exists and everything downstream — inheritance at scale, large

genomes, multicellularity — becomes possible. The link is a sulfur radical chemistry and has no known alternative.

268. Link four: the code opens on sulfur

[E] Translation initiates at methionine, a sulfur amino acid, and in mitochondria at formylmethionine, which preserves the bacterial pattern. The tripeptide that defends the cell against oxidative damage, glutathione, is built around a cysteine and is not encoded as a gene product: it is made by two ligases in sequence.

[F] The code therefore opens on a sulfur amino acid, and the cell's principal chemical defense is a sulfur tripeptide that the code does not spell at all. Both facts are consistent with sulfur chemistry being older than the coding system that now sits on top of it.

[VOL p.323] ## 269. Link five: the event that changed the economy

[E] Cyanobacteria changed the reductant of photosynthesis from hydrogen sulfide to water, which released oxygen as waste. The Great Oxidation followed, dated by multiple independent proxies, among them the disappearance of mass-independent sulfur isotope fractionation from the rock record, which is itself a sulfur signal.

[F] Oxygen did not replace sulfur. It replaced sulfur's terminal electron acceptor and left every other job the element was doing in place: the clusters stayed, the thioesters stayed, the radical chemistry stayed, the methyl donor stayed. What changed is the end of the electron chain, and what that change bought is roughly an order of magnitude more free energy per carbon oxidized.

[E] The enzymes record the event. Nitrogenase, which predates oxygenation, holds its metal in a cluster with nine sulfurs and is irreversibly poisoned by oxygen; the molybdenum cofactor enzymes that arose later hold the same metal with two. The collapse from nine sulfurs to two is a chemical fossil of the atmospheric change, and Chapter 24 follows it.

270. Link six: the editors run on sulfur

[E] The enzymes used to edit genomes and epigenomes divide by chemistry. Nucleases cut, and cutting is magnesium chemistry: the two-metal-ion mechanism of phosphodiester hydrolysis uses magnesium, not sulfur. Writers — deaminases, methyltransferases, radical SAM enzymes, dioxygenases — run on sulfur chemistry in one form or another: a sulfonium methyl donor, a cluster, a zinc site with cysteine ligands, or a thiol in the active site.

[F] So the field's division between cutting and writing is, at the level of atoms, a division between magnesium chemistry and sulfur chemistry. The tools that only cut do not need the element; the tools that rewrite do.

271. Link seven: the clinic

[F] The last link is the one Part Six prices. The therapeutic traditions now in use — engineered proteins, antibodies, conjugates, modified-nucleoside RNA, editors, engineered cells, biomanufacturing — are built on the chemistry of the preceding six links, and six of the seven traditions depend on sulfur chemistry directly. The chain that started at a mineral ends in a manufacturing plant.

[VOL p.324] ## 272. The chain, stated as one line

[F] Everything to this point has been a map of one moment: a cell as it now stands, a pathway as now drawn, a trial as now reported. The chain in this Part runs the other axis. It starts in a mineral that formed before there was life to use it and ends in the enzymes now used to rewrite genomes, and at every link the thing that carries the step forward is a sulfur atom. Stated as one line: an iron-sulfur mineral became an electron-transfer cofactor; a thiophosphate backbone preceded the phosphate one; a thiyl radical converted RNA into DNA; the eight nucleotides of de novo synthesis were built with three one-way gatekeepers; the code they spell is read through a wobble position that carries sulfur modifications beside its inosine; the jumping genes that threatened to read self as foreign were marked with inosine instead; the two amino acids that open and close the reading are the two that carry sulfur; the tripeptide that defends the whole arrangement is a thiol; and the enzymes now used to edit all of it hold their catalytic metals with cysteine and cleave their methyl donor with a 4Fe-4S cluster.

273. Fe4S4: the mineral that became the cofactor

[E] Iron and sulfur precipitate together without any help from biology. Mackinawite and greigite form where hydrogen sulfide meets dissolved iron, and the cubane unit at the center of greigite is geometrically the same 4Fe-4S arrangement that sits in ferredoxin, in aconitase, and in Complexes I, II and III. At the Lost City hydrothermal field the chemistry still runs: alkaline fluid, dissolved sulfide, iron, and pore spaces with standing gradients across thin inorganic walls.

[F] The oldest cofactor in biology is a mineral that life did not have to invent, only to enclose.

That is why §231's finding — that every electron in respiration moves through an iron held by sulfur — is not an engineering choice. The electron-transfer chemistry predates the cell. The protein's contribution was to hold four of those clusters in series and tune their potentials, which is a packaging problem, not a chemical one. Ferredoxin, the smallest and most conserved of them, is close to the mineral with a peptide wrapped round it.

[E] The variety of sulfur minerals and salts available to that chemistry was not narrow. Pyrite, pyrrhotite, mackinawite, greigite and the metal sulfides generally; gypsum and the sulfate evaporites; native sulfur as a mineral species in its own right; and in the fluid phase sulfide, polysulfide, thiosulfate, sulfite and sulfate — nine formal oxidation states, all reachable without enzymes, all reachable at the

temperature of water.

[F] That range is the reason the first operation on the list of seven is the one that carries everything [VOL p.325] else. An element that can sit at nine oxidation states in a warm aqueous environment is an element that can run a redox economy before there are proteins to run it, and a redox economy is what a metabolism is.

274. Hydrogen sulfide before water, and a thiophosphate backbone

[E] The prebiotic syntheses that reach the nucleotides run through hydrogen sulfide. In the Sutherland chemistry hydrogen sulfide is the reductant, with ultraviolet light, that takes hydrogen cyanide through to the precursors of nucleotides, amino acids and lipids in one network. Inosine and its precursors fall out of that chemistry readily, and the same work found that a nucleoside with hypoxanthine is formed under conditions where the canonical purines are not.

[F] That matters for which four letters count as first. If inosine is prebiotically easier than guanine, then the base the modern record writes as G, and which §306 showed cannot be distinguished from an editor's product, was also the later arrival. The gatekeeper is older than the thing it gates.

[E] The backbone has the same two-phase history. Phosphorothioate linkages — a backbone in which one non-bridging oxygen is replaced by sulfur — form readily, resist hydrolysis far better than the all-oxygen linkage, and are still used by bacteria today as a genuine genomic modification, written by the Dnd enzymes and read as a restriction mark. They are also what every antisense oligonucleotide drug is built from, for exactly the stability reason.

[F] A sulfur-substituted backbone is more stable than the one life settled on, is made by a simpler chemistry, still exists in modern genomes, and is what the pharmaceutical industry reaches for when it needs an oligonucleotide to survive in a body. The canonical phosphate backbone is not the most durable option available; it is the one that permitted controlled degradation. Stability was traded for turnover, and the sulfur version is what the trade was made against.

275. Ribonucleotide reductase: a thiyl radical made DNA

[E] There is exactly one route from the RNA world to the DNA world, and every organism uses the same enzyme family to take it. Ribonucleotide reductase removes the 2′-hydroxyl from a ribonucleotide to give a deoxyribonucleotide. The mechanism begins with a transient thiyl radical on a cysteine, which abstracts the 3′-hydrogen; two further cysteines supply the reducing equivalents as a disulfide pair; and that disulfide is then re-reduced by thioredoxin or glutaredoxin, which are themselves regenerated by NADPH.

[VOL p.326] **[F]** Every deoxyribonucleotide in every genome on Earth was made by a sulfur radical, using two more sulfurs as the reductant, regenerated by a fourth. DNA does not contain sulfur. DNA exists because of it. The transition that the whole

history of life turns on is a single thiyl radical abstraction, and the enzyme that performs it in one of its three classes is itself a radical SAM enzyme carrying a 4Fe-4S cluster — which closes §273 and §274 into this section without any step in between.

[F] It also sets the clock. §231 of the sulfur account notes that entry into S-phase is gated by this enzyme: no reduced thioredoxin, no deoxyribonucleotides, no replication. A cell cannot divide until its sulfur is in the reduced state, which places a redox condition on the cell cycle upstream of every arrow in the Akt fan that ends in a balloon labeled cell cycle progression.

276. The synthetases, the tripeptide, and the bond

[E] The aminoacyl-tRNA synthetases are where the code is physically enforced: twenty enzymes, each charging one amino acid onto its tRNA, and the fidelity of the genetic code is their fidelity and nothing else. Two of them are the sulfur pair. Methionyl-tRNA synthetase charges the start. Cysteinyl-tRNA synthetase charges the residue that will become every disulfide, every catalytic thiolate, every iron-sulfur ligand and every conjugation site in Part IV.

[F] Selenocysteine is the exception that shows the rule's shape. There is no selenocysteinyl-tRNA synthetase. The twenty-first amino acid is not charged directly: a serine is loaded onto tRNA-Sec and then converted in place, through a phosphoserine intermediate, by selenocysteine synthase using selenophosphate. The code has no front door for it. It is made on the tRNA, at the ribosome, by rewriting a stop codon — which is why §204 assigns the ribosome to selenium and why the twenty-second amino acid, pyrrolysine, arrives the same way through the other leaky stop.

[E] Glutathione is the tripeptide the whole arrangement defends itself with: glutamate, cysteine, glycine, with the cysteine thiol doing the work and an unusual gamma-linkage at the glutamate end that protects it from ordinary peptidases. It is present at millimolar concentration, which is extraordinary for a tripeptide, and the ratio of its reduced to oxidized form is the cell's redox potential in the most literal sense — the number that the cell cycle tracks.

[F] Glutathione is not synthesized by the ribosome. It is made by two ATP-dependent ligases, outside the code entirely. The molecule that sets the redox state on which the code's own fidelity depends is the one molecule in this chain that the code does not spell. That is worth [VOL p.327] stating plainly rather than passing over: the defense is older than the notation that would have described it.

[E] The disulfide then carries the result into protein. It is the only reversible covalent crosslink between side chains in the canonical twenty — insulin's three, the four chains of an immunoglobulin, keratin's density, the rhodopsin bond in the eye. And it is the bond §290 showed switching PTEN off and §304 showed carrying three of the seven engineering traditions.

277. The sulfur enzymes of gene and epigenetic editing

[F] The chain ends in the instruments now used to rewrite what it built, and the instruments are made of the same element. Table 9 gives the sulfur in each. Every editing enzyme in current clinical or preclinical use either holds its catalytic metal with cysteine, uses a cysteine thiolate as its nucleophile, or cleaves its methyl donor with a 4Fe-4S cluster — and several do two of the three.

Adenine base editor Catalytic zinc held by Deaminates A to I; The tool was made from the (TadA) cysteine residues evolved from the target: TadA does at DNA what tRNA-34 enzyme of §61 ADAT does at position 34 Cytosine base Catalytic zinc held by Deaminates C to U, read Same zinc-thiolate architecture editor cysteine residues as T as the adenine editor (APOBEC/AID)

DNA Catalytic cysteine Attacks C6 of C to form Two sulfurs in one mechanism: methyltransferase thiolate; a covalent intermediate, the nucleophile and the donor (DNMT) S-adenosylmethionine then transfers the methyl as donor **Histone methyltransferase S-adenosylmethionine Writes every histone as donor methyl mark Supply-limited by the sulfonium pool of §233** Histone acetyltransferase Acetyl-coenzyme A Writes every histone — a thioester acetyl mark Supply-limited by mitochondrial citrate export TET demethylase Zinc-binding domain Oxidizes 5-methylC; the Inhibited by succinate and with cysteines; Fe(II) dCas9-TET1 fusion of fumarate from the cycle of §230 center Table 7 Radical SAM 4Fe-4S cluster that Generate a The mineral of §273 and the enzymes cleaves 5′- deoxyadenosyl sulfonium of §233 in one active S-adenosylmethionine radical for chemistry site nothing else reaches [VOL p.328] MiaB and the meth 4Fe-4S clusters plus a Add a thiomethyl group A radical SAM enzyme that ylthiotransferases sulfur donor to tRNA installs sulfur using sulfur MTU1/TRMU, Persulfide relay from Install 2-thiouridine at The same donor that builds the **MnmA NFS1 wobble position 34 iron-sulfur clusters** Cysteine Persulfide on its own Supplies sulfur to desulfurase (NFS1) active-site cysteine clusters, to tRNA thiolation, to the molybdenum cofactor The single upstream source for the whole table Zinc-finger Zinc held by cysteine Sequence-specific nucleases and histidine cleavage The oldest programmable editor, and a thiolate-held metal Cas9 nuclease Cysteines structural; Double-strand cleavage Mg in the active site The one editor whose catalysis is not sulfur-dependent Thioredoxin / Vicinal cysteine pair Re-reduce No deoxyribonucleotides for glutaredoxin ribonucleotide reductase any editor to act on without after every turn them **Table 9.** The sulfur chemistry of the enzymes used in gene and epigenetic editing.

[F] One row in that table is the exception and it is worth naming. Cas9’s catalysis is magnesium, not sulfur — the only entry where the element does not carry the chemistry. And Cas9 is also the only one of these that does nothing but cut. Every editor that writes rather than cuts — both base editors, both methyltransferase classes, the acetyltransferases, the demethylases, the radical SAM family — runs on sulfur. Cutting is a magnesium operation; writing is a sulfur operation. That division

is not something this chapter set out to find.

278. The chain closed

[F] Run the chain once more in a single pass, and the shape is a circuit rather than a line. An iron-sulfur mineral precipitated out of sulfidic water and became the electron-transfer cofactor every respiratory chain still uses. Hydrogen sulfide was the reductant that reached the first nucleotides, and inosine came out of that chemistry before guanine did. A thiophosphate backbone was available and more stable than the one life chose. A thiyl radical on a cysteine converted ribonucleotides into deoxyribonucleotides and made the DNA world possible, and in one of its three enzyme classes the radical is generated by a 4Fe-4S cluster cleaving S-adenosylmethionine — the mineral and the methyl carrier in a single active site. De novo [VOL p.329] synthesis built eight nucleotides through three one-way gatekeepers with inosine monophosphate as the trunk. The code those nucleotides spell opens on methionine, a sulfur amino acid, and is read through a wobble position that carries both inosine and 2-thiouridine, the thiolation installed by the same cysteine desulfurase that builds the clusters. The jumping genes that would have been read as foreign were marked as self with inosine. The tripeptide holding the whole redox state is a thiol the code does not spell. The bond carrying the result into protein is the disulfide. And the enzymes now used to rewrite any of it hold their metals with cysteine and cleave their methyl donor with the cluster the chain started from.

[F] The element does not appear once at each stage. It appears as the same seven operations, in a different arrangement, at every stage — which is why the mapping in §289 closed without remainder and why the list in §202 is a structure rather than an inventory. Nothing in this is design. Sulfur was the most chemically versatile atom available when the foundations were laid, it was built into them, and it cannot be replaced now because replacing it would mean rebuilding everything standing on top of it.

[F] And at every link the same thing fails in the same way. The chemical state that decided the step is not in the record of the step. A disulfide is one letter. An inosine prints as G. A thiolation at position thirty-four is absent from the sequence. A 4Fe-4S cluster is four cysteines in a row and nothing else. The three registers that lose the atom — the sequence file, the nutrition label, the clinical differential — lose it for one reason, and this chain is the long form of that reason: the atom is always inside a molecule by the time anyone looks.

279. What would break the chain

[F] Each link has a specific failure condition, and listing them is the point of stating the chain as a chain. **link what would break it** the mineral a demonstration that cluster geometry in proteins differs structurally from the mineral unit in a way that rules out capture sulfide before phosphate prebiotic routes to nucleotides that are efficient without any sulfur species, under plausible conditions the radical that made DNA an alternative de novo route to deoxyribonucleotides not using a cysteine

radical [VOL p.330] **link what would break it** the code opens on sulfur an organism initiating translation with a non-sulfur residue as its standard start the oxidation event evidence that cluster chemistry postdates oxygenation rather than predating it the editors a writing chemistry at scale that uses no sulfur-dependent cofactor the clinic a therapeutic tradition set that is majority non-sulfur in its enabling chemistry **Table.** The seven links and the observation that would break each.

[F] Three of the seven are exposed to existing data and could fail tomorrow. The prebiotic link is the weakest and is marked open in the text; the volume does not depend on it, and removing it leaves a chain from the mineral to the clinic that still closes.

280. What the chain does not claim

[F] It does not claim that sulfur caused any of these transitions in a historical sense. The mineral did not become a cluster by intention, and the claim is chemical continuity, not agency.

[F] It does not claim priority over competing accounts of the origin of life. Several accounts are live, and the volume's dependency is narrow: nucleotide chemistry was available before coded protein synthesis, and sulfur chemistry was available before both.

[F] It does not claim that the Great Oxidation was unimportant. It claims something more specific — that oxygen's arrival changed the terminal acceptor and left the rest of the sulfur economy intact — and the evidence for that is the persistence of every other sulfur function in every aerobic organism alive.

281. Consequences

[F] The chain's main consequence is interpretive. It explains why an element with no letter in the code should nonetheless be found at the catalytic step of so many processes: because those processes were built on chemistry that existed before the code did, and the code was laid over a working metabolism rather than the other way round.

[F] It also predicts where to look for further instances. Any process that is universal across the tree of life, requires a difficult chemical step, and has no alternative route, should be expected to run on sulfur, iron or both. Three of the volume's later discoveries — the cluster helicases, [VOL p.331] the molybdenum cofactor's three sulfur steps, and the shared desulfurase supply — were found by applying that expectation rather than by accident.

[O] The open question the chain raises is the one Chapter 25 confronts head on: if sulfur chemistry is older than the code, why are the two sulfur amino acids late additions to the code? The objection is serious, it is stated there at full strength, and the answer offered — that supply is not repertoire, and that an element can run a metabolism for a billion years before it is assigned a codeword — bounds the claim rather than defeating it.

282. Notes to Chapter 21: the chain, dated

Quantities worth carrying

[E] The Great Oxidation. Conventionally dated to approximately 2.4 billion years ago, with the sharpest single marker being the disappearance of mass-independent sulfur isotope fractionation from the sedimentary record, which requires an atmosphere essentially free of oxygen to be generated.

[E] Banded iron formations. Deposited in large volume before and across the transition, and interpreted as the precipitation of oxidized iron from an ocean that had carried dissolved ferrous iron for hundreds of millions of years.

[E] Energy yield. Aerobic oxidation of glucose releases roughly an order of magnitude more free energy than anaerobic fermentation of the same substrate, which is the quantitative statement of what the change in terminal acceptor bought.

[E] Cluster geometry. The Fe4S4 cubane in greigite and the [4Fe-4S] cluster in ferredoxins share the same core arrangement; in the protein the cluster is held by four cysteine thiolates and its redox potential is tuned by the surrounding fold.

[E] Nitrogenase. The iron-molybdenum cofactor contains seven irons, nine sulfurs, one molybdenum and an interstitial carbon, and is irreversibly damaged by oxygen, which is why nitrogen fixation in aerobic organisms requires physical protection of the enzyme.

Methods box: how deep-time claims are supported

[F] Isotopic signatures. Sulfur has four stable isotopes, and mass-independent fractionation among them is produced by gas-phase photochemistry that requires an ozone-free atmosphere. Its presence in old rocks and absence in younger ones is the most direct available proxy for atmospheric oxygen.

[F] Mineral phase relations. Which iron sulfide precipitates depends on temperature, sulfide [VOL p.332] activity and pH, so the mineral assemblage constrains the chemistry of the water it formed in. Laboratory syntheses under controlled conditions provide the calibration.

[F] Phylogenetic distribution of enzyme classes. The distribution of the three ribonucleotide reductase classes, and of oxygen-sensitive versus oxygen-tolerant chemistries generally, gives a relative ordering. Calibrating that ordering to absolute dates requires molecular clock assumptions that carry substantial uncertainty.

[F] Prebiotic synthesis. Demonstrating that a reaction proceeds under plausible conditions establishes availability only. The volume marks all such claims open, and the chain's prebiotic link is the one it does not lean on.

Worked example: reading the collapse from nine sulfurs to two

[F] Set two cofactors side by side. Nitrogenase's cofactor holds molybdenum in a cluster with nine sulfurs and seven irons, performs the six-electron reduction of dinitrogen, operates only in the absence of oxygen, and requires sixteen ATP per

turnover in the physiological reaction.

The molybdenum cofactor of sulfite oxidase and xanthine dehydrogenase holds the same metal with two sulfurs of a dithiolene, performs two-electron oxygen-atom transfer, and operates in air.

[F] Read as a pair, the two record the change in what the metal was asked to do. Breaking the dinitrogen triple bond requires a large, electron-rich, highly reduced cluster, which is incom-patible with oxygen. Transferring an oxygen atom to a substrate requires a mononuclear site with a high-valent metal, which is only available when oxygen is present. The metal did not change. The chemistry it was asked to perform changed, and the sulfur ligation changed with it.

[F] That is the chapter's argument in miniature, and it is checkable: both structures are solved, both chemistries are characterized, and the phylogenetic ordering of the two enzyme families is established.

Problems

[O] 21.1 For each of the seven links, find the single publication you would cite as its strongest support, and judge whether the link is established, probable or open.

[O] 21.2 Construct the chain without its prebiotic link and determine whether any later argument weakens.

[O] 21.3 The chapter claims oxygen replaced sulfur's terminal acceptor and nothing else. Enumerate sulfur's jobs before and after oxygenation and test the claim job by job.

[VOL p.333] **[O] 21.4** The cubane geometry argument is structural. How similar is similar enough? Specify a quantitative criterion and apply it.

[O] 21.5 Six of seven therapeutic traditions depend on sulfur chemistry. Score them yourself from primary sources and see whether you get six.

[O] 21.6 Design the analysis that would test whether cluster-dependent enzymes are systematically older than their cluster-independent functional equivalents.

Connections

[F] The chain organizes Part Five's historical material and hands two things forward: the cofactor comparison that Chapter 24 develops into a case study, and the editing-versus-cutting distinction that Chapter 23 uses to separate therapeutic traditions by chemistry.

Worked example: checking one link against its breaking condition

[F] Take link one — the mineral — and run it against the breaking condition stated in the chapter's table: a demonstration that cluster geometry in proteins differs structurally from the mineral unit in a way that rules out capture.

[F] What the claim requires. That the Fe4S4 unit in greigite and the [4Fe-4S] cluster in ferredoxins are the same arrangement of atoms, within the tolerance that a

protein environment imposes.

[F] What the evidence is. Both are cubane arrangements of four irons and four sulfides at alternating vertices. The mineral's unit sits in an extended lattice; the protein's is discrete, terminated by four cysteine thiolates, and distorted by the protein's geometry. Bond lengths differ modestly; the topology does not.

[F] What would break it. A demonstration that the protein cluster's core geometry differs from the mineral's in a way that cannot be reached by relaxing a fragment of the lattice — a different connectivity rather than a different distortion.

[F] Where the claim is weakest. Not in the structures, which are well determined, but in the inference from structural similarity to historical capture. Convergence is possible: a cubane is a compact, electronically favorable arrangement, and a protein might arrive at it independently. The honest statement is that the geometry is the same and that sameness is consistent with capture without demonstrating it.

[F] How a reader should weight it. As the volume does: the chain is stated with this link included, and the chapter notes that removing the prebiotic link still leaves a chain that [VOL p.334] closes. Link one is stronger than link two and weaker than link three, and its function in the argument is to explain why the cluster did not have to be invented, not to prove that it was not.

[F] The general lesson for reading chains. A chain's strength is its weakest link, so every link should carry its own breaking condition in print. A chain presented without breaking conditions is a narrative, and narratives are not checkable.

[VOL p.335] Review of Part V

What Part Five established

[F] The element has an entry at every register and performs seven operations. Twelve scales at which an account of matter is kept, an entry at each, and seven operations — carrying electrons, forming reversible cross-links, holding metals, transferring acyl groups, carrying methyl groups, tuning recognition, absorbing oxidative damage — that exhaust what the element does at any of them. The list is offered as complete and is therefore falsifiable.

[E] The organizing structure is a ladder, and its lower half is reversible. Thiol to sulfenic acid to disulfide and back is routine cellular chemistry; oxidation past sulfinic acid is, with one slow exception, terminal. That boundary is the physical location of the distinction between signaling and damage, and selenium is placed in the proteome exactly where a thiol would cross it.

[E] All three pillars of respiration have a sulfur switch at the decisive step. A thioester at the one energy-conserving step of glycolysis; lipoate at both dehydrogenase complexes of the citric acid cycle; iron held by cysteine sulfur at every intermediate electron transfer of the chain. The two currencies the mitochondrion exports — acetyl and methyl groups — are both carried on sulfur.

[E] The genome is made, opened and read with sulfur chemistry. A transient thiyl radical converts ribonucleotides into deoxyribonucleotides, which is the chemical event that makes an archival genome possible; cluster helicases open the helix for repair and replication; and the wobble base that holds the reading frame is thiolated from cysteine sulfur.

[E] One supplier serves both ends. The mitochondrial cysteine desulfurase delivers sulfur to cluster assembly, which supports respiration and nuclear repair, and to wobble thiolation, which supports translational accuracy. Cluster assembly is mitochondrial and exclusive, which is why mitochondrial failures cannot stay local.

[F] The chain from mineral to editor closes. Seven links, each with a stated breaking condition: the Fe4S4 cubane of an iron sulfide mineral; sulfide chemistry before phosphate; the radical that made DNA; a code that opens on a sulfur amino acid and a defense tripeptide the code does not spell; the Great Oxidation, which replaced sulfur's terminal acceptor and left the rest intact; editors that write on sulfur chemistry while nucleases cut on magnesium; and a [VOL p.336] clinic whose traditions are six-sevenths sulfur-dependent.

What Part Five did not establish

[O] The compartment keying rests on a chemistry argument with two independent confirmations out of thirteen. The propagation experiment at the end of Chapter 20 is the test, and it has not been done.

[O] The priority among the desulfurase's outputs is unknown. When sulfur is scarce, whether the cell protects respiration or the reading frame is the Part's sharpest open question and the cheapest to settle.

[O] The prebiotic link of the chain is contested in its strong form, and the volume takes only the weak form. Removing it leaves a chain that still closes from the mineral forward.

Questions a reader should be able to answer

[O] R5.1 Name the seven operations and give one carrier for each.

[O] R5.2 Where on the oxidation ladder does signaling end and damage begin, and what is the one exception?

[O] R5.3 Why is sulfur, rather than oxygen, the element that holds metals in biological clusters?

[O] R5.4 Trace the five sulfur atoms involved in making one deoxyribonucleotide.

[O] R5.5 Why can a failure in the mitochondrion not stay local, when a failure in the endoplasmic reticulum can?

[O] R5.6 State the breaking condition for any three links of the chain in Chapter 21.

Where to go next

[F] Part Six puts the account at risk: one signaling node mapped by compartment, a clinical record read against the map, a cofactor case study chosen because it can fail cleanly, and the strongest objection stated without softening. A reader who has accepted Part Five should expect Part Six to be where the account either earns its keep or does not.

8. The network, the fan and the clinic

[VOL p.337] **Part VI**

The Network, the Fan and the Clinic

[VOL p.338] Four chapters in which the account is put at risk.

The third leg of the argument is the network: one mitochondrion in conversation with twelve other compartments, and a signaling architecture whose outputs are distributed across them unevenly. Chapter 22 maps that architecture at one node, Akt, with twenty-seven outward arrows filed by organelle rather than by pathway. Chapter 23 reads the clinical record against the map: five Phase 3 programs against the hub with no overall-survival benefit, four of four programs against single spokes with one, and redundancy of output as the variable that separates them. Chapter 24 is a case study chosen because it can fail cleanly — one cofactor, built in three sulfur steps, carried by two enzymes, with three inherited deficiencies whose severity grades by which atom is stranded. Chapter 25 states the strongest objection to the whole account without softening it, answers what can be answered, concedes what cannot, and sets out what follows for a development program.

A volume that only accumulated agreement with itself would be worth less than one that names the conditions under which it would be abandoned. Those conditions are stated at the end of Chapter 25 and again in Appendix C. They are ordinary experimental conditions, and most of them are cheap.

[VOL p.339] **CHAPTER 22**

Twenty-Seven Arrows from One Node

Abstract. One kinase node in human cells carries twenty-seven documented outward arrows. Filed by pathway, the fan looks like a list of substrates. Filed by organelle, it resolves into an architecture in which some compartments receive many arrows and others receive one, and the unevenness predicts which interventions will be compensated. This chapter maps the fan, places the seven operations of sulfur onto it, and takes apart the one node in the system that is switched by a reversible disulfide rather than by a mutation.

283. The node and its arrows

[E] Akt is a serine-threonine kinase recruited to the plasma membrane by the lipid product of phosphoinositide 3-kinase, activated by two phosphorylations, and opposed by the lipid phosphatase PTEN, which removes the lipid signal. Its substrates run into the dozens; the well-documented outputs include GSK3 and glycogen synthesis, the TSC complex and mTORC1, FOXO transcription factors, the apoptotic regulator BAD, MDM2 and thereby p53, GLUT4 trafficking, and a set of

metabolic enzymes.

[F] Filed as a list, this is unhelpful: a node with dozens of substrates is a hub, and hubs are assumed to be important. Filed by the compartment in which the output is executed, the picture changes, because the number of distinct compartments is small and the distribution across them is uneven.

[F] The arrows sort into outputs executed at the nucleus (transcription factor localization, MDM2 and p53), at the mitochondrion (apoptotic regulation, metabolic enzyme phosphorylation), at the plasma membrane and its vesicle traffic (glucose transporter translocation), at the endoplasmic reticulum (calcium handling and stress response), at the ribosome and translational machinery via mTORC1, and at the cytoskeleton. Some of those compartments receive several independent arrows; others receive a single one.

284. Why the sort matters

[F] The therapeutic claim that follows is simple to state and is tested against the record in Chapter

23. An output that is reachable by several independent routes will be restored after a node is inhibited; an output reachable by one route will not. Redundancy is a property of the [VOL p.340] architecture, and the architecture is organized by compartment because that is where the outputs are executed.

[F] It follows that the right question about a drug target is not how central it is but how distributed its output is. Centrality predicts the breadth of the effect; distribution predicts whether the effect can be bypassed. The field has optimized for the first and has measured the second only after Phase 3.

285. The seven operations on the architecture

[F] The seven operations of Chapter 16 map onto seven distinct points of this architecture, one

to one, with no operation spare and no point unaccounted for.		
operation	**where it lands on this architecture**	**what it decides**
carries electrons	the redox tone that sets Akt and PTEN	the set point of the entire fan
reversibly	activity	
forms reversible	the PTEN disulfide between two	whether the brake is on or off
cross-links	cysteines	

holds metals	iron-sulfur clusters in respiration and in base-excision repair	whether the mitochondrion produces, and whether an edit is made permanent
transfers acyl	acetyl-coenzyme A	the citric acid cycle and every histone
groups		acetylation mark
carries methyl	S-adenosylmethionine, and the	every methyl mark, and one input to growth
groups	sulfonium sensed upstream of mTORC1	signaling
tunes recognition	2-thiouridine at anticodon position 34	the reading frame of every protein the fan produces
absorbs oxidative	glutathione, thioredoxin, peroxiredoxin	whether an oxidative episode is signal or
damage		damage

Table. The seven operations of sulfur mapped onto seven distinct points of one signaling and therapeutic architecture.

[F] That the mapping closes without remainder is not proof of anything by itself. What it does is place the element at seven independent points of a system that was described without any reference to it, which is the condition under which a claim of control becomes testable rather than rhetorical.

[VOL p.341] ## 286. PTEN is a disulfide switch

[E] PTEN is the phosphatase that removes the lipid signal recruiting Akt to the membrane. It is the brake on the entire fan, and it is among the most frequently inactivated tumor suppressors in human cancer.

[E] It is also inactivated reversibly by oxidation. Two cysteines in and adjacent to the active site form an intramolecular disulfide under oxidative conditions, which abolishes catalytic activity; reduction restores it. The modification is physiological — growth factor signaling generates a peroxide burst that transiently oxidizes PTEN as part of normal signal transduc-tion — and it is the mechanism by which the brake is released on purpose.

[F] A tumor with an intact PTEN sequence and an oxidized PTEN protein is Akt-active and genotypically normal. It will not be selected by any genotype-based enrollment criterion, and it will not appear in any sequencing-based analysis of why a trial failed. Chapter 23 shows what that cost in the trial record.

[E] A parallel input sits on the same architecture through a different sulfur species. The sensor that gates mTORC1 in response to methionine availability binds S-adenosylmethionine — a sulfonium — and relieves its inhibition of the growth complex when the methyl economy is replete. Growth signaling therefore has a direct sulfur-metabolite input running in parallel to the kinase fan.

287. Twenty-seven arrows from one node

[E] Akt sits at the center of the canonical pathway diagram with a radiating set of outward arrows, each ending in a labeled outcome. Tracing every arrow from hub to terminal label gives twenty-seven routes: TSC2 released to mTOR, ending in protein synthesis; GSK3 inhibited, ending in glycogen synthesis; BAD sequestered, ending in cell survival; caspase-9 inhibited, ending in a blocked caspase cascade; MDM2 activated, ending in p53 degradation; FOXO exported, ending in death genes switched off; p21 and p27 held in the cytoplasm, ending in cell cycle progression; eNOS activated, ending in nitric oxide; the GLUT4 vesicle translocated, ending in glucose import; and eighteen more.

[F] The important property is not the identity of any one arrow but the arity of the node. Twenty-seven outputs from one kinase is an unusual architecture, and it is the architecture, not the kinase, that the rest of this chapter is about.

[VOL p.342] ## 288. The fan is organelle-sorted, and the sort is uneven

[F] Filing the twenty-seven arrows by the organelle in which each target acts gives a markedly uneven distribution. Nine land in the nucleus. Seven are cytoplasmic. Three land at the mitochondrion and all three concern the same decision. Two land at the lysosome, both on mTORC1, which is assembled on the lysosomal surface. Two at the ribosome. The Golgi, the peroxisome and the chloroplast receive none at all.

Lysosome 2 protein synthesis and translation; apoptosis inhibition **Table 3.** The twenty-seven outward arrows of the Akt fan, filed by the organelle in which each target acts.

[F] The zeros are as informative as the counts. The Golgi and the peroxisome are run by manganese and iron, and neither appears anywhere in the fan. An organelle governed by a metal outside the seven is an organelle the pathway does not signal to directly — it reaches them, when it reaches them at all, through the mitochondrion’s conversations in Table 2 rather than by its own arrow.

289. The seven operations mapped onto the architecture

[F] The seven operations of §202 were derived from twelve scales of matter with no reference to a signaling pathway. Mapped onto this architecture they land one to one, on seven distinct points, with no operation spare and no point unaccounted for. Table 4 sets out the correspondence. operation where it lands on this what it decides architecture

1. Carries electrons The redox tone that sets Akt Akt’s own cysteines and PTEN’s are **reversibly and PTEN activity oxidation-sensitive; the fan’s set point is a redox state** operation where it lands on this architecture what it decides

2. Reversible covalent cross-link The PTEN Cys71–Cys124 disulfide The brake on the entire fan is thrown by a bond that can be made and unmade (§290)

3. Holds metals Iron-sulfur clusters in the respiratory chain and in DNA repair Respiration (§231); and the base-excision-repair fork that decides whether an edit is

permanent (§305)

[VOL p.343] **4.** Transfers acyl groups Acetyl-coenzyme A The citric acid cycle (§230) and every histone acetylation mark (§233)

5. Carries methyl groups S-adenosylmethionine, and Every methyl mark; and the sulfonium gate on SAMTOR mTORC1, a balloon of the fan (§291)

6. Tunes recognition 2-thiouridine at anticodon position thirty-four Reading frame at the ribosome — the same position at which inosine does the wobble work

7. Absorbs oxidative damage Glutathione, thioredoxin, the peroxiredoxins, GPX4 Engineered-cell persistence (§304); and the ferroptosis axis that limits tradition six **Table 4.** The seven operations of sulfur mapped onto seven distinct points of the signaling and therapeutic architecture.

[F] Seven operations, seven landing points, one to one. That the mapping closes without remainder is not proof of anything on its own — a list of seven will often cover seven slots if the slots are chosen loosely. What makes it worth printing is that the operations were fixed first, derived from molecular clouds and mineral species and industrial chemistry, and the landing points were fixed independently by tracing arrows on a pathway diagram. Neither list was built to fit the other.

290. PTEN is a disulfide switch, and the trials selected on the wrong register

[E] PTEN is the phosphatase that removes the lipid signal recruiting Akt to the membrane. It is the brake on the entire fan. It is inactivated by deletion and by mutation, and it is also inactivated, reversibly, by oxidation: hydrogen peroxide drives formation of an intramolecular disulfide between the catalytic cysteine at residue 124 and cysteine 71, which abolishes phosphatase activity until thioredoxin reduces it back.

[F] A tumor with an intact PTEN sequence and an oxidized PTEN protein is Akt-active and genotypically normal. It has the phenotype the trial is selecting for and it fails the entry criterion. Every patient so constituted was screened out of CAPItello-281 and IPATential150, both of which enrolled on PTEN loss — IPATential150 by immunohistochemistry, which sees protein level and not redox state, and both by a register that cannot represent a disulfide at all.

[F] This is the notation argument reaching a clinical trial. The sequence file records a cysteine as one letter whether it is a free thiol, half of a structural disulfide, a catalytic thiolate or an [VOL p.344] oxidized artifact. A trial enrolling on PTEN genotype is enrolling on the register that loses the atom, and it will therefore contain, in its control arm and outside its enrollment entirely, patients whose Akt pathway is switched on by exactly the mechanism the drug was built to oppose.

[H] The hypothesis this licenses is specific and testable. If oxidative PTEN inactivation accounts for a meaningful share of Akt-active disease, then the trials’

PTEN-genotype-selected populations are diluted in both directions, and a redox-state assay — a simple non-reducing immunoblot distinguishes the oxidized from the reduced form — would identify responders the genotype misses. That is a cheap experiment on banked tissue and it has not been done.

[O] Whether it would change the survival result in §302 is a separate question and this chapter does not claim it would. The redundancy argument of §303 predicts that better patient selection improves the effect size at the hub without converting progression-free benefit into survival benefit, because selection does not reduce the number of escape routes. The two predictions are distinguishable in one trial.

291. SAMTOR: a sulfur sensor sitting on the fan

[E] SAMTOR binds S-adenosylmethionine directly — a sulfonium, one of the classes the eighteen-group table omits — and gates mTORC1 through the GATOR1 complex. When the sulfonium is scarce, SAMTOR represses mTORC1; when it is plentiful, the repression lifts. mTORC1 is therefore gated by methionine availability as well as by growth-factor signaling.

[F] mTORC1 is one of the twenty-seven balloons. Akt reaches it by inhibiting TSC2; SAMTOR reaches it by reporting the sulfonium pool. The lysosomal balloon has two independent upstream inputs, and only one of them is Akt. That is a structural fact about the fan that the pathway diagram does not show, because the diagram draws signaling and not supply.

[F] It supplies a mechanism for a result in the trial record that the redundancy argument alone explains only in part. Inhibiting Akt removes one of mTORC1's two inputs and leaves the other intact: a cell with a full methionine supply continues to relieve SAMTOR repression and continues to run mTORC1 whatever the hub inhibitor is doing. Inhibiting mTOR directly removes the output regardless of either input. That is why temsirolimus won overall survival where capivasertib and ipatasertib did not, stated as a mechanism rather than as a correlation: the hub inhibitor is bypassed at this balloon by the sulfur economy.

[H] The prediction is direct. Methionine restriction should potentiate an Akt inhibitor specifically at the mTORC1-dependent outputs, and should do so without potentiating it at the mitochondrial [VOL p.345] or nuclear balloons. Dietary methionine restriction is already under study in oncology for other reasons, which makes the combination testable without new chemistry.

[F] Read against §232 of the sulfur account, this is the same finding arrived at from the other side. There is no sensor that counts sulfur atoms; every sensor for sulfur is built out of sulfur and reports the atom's work rather than its quantity. SAMTOR is one of those sensors, and what it reports its reading to is the growth decision. The cell does not measure how much sulfur it holds, but it does let the sulfonium pool decide whether to grow.

292. What the fan looks like when the sort is done

[F] Three features of the organelle-sorted fan carry forward into the clinical chapter.

• **The sort is uneven.** A small number of compartments receive multiple independent arrows, and those compartments are where inhibition of the hub is most easily compensated. The compartments receiving a single arrow are where a hub inhibitor should produce its only durable effects, and they are also where a spoke-directed agent should work.

• **Two arrows are chemical rather than phosphorylative.** The redox tone that sets the activity of both the kinase and its phosphatase is a chemical input, not a signaling one, and the methionine sensor is a metabolite input. Neither appears in a kinase-substrate map, and both change the output of the fan.

• **The brake is thrown by a bond.** Of everything in the architecture, the single most consequential switch — the one that releases the brake on the entire fan — is a reversible disulfide. No sequencing of any kind reports it.

293. Objections

[F] Twenty-seven arrows is an arbitrary count. It is a count of well-documented outputs at the time of compilation, and the number will move as the literature grows. Nothing in the argument depends on the number; it depends on the distribution across compartments, which is robust to adding or removing individual substrates.

[F] Oxidative inactivation of PTEN is a cell-culture phenomenon. The modification has been demonstrated in cells under physiological growth factor stimulation and is detectable in tissue. The honest statement of its status is that its quantitative contribution to human tumors is unmeasured, which is precisely why the test proposed below is worth running.

[F] Mapping seven operations onto seven points is numerology again. The mapping is exposed in the same way as the rest: an eighth operation, or a point of the architecture that no [VOL p.346] operation lands on, breaks it. The seven were fixed in Chapter 16 before this architecture was examined.

294. Tests

• **Redox state of PTEN in primary tumors.** A non-reducing immunoblot or a differential alkylation assay on banked tumor lysates, stratified by PTEN genotype. The prediction is that a measurable fraction of sequence-wild-type tumors carry oxidized, inactive protein, and that this fraction is enriched in tumors with high oxidative tone.

• **Fan output under redox clamp.** Hold the compartmental redox state fixed with genetically encoded tools and measure how much of the variability in Akt output across cells disappears. This partitions the fan’s variance into signaling and chemical components, which has never been done.

• **Methionine input to growth signaling.** Vary methionine availability while holding growth factor stimulation constant and measure mTORC1 output through the

sulfonium sensor. The experiment is standard and the quantitative result — how much of growth signaling is metabolite-driven — is not in the literature.

295. Consequences

[F] The chapter's result is that a signaling architecture described entirely in terms of phosphorylation has at least three decisive inputs that are chemical: the redox tone that sets the activity of the kinase and its phosphatase, the disulfide that switches the brake, and the sulfonium that reports the methyl economy. A model that contains only the phosphorylation events is incomplete in a way that matters for drug development, because two of the three chemical inputs can inactivate a tumor suppressor or activate growth signaling without any genetic change.

[F] The practical consequence is an enrollment criterion. If a fraction of sequence-wild-type tumors are functionally PTEN-null by oxidation, then trials selecting on PTEN genotype have been enrolling a mixed population and attributing the resulting heterogeneity to biology they could not see. Chapter 23 examines what happened in the trials that did exactly that.

296. Notes to Chapter 22: the fan, measured

Quantities worth carrying

[E] Pathway components. Three Akt isoforms in human cells with overlapping but non-identical substrate preferences and tissue distributions; a lipid kinase upstream with its own [VOL p.347] catalytic and regulatory subunits; and a lipid phosphatase opposing it.

[E] Mutation frequency. Activating mutations in the lipid kinase are among the most common in human cancer, with a small number of hotspot residues accounting for most of them. Loss of the phosphatase occurs by deletion, by mutation and by promoter methylation.

[E] Peroxide burst. Growth factor stimulation generates a transient, localized rise in peroxide concentration, which oxidizes the phosphatase reversibly and is required for full signaling. The burst is measured with targeted sensors and is spatially restricted.

[E] Disulfide timing. Oxidative inactivation of the phosphatase and its reduction back occur on timescales of minutes, which places the switch in the same temporal regime as the phosphorylation events it modulates.

[E] Sulfonium sensing. The regulator that reports methionine status binds S-adenosylmethionine with an affinity in the physiological range, which is what makes it a sensor rather than a constitutive inhibitor.

Methods box: measuring a redox switch in tissue

[F] Non-reducing immunoblot. Lysate prepared with free thiols blocked and without reducing agent; the oxidized, disulfide-linked form migrates differently from the reduced form. Simple, cheap, and critically dependent on preventing oxidation

during lysis, which is controlled by degassed buffers, chelators and rapid processing.

[F] Differential alkylation with mass spectrometry. Gives site-level resolution and quantitation, distinguishing the specific cysteine pair involved from other oxidation events.

[F] Targeted sensors in live cells. Genetically encoded peroxide and redox sensors directed to the plasma membrane report the local burst rather than the bulk state, which matters because the burst is spatially confined.

[F] Functional readout. Lipid phosphatase activity can be assayed directly on the immuno-precipitated protein, giving the physiologically relevant number — active enzyme per total enzyme — rather than a modification state inferred from a gel.

Worked example: sorting one output by compartment

[F] Take glucose uptake. The output is executed at the plasma membrane by translocation of a glucose transporter from intracellular vesicles. The kinase contributes by phosphorylating a tethering protein, releasing the vesicles.

[F] Now ask what else can produce the same output. Exercise-associated signaling through an energy-sensing kinase mobilizes the same transporter by a different route; several stress [VOL p.348] pathways converge on the same traffic step. The output therefore has at least two independent inputs, and inhibiting the hub should reduce but not abolish it, which is exactly what is observed clinically as the hyperglycemia that limits dosing of inhibitors of this pathway.

[F] Repeat the exercise for apoptotic regulation at the mitochondrion, for transcription factor localization at the nucleus, and for translational control at the ribosome, and the distribution of independent inputs per output is the quantity that Chapter 23 argues predicts clinical outcome. The exercise can be done from the published literature for any node, and doing it before a program starts costs a week.

Problems

[O] 22.1 Build the organelle-sorted fan yourself from a curated substrate list, and count independent inputs per output. Where your count differs from the chapter’s, determine whether the difference is substantive or definitional.

[O] 22.2 Design the enrollment assay that would stratify patients by phosphatase redox state rather than by genotype. Specify sample handling, because that is where the assay will fail.

[O] 22.3 Three inputs to the fan are chemical rather than phosphorylative. Find a fourth, or show that the list is complete.

[O] 22.4 For the methionine sensor, predict the consequence of dietary methionine restriction on growth signaling in a tumor, and reconcile the prediction with the published effects of methionine restriction on tumor growth.

[O] 22.5 The seven operations map onto seven points of this architecture. Attempt the same mapping for a different signaling architecture and report whether it closes.

[O] 22.6 Estimate what fraction of tumors with wild-type phosphatase sequence would need to be redox-inactivated for the effect to have confounded published trial results, given the trial sizes and effect sizes reported.

Connections

[F] The fan is the structure Chapter 23 reads the clinical record against. Its chemical inputs come from Chapters 17 and 18, its compartmental sort from Chapter 16, and its most consequential switch — a reversible disulfide — is the clearest clinical instance of Chapter 8's third class of unrepresentable change.

Worked example: the brake, measured in a tumor sample

[F] The chapter's sharpest clinical claim is that a tumor can be genotypically normal for a tumor suppressor and functionally null for it, because the protein is held inactive by a reversible [VOL p.349] disulfide. This example specifies how that would be established in banked material.

[F] The sample problem first. Thiol oxidation states change within seconds of tissue handling, and the dominant artifact is oxidation during collection and thaw. Any result from material not collected with thiol blocking at the moment of harvest is uninterpretable. For banked material the honest approach is to state the limitation and to use the comparison between samples handled identically rather than the absolute fraction.

[F] The measurement. Lysis under argon with a metal chelator and an alkylating reagent present, to block free thiols instantly; separation by non-reducing gel; detection of the phosphatase, with the oxidized intramolecular-disulfide form migrating differently from the reduced form. Confirmation by differential alkylation with mass spectrometry at the two cysteines involved.

[F] The comparison. Stratify by genotype: samples with intact sequence, samples with deletion, samples with point mutation. The prediction is that a measurable fraction of the intact-sequence group carries oxidized, inactive protein, and that the fraction is higher in tumors with markers of high oxidative tone.

[F] The control that makes it interpretable. Measure the same quantity in matched normal tissue from the same patients, handled identically. The claim is about tumors specifically, and without the matched control an elevated oxidized fraction could reflect tissue handling rather than biology.

[F] What a positive result would imply. That trials enrolling on phosphatase genotype have been enrolling a mixed population, that the mixture's composition was unmeasured, and that the reported heterogeneity of response has a candidate explanation that was available all along and costs a gel to measure.

[F] What a negative result would imply. That the redox inactivation demonstrated in cells is not quantitatively important in tumors, that the chapter's clinical extension fails, and that the switch remains a signaling mechanism rather than a disease mechanism. Both results are publishable; only one of them is currently

anticipated by the field.

[VOL p.350] **CHAPTER 23**

Therapy Across the Fan

Abstract. The clinical record at one signaling hub is unusually clean as a natural experiment. Multiple Phase 3 programs have attacked the hub itself and produced no overall-survival benefit, while programs directed at single downstream outputs have produced survival benefit repeatedly. Potency was never the distinguishing variable: the hub inhibitors are potent, well characterized and correctly dosed. This chapter argues that the distinguishing variable is redundancy of output, that redundancy is a property of the organelle architecture of Chapter 22, and that the architecture predicts the result in advance.

297. What the record shows

[E] Inhibitors of the kinase hub and of the lipid kinase above it have been tested in large randomized trials across several tumor types. The pattern in the reported outcomes is consistent: improvements in progression-free survival in selected populations, toxicity that constrains dosing — hyperglycemia in particular, because the pathway is the insulin pathway — and no demonstrated overall-survival benefit at the hub.

[E] By contrast, agents directed at single downstream effectors or at parallel single nodes — including inhibitors of a cyclin-dependent kinase pair, of a specific anti-apoptotic protein, and of individual receptor tyrosine kinases in defined genotypes — have delivered overall survival benefit in randomized trials.

[F] The contrast is the datum. Both classes act on the same architecture. One class attacks a node with many outputs distributed across many compartments; the other attacks a node with few outputs concentrated in one. The first fails on survival; the second succeeds.

298. The redundancy argument

[F] The argument has three steps and each is independently checkable.

1. Output distributed across compartments has independent routes. Glucose uptake, apoptotic regulation, protein synthesis and transcription factor localization are executed by different machinery in different places. Each is reachable by signaling pathways other than the hub.

2. Inhibiting the hub therefore removes one input to each output rather than removing the [VOL p.351] **outputs.** The cell compensates at each one, and the compensation is not a single resistance mutation but a distributed restoration.

3. Inhibiting a single spoke removes the output. Where the effector is the only route — an anti-apoptotic protein that a tumor depends on, a cell cycle kinase pair with no parallel — the removal is not compensable, and the survival benefit follows.

[F] Stated that way the argument makes a prediction that does not depend on any particular drug: the clinical value of inhibiting a node is inversely related to the number of independent compartments its output is executed in. That is a structural claim about targets, and it can be tested against the historical record of randomized trials by scoring targets for output distribution and relating the score to outcomes.

299. Why the hub programs were selected on the wrong variable

[F] Trials at the hub enrolled patients on genotype: mutations in the lipid kinase, loss of the phosphatase, or related alterations. Chapter 22 established that the phosphatase is also inactivated by a reversible disulfide, which no genotype test reports.

[F] Two consequences follow for interpretation of the record. First, the genotype-selected arms contained patients whose pathway was active for reasons the assay could not see, which dilutes any true effect. Second, the control arms contained the same contamination in the opposite direction. A trial run on a mixed population will report an average effect over a mixture, and the mixture's composition was unknown and unmeasured.

[F] This is not a claim that redox-stratified enrollment would have rescued the programs. It is a narrower claim: the trials could not have detected the difference even if it existed, because the stratifying variable was not measured. The experiment that would settle it is a retrospective redox assay on banked trial tissue.

300. The seven engineering traditions

[E] The therapeutic traditions now in use sort into seven: engineered proteins; antibodies, including bispecifics; antibody-drug conjugates; modified-nucleoside RNA medicines; genome and base editing; engineered cell therapies; and biomanufacturing platforms.

[F] Six of the seven are built on sulfur chemistry: engineered disulfides and free-thiol management in proteins; interchain disulfides in antibody architecture; thiol-maleimide conjugation chemistry in conjugates; 2-thiouridine and related modified nucleosides in RNA medicines; iron-sulfur-dependent repair enzymes that determine whether an edit becomes permanent; [VOL p.352] and selenium and thiol redox management in engineered cell persistence. The seventh, biomanufacturing, depends on cysteine supply and nucleotide pool management.

[F] Sorting the traditions onto the architecture gives the chapter's practical result. The traditions that act at a spoke — antibodies, conjugates, engineered proteins — act where output is not redundant. The traditions that act upstream of the fan — editing in particular — escape the redundancy argument entirely, because they act before the output distribution exists.

301. The hub: five Phase 3 programs, no survival win

[E] Five Phase 3 programs have inhibited Akt itself. CAPItello-291 tested capivasertib with fulvestrant in hormone-receptor-positive advanced breast cancer and met its progression-free endpoint, 7.3 against 3.1 months in the pathway-altered population, hazard ratio 0.50; the final overall-survival analysis gave 28.5 against 30.4 months, hazard ratio 0.83, p = 0.201, not significant. CAPItello-281 tested capivasertib with abiraterone in PTEN-deficient hormone-sensitive prostate cancer and met its radiographic endpoint, 33.2 against 25.7 months, hazard ratio 0.81, p = 0.034, with survival immature at hazard ratio 0.90. CAPItello-280 was discontinued for futility. CAPItello-290 missed its survival endpoint in triple-negative breast cancer. IPATential150 tested ipatasertib with abiraterone, improved radiographic progression-free survival in PTEN-loss disease, and returned a final survival hazard ratio of 0.94, p = 0.57.

[F] Five programs, two approvals, and no significant overall-survival benefit anywhere in the set.

The approvals rest on progression-free endpoints. That is consistent across two molecules, four tumor settings and both breast and prostate biology, and consistency of that kind is a property of the target rather than of any one compound.

302. The spokes, and the whole record

[E] Four Phase 3 programs have inhibited a single terminal node of the same fan, and every one produced a significant survival benefit. Table 5 gives the whole record across the fan.

Table 5. The Phase 3 record across the whole Akt fan, by balloon. Data current to 13 October

[VOL p.354] 2026.

[F] Zero of five at the hub. Four of four at the spokes. No overlap in direction, across different molecules, sponsors, tumor types and decades.

303. The variable is redundancy, and the organelle predicts it

[F] The obvious reading of the hub failures is pharmacological — that a better inhibitor would convert the progression-free benefit into a survival benefit. The assembled fan argues otherwise, and the argument is structural. A node with twenty-seven outputs is a node with twenty-seven ways to be bypassed. Inhibiting it removes signal from all twenty-seven at once, which is exactly why progression-free survival improves. But no single output is individually required, and the cell has parallel routes to most of them. The hub is redundant by construction, and breadth without depth is the signature of a progression-free benefit that never becomes a

survival benefit.

[F] A spoke with one terminal effector is the opposite case. BCL-2 is the single protein standing between the mitochondrial outer membrane and apoptosis. CDK4/6 is the single gate from G1 into S phase. BRAF V600E is the single constitutively active input to ERK where it is mutated. Each is a point of genuine non-redundancy, and non-redundancy

[F] The organelle sort of §288 predicts which balloons are non-redundant, and this is where the cell map and the trial record meet. The mitochondrion receives three arrows and all three converge on one decision: whether the cell dies. One decision, one terminal effector, no alternative route — and the clearest survival benefit in the whole set. The nucleus receives nine arrows running at least six different programs, and no single drug at any one node removes the others. Navtemadlin is the cleanest test: one nuclear node, correctly drugged, primary endpoint missed at p = 0.08.

[F] Stated as a rule: count the arrows into the organelle and count the decisions they serve. Where many arrows serve one decision, a drug at the terminal effector will convert. Where few arrows each serve their own decision, it will not. §291 supplies the second mechanism at the lysosomal balloon, where the bypass is not a parallel kinase but the sulfonium pool.

304. The seven traditions, six of them sulfur

[F] Seven engineering traditions are normally surveyed as seven separate platforms. Six of the seven are built on sulfur chemistry, and all seven sort onto this geometry by the level at which each acts. Table 6 gives both readings together.

[VOL p.355]

tradition the sulfur in it state-of-the-art modality

Table 6. The seven engineering traditions, the sulfur chemistry each rests on, and the level at which each acts on the Akt output fan.

[F] The clinical record tracks the level, not the platform. Traditions one through three act at a spoke and have produced survival benefits. Traditions four and five act upstream of the fan and are the ones with no Akt-pathway clinical data at all. Traditions six and seven act outside the fan entirely, and tradition six is the only place editing has reached cancer patients — not because the editing is better there, but because an engineered cell does not have to solve the [VOL p.356] redundancy problem. It kills the target cell from outside, where none of the twenty-seven escape routes are available.

[F] Tradition six's limiting variable is its own persistence, which runs on a redox axis whose terminal enzyme, GPX4, is a selenoprotein requiring a trace element supplied by the medium, and whose substrate supply is cystine imported through SLC7A11. The engineered cell's survival after infusion is a cysteine and selenium accounting problem, which is a manufacturing attribute and not a biology problem, and it does not appear among the critical quality attributes release testing measures.

305. Editing acts before the fan opens

[F] Every intervention in §301 through §304 acts after the fan has opened and inherits the redundancy of whatever level it attacks. Gene editing is categorically different. Correcting PTEN, or restoring TP53, resets every one of the twenty-seven arrows at once and permanently, because it acts on the instruction rather than on the signal. It is the only class of intervention here not subject to the redundancy argument at all, and that, rather than novelty, is the structural case for it.

[E] The two base editors do different jobs, and the division is chemical. The adenine base editor converts an A-T pair to a G-C pair; most pathogenic point mutations are G-C to A-T transitions arising from deamination at methylated cytosine positions, so the adenine editor is the corrector — the TP53 hotspots R175H, R248Q and R273H are all G to A changes and are in principle revertible. The cytosine base editor converts C-G to T-A, which rarely corrects but reliably installs a premature stop, so it is a knockout tool.

[F] The two editors sort onto the fan the way the organelles do. The adenine editor is the instrument for the nuclear balloon, where the targets are tumor suppressors needing restoration. The cytosine editor is the instrument for the cytoplasmic and membrane balloons, where the targets are oncogenes needing silencing.

306. The transversion wall, and an inosine written as G

[E] Both editors perform transitions. Neither performs a transversion. BRAF V600E is c.1799T>A — a transversion — and is therefore outside the reach of both editors under any guide or delivery. Correcting it requires prime editing.

[F] This runs against the geometry of §303. BRAF V600E is simultaneously one of the few genuinely non-redundant spokes in the fan — the node where dabrafenib with trametinib won survival — and a node base editing cannot chemically address. The place where the pharmacology works best is the place where the editing chemistry fails outright. Any program assuming editing will subsume small-molecule inhibition at the spokes has to answer this case first.

[E] A second limit is in the record rather than the chemistry. The adenine editor's chemical product is inosine, and the sequencing record writes G. The cell's own ADAR enzymes make the same A to inosine change continuously, and both print as G. An A-to-G call in an edited cell therefore cannot be attributed to the editor rather than to the cell, and the ambiguity is created at the alphabet rather than lost to coverage. Deeper sequencing does not fix it.

[F] That is the same failure as §290's, in a different register. In §290 a disulfide was invisible to a sequence file and a trial enrolled the wrong population. Here an inosine is invisible to a sequence file and an off-target call cannot be assigned. Both are cases of a chemical state that decided an outcome not being representable in the notation used to record the outcome. The atom is inside a molecule when anyone looks.

[VOL p.359] ## 307. Editing acts before the fan opens

[F] Gene editing is the one tradition on the list that is not subject to the redundancy argument, and the reason is positional: an edit changes the gene, so the output distribution downstream never forms. That is a genuine structural advantage and it is why the volume's criticism of editing is about validation rather than about strategy.

[F] The advantage is bounded in three ways, each developed elsewhere in this volume.

• **By what the alphabet can represent.** An editor can write a substitution. It cannot write a cofactor, a disulfide register or a pool composition, so the phenotypes that depend on those are not reachable by editing at all (Chapters 8 and 13).

• **By the chemistry of the editor itself.** The writing enzymes run on sulfur chemistry and their products include an unlettered base; permanence depends on a repair fork whose enzymes are cluster proteins (Chapters 14 and 19).

• **By the cell that receives it.** An ex vivo product must be expanded, and expansion selects (Chapter 15).

[F] Those three bounds do not argue against editing. They argue that the validation package for an edited product should measure the chemistry of the editor, the state of the repair fork and the replicative reserve of the product — three measurements that are currently rare, and all of which exist.

308. The transversion wall

[F] One specific limitation deserves its own statement because it is a direct consequence of the volume's alphabet argument. The deaminase editors convert purine to purine or pyrimidine to pyrimidine: they write transitions. Transversions require either a nuclease with template repair, prime editing, or chemistry that the current deaminase toolkit does not perform effi-ciently.

[E] A substantial fraction of pathogenic point mutations are transversions. The editing toolkit is therefore well matched to part of the mutational spectrum and poorly matched to the rest, and the part it is poorly matched to is not a small remainder.

[F] The connection to the alphabet is that the editing chemistry available is the chemistry of deamination, and deamination moves within a chemical family. The product of adenosine deamination is inosine — the unlettered trunk base again — and the reason it reads as guanosine is that hypoxanthine's pairing face resembles guanine's. The tool's reach is set by the chemistry of the bases rather than by engineering effort.

[VOL p.360]

309. Predictions

• **Prediction one.** Score approved and failed oncology targets by the number of distinct compartments in which their output is executed. The prediction is a negative relationship between that score and the probability of demonstrated overall-survival benefit. The data are public and the analysis is a weekend's work.

• **Prediction two.** In banked tissue from hub-inhibitor trials, redox-based inactivation of the phosphatase will be detectable in a fraction of sequence-wild-type tumors, and that fraction will differ between responders and non-responders.

• **Prediction three.** Agents directed at effectors with a single execution compartment will continue to deliver survival benefit at a higher rate than hub-directed agents, holding potency and tumor type constant, over the next cohort of readouts. This is a standing prediction about trials not yet reported.

310. Consequences

[F] For target selection the rule is: measure the distribution of output before measuring the potency of inhibition. Distribution is knowable from cell biology in advance, and it predicts compensability, which is the variable that has repeatedly decided these programs.

[F] For trial design the rule is: if a target's activity can be set by chemistry as well as by genotype, stratify on the chemistry. The assays exist, they are inexpensive, and the alternative is to run a randomized trial on a mixture of unknown composition.

[O] The open question is how general the pattern is. One hub is not a sample. The volume's prediction is that the same relationship holds at other hubs with distributed output — and that it will be found in the published record once anyone scores targets this way. If a systematic analysis finds no relationship between output distribution and survival benefit, the central claim of Part Six is wrong.

311. Notes to Chapter 23: the record, read

Quantities worth carrying

[E] **Endpoints.** Progression-free survival measures time to radiographic progression or death; overall survival measures time to death. The two can diverge, and

divergence is informative rather than anomalous: an agent can delay progression without extending life if the disease resumes on the same trajectory afterward.

[E] Hazard ratios. A hazard ratio below one favors the experimental arm. Confidence intervals matter more than point estimates in programs where several trials report similar modest [VOL p.361] effects, because the question is whether the aggregate is consistent with no effect on survival.

[E] Dose limitation. Inhibitors of this pathway produce on-target hyperglycemia because the pathway is the insulin pathway. Dose is therefore limited by the mechanism itself rather than by an off-target liability, which bounds achievable target inhibition in patients.

[E] Single-spoke successes. Agents directed at individual effectors — a cyclin-dependent kinase pair, an anti-apoptotic protein, specific receptor kinases in defined genotypes — have delivered overall survival benefit in randomized trials, in several cases substantially.

Methods box: scoring a target for output distribution

[F] The prediction of this chapter can be tested systematically, and the scoring procedure is worth specifying so that different people produce comparable numbers.

1. Enumerate outputs. From curated pathway databases plus primary literature, list the direct outputs of the node that have a demonstrated functional consequence.

2. Assign each output to a compartment. Where the output is executed, not where the substrate is phosphorylated.

3. Count independent inputs per output. For each output, count the other nodes with a demonstrated ability to produce it. This is the redundancy number.

4. Aggregate. A node’s score is the distribution of redundancy numbers across its outputs, summarized as the fraction of outputs with redundancy greater than one.

5. Relate to outcome. For targets with completed randomized trials, relate the score to whether overall survival benefit was demonstrated.

[F] The procedure’s weak point is step three, where literature coverage differs between well-studied and less-studied outputs. The control is to repeat the scoring restricted to outputs above a citation threshold and confirm that the relationship survives.

Worked example: two targets, two predictions

[F] Target one is the hub: many outputs, executed across at least five compartments, most with at least one alternative input. Predicted redundancy fraction high; predicted survival benefit low; observed, across multiple Phase 3 programs, no demonstrated overall survival benefit.

[F] Target two is an anti-apoptotic protein at the mitochondrial outer membrane in a tumor type dependent on it. One output — suppression of apoptosis at one compartment — with no alternative input in that dependency state. Predicted

redundancy fraction low; predicted survival benefit plausible; observed, survival benefit in randomized trials.

[F] The two cases are not a test, because they were chosen after the fact. The test is the systematic [VOL p.362] scoring described above applied to targets whose trials have not yet read out, and that is prediction three of the chapter: a standing bet on the next cohort of results.

Problems

[O] 23.1 Perform the scoring for five targets with completed Phase 3 programs, blind to the outcomes, then compare. Report your scoring rules in enough detail that someone else could reproduce them.

[O] 23.2 The redundancy argument predicts failure at hubs. Find a hub inhibitor that delivered a survival benefit and determine what, in that case, made the output non-redundant.

[O] 23.3 Dose is limited by on-target metabolic toxicity. Estimate the target inhibition achievable at tolerated doses and ask whether the trials tested the hypothesis they were designed to test.

[O] 23.4 Design a trial that would test the redundancy hypothesis directly, rather than inferring it from the historical record.

[O] 23.5 Editing acts before the fan opens. List the diseases for which that positional advantage is decisive, and the diseases for which it is irrelevant because the causal variable is not a letter.

[O] 23.6 The transversion wall bounds the editing toolkit. Quantify it: what fraction of pathogenic point mutations in a clinical variant database are transversions, and what fraction of those are addressable by current prime editing efficiencies?

Connections

[F] This chapter is where Part Six’s architecture meets the clinic, and it depends on Chapter 22 for the fan and on Chapter 16 for the compartment map. Its bounds on editing come from Chapters 8, 13, 14 and 15, and its conclusion — choose the level at which to act — is restated as the practical recommendation of Chapter 25.

Worked example: scoring one target before the trial

[F] Take a node that has not yet been tested in a randomized trial and score it by the procedure of this chapter’s notes, to see what the score says and how long it takes.

[F] Step one, enumerate outputs. From pathway databases and primary literature, list the node’s direct outputs with demonstrated functional consequence. Suppose there are eleven.

[F] Step two, assign compartments. Place each output where it is executed, not where the substrate is phosphorylated. Suppose they fall as: four at the nucleus, three at the mitochondrion, two at the plasma membrane, one at the ribosome, one at the cytoskeleton.

[VOL p.363] **[F] Step three, count independent inputs.** For each output, count the other nodes with a demonstrated ability to produce it. Suppose eight of the eleven have at least one alternative and three do not.

[F] Step four, aggregate. Redundancy fraction: eight of eleven, or about 0.73. On the chapter's argument this is a high-redundancy target, and hub-like behavior should be expected: inhibition will reduce many outputs partially and abolish few.

[F] Step five, decide what to do with the score. Three options follow, and all are better than proceeding without the number. Pick instead one of the three non-redundant outputs and find an agent that acts there. Combine, with the combination chosen to cover the alternatives at the outputs that matter. Or proceed at the hub with a non-genetic stratification, since the score predicts heterogeneity rather than uniform failure.

[F] Time required. A week of literature work by someone who knows the pathway, and the result is a number that can be compared with other targets rather than an impression.

[F] What would show the scoring is useless. If, across targets with completed trials, the score shows no relationship with demonstrated survival benefit. That analysis is the chapter's first prediction and is the cheapest falsifier in the volume, because the data are public and the work is analysis rather than experiment.

[VOL p.364] **CHAPTER 24**

One Cofactor Across the Whole Arc

Abstract. A case study is worth running only if it can fail cleanly. The molybdenum cofactor qualifies: it is built from a nucleotide in three successive sulfur steps, it is carried by two human enzymes at opposite ends of metabolism, and its three inherited failures produce a graded clinical series in which severity tracks which atom is stranded. If the volume's account is right, the severity ordering should follow the chemistry; if it is wrong, the ordering should be arbitrary. This chapter runs that test and then follows the same cofactor family backward to an enzyme that predates the oxygenation of the atmosphere.

312. Why this case

[F] Four properties make this cofactor the right test object.

• **It is built from a nucleotide.** The pathway begins with GTP and converts it, through a radical SAM enzyme, into a pterin intermediate. The volume's first leg claims the nucleotide is the unit; here a nucleotide is the raw material for a cofactor that has nothing to do with information.

• **It is built in sulfur steps.** Two sulfur atoms are installed to make the dithiolene that holds the metal, and a third terminal sulfur is installed on one of the two enzymes that use it. Three sulfur steps, each catalyzed by a distinct activity.

• **It serves two enzymes at opposite ends of metabolism.** Sulfite oxidase performs the terminal step of sulfur amino acid catabolism; xanthine dehydrogenase performs the last two steps of purine degradation. One cofactor, the sulfur exit and the purine exit.

• **Its failures are graded and documented.** Three inherited deficiencies exist with different severities, and the differences are chemically interpretable.

313. The three sulfur steps

[E] The pathway runs in four stages. A radical SAM enzyme converts GTP to cyclic pyranopterin monophosphate. A second enzyme complex installs two sulfur atoms to form the dithiolene of molybdopterin, with the sulfur delivered as a thiocarboxylate on a small protein that is charged by a sulfurtransferase. A third activity adenylylates the intermediate and inserts molybdenum.

Finally, for one of the two enzymes, a dedicated sulfurase installs a terminal sulfur ligand on the [VOL p.365] metal.

[F] Count the element's appearances: two sulfurs in the dithiolene that holds the metal, one more as the terminal ligand on the enzyme that needs it, and the delivery chemistry for all three is a thiocarboxylate charged by the same desulfurase system of Chapter 20. The cofactor is a sulfur construction around a metal, built on a nucleotide scaffold.

[E] The final sulfur is the on-switch for xanthine dehydrogenase: without the terminal ligand, the enzyme is correctly folded, correctly loaded with metal, and inactive.

314. The graded failures

[E] Three inherited conditions are informative, and their severities differ sharply.

• **Molybdenum cofactor deficiency.** A failure in the biosynthetic pathway itself. Both cofactor-dependent enzymes are lost. The presentation is catastrophic neonatal encephalopathy, in-tractable seizures and early death in the untreated classical form; one subtype is treatable by supplying the missing intermediate, which is one of the clearest demonstrations in medicine that a chemical substitution can rescue a genetic disease.

• **Isolated sulfite oxidase deficiency.** The cofactor is made; the one enzyme is absent. The presentation is nearly as severe as the complete cofactor deficiency.

• **Xanthinuria.** The purine arm alone fails. The presentation is mild: xanthine stones in some patients, and in many cases a laboratory curiosity discovered incidentally.

[F] The ordering is the chapter's result. Losing both arms is lethal. Losing the sulfur arm alone is nearly lethal. Losing the purine arm alone is mild. The severity therefore tracks the sulfur arm, and the explanation is chemical: when sulfite oxidase fails, sulfite accumulates, and sulfite is an excitotoxin that destroys the developing brain. When the purine arm fails, xanthine accumulates, and xanthine is insoluble but not

toxic — it deposits.

[F] One cofactor, two arms, two accumulating substrates, and the difference between a catastrophic disease and a mild one is which atom is stranded. That is as close to a controlled experiment as inherited human disease provides, and it comes out the way a sulfur-centered account requires.

315. The same metal, nine sulfurs earlier

[E] Nitrogenase, the enzyme that reduces atmospheric nitrogen, holds the same metal in a very different cofactor: an iron-molybdenum cluster with nine sulfurs and an interstitial carbon.

It is irreversibly poisoned by oxygen, and its distribution and phylogeny place it before the [VOL p.366] oxygenation of the atmosphere.

[F] Set the two side by side. In the anaerobic world, the metal is held by nine sulfurs in a cluster that breaks the strongest bond in ordinary chemistry. In the aerobic world, the same metal is held by two sulfurs in a mononuclear cofactor performing oxygen-atom transfer. The collapse from nine to two is a chemical record of the atmospheric transition, written in the ligation of a single metal.

[F] The volume's claim about that transition — that oxygen replaced sulfur's terminal acceptor and left the rest of its jobs intact — is visible here in a single comparison. Sulfur did not stop holding the metal. It stopped needing to hold nine of them, because the chemistry the metal was asked to perform changed.

316. Why this case, and what it is a test of

[F] An arc that runs from a mineral to an editing enzyme is only worth having if it accounts for something specific better than the separate literatures do. This Part takes one cofactor and follows it across every register the arc names: the stellar and mineral supply, the anaerobic world, the Great Oxidation Event, the modern metabolic pathway, the inherited diseases, the clinical assay, and a metabolic step the human lineage deleted. The molybdenum cofactor is chosen because it is the hinge on which a sulfur economy was converted into an oxygen economy, and because it is held by sulfur at every step of its own construction.

[E] The cofactor, abbreviated Moco, is a molybdenum atom bound to an organic pterin called molybdopterin. The structure is highly conserved and is shared by almost every molybdenum enzyme in existence. Four of them matter here: sulfite oxidase, xanthine dehydrogenase, aldehyde oxidase, and the mitochondrial amidoxime reducing component. Nitrate reductase carries it too.

317. Three sulfur steps to build one cofactor

[E] The metal is not held by the pterin directly. It is held by a dithiolene — two sulfur atoms on the pterin ring — and those two sulfurs are installed, not inherited. Molybdopterin synthase inserts them into the precursor cPMP. The enzyme is encoded by MOCS2 as two subunits: MOCS2A, the small subunit, which carries the

sulfur as a thiocarboxylate on its own C-terminus, and MOCS2B, the large catalytic subunit. MOCS2A is consumed in the reaction and must be recharged, and MOCS3, a sulfurtransferase, does the recharging.

[F] Sulfur holds the metal; sulfur delivers the sulfur that builds the holder; and a third sulfur enzyme recharges the deliverer. Three sulfur steps, three genes, one cofactor. The [VOL p.367] thiocarboxylate on MOCS2A is group thirteen of the eighteen in Table 1, and this is its principal biological job. A functional group that occupies one row of a chemical-class table turns out to be the delivery mechanism for a cofactor family that runs five enzymes.

[F] It follows that molybdenum cofactor deficiency type B is not, at root, a molybdenum disease.

It is a sulfur-delivery failure. The atom is abundant, the metal is available, and the carrier is broken. That is the same distinction §41 drew between absence and arrest, arriving here at a specific gene.

318. FeMoco, and the collapse from nine sulfurs to two

[E] Exactly one enzyme in all of biology uses molybdenum without molybdopterin. Nitrogenase holds its molybdenum in FeMoco, a cluster of seven iron atoms, nine sulfur atoms, one carbon and one molybdenum. Nitrogenase arose about 3.2 billion years ago in the Archean, long before the Great Oxidation Event, to break the triple bond of atmospheric dinitrogen, and it split off from an ancient maturase — an assembly scaffold whose descendants, such as NifEN, still exist only as helpers that build complex metal clusters.

[E] Ancestral-sequence resurrection work bears on how fixed that solution is. Phylogenetically reconstructed nitrogenase ancestors, inserted into a living diazotroph, are active, and every ancestor shows the same reversible dinitrogen-reduction mechanism as the modern enzyme, hydrogen inhibition included. The authors read this as life having been constrained to one sampling of sequence space for one of the hardest reactions in nature.

[F] Set the two cofactors side by side and a number changes across the Great Oxidation Event.

The pre-oxygen molybdenum enzyme holds its metal in a nine-sulfur iron cluster. Every post-oxygen molybdenum enzyme holds its metal in a two-sulfur pterin. Nine to two, in the same element, around the same metal, across the same boundary. Nitrogenase is also poisoned by oxygen and has never adapted to it — it is sequestered instead, in heterocysts, by temporal separation, or inside an endosymbiont such as the diazoplast of the diatom Epithemia, which descends from a free-living cyanobacterium.

[F] That is a third independent dating of one moment. The sulfur isotope record dates the Great Oxidation Event from the rock. The peroxiredoxin redox rhythm, conserved across all three domains and running on the oxidation state of a

peroxidatic cysteine, dates it from the clock.

The sulfur count in the molybdenum cofactor dates it from the enzyme. Three registers, one date, and none of the three derived from the others.

[VOL p.368] ## 319. The event itself: the reductant changed

[E] Cyanobacteria evolved oxygenic photosynthesis around 2.7 billion years ago. For hundreds of millions of years the oxygen released was absorbed by planetary sinks — above all dissolved iron in the oceans, which precipitated as the banded iron formations, alternating layers of iron oxide and silica-rich chert that are the physical evidence of the transition. Once the sinks saturated, free oxygen accumulated in the atmosphere for the first time. It was toxic to the dominant anaerobes and caused a mass extinction; it destroyed atmospheric methane and triggered the Huronian glaciation; and it opened the way to aerobic respiration, the ozone layer and eukaryotic life.

[F] Stated in the arc's terms the event has one sentence. Photosynthesis already existed; what changed was the reductant. Anoxygenic photosynthesis splits hydrogen sulfide and deposits sulfur. Oxygenic photosynthesis splits water and releases oxygen. The purple sulfur bacteria that made a living from sulfide were not outcompeted on sunlight; they were outcompeted on substrate, because water is everywhere and sulfide is not.

[F] The ledger of that switch is written in iron, which is the element sulfur was partnered with.

The banded iron formations are the record of oxygen consuming the dissolved iron that iron-sulfur chemistry had been running on, and they stop forming when the sinks saturate. The rock that marks the end of the anaerobic world is made of the metal that the anaerobic world's principal cofactor was built around.

[E] The event is dated, however, by sulfur itself, and that evidence belongs in this section rather than being left implicit. Isotopes of one element are chemically near-identical, so they normally fractionate in proportion to mass. Sulfur in rocks older than about 2.45 billion years does not: it carries anomalies in 33S that no mass-dependent process produces. Above that horizon the anomalies disappear and never return. The accepted account is that ultraviolet light reaching an unscreened atmosphere photolyzed volcanic sulfur dioxide and generated mass-independent fractionation, and that the signal stops when oxygen builds an ozone layer and removes the ultraviolet. The measurement was reported in 2000 by Farquhar, Bao and Thiemens.

[F] It is worth being explicit about what that means for this chapter. The clock on the whole transition is a sulfur clock. The event that is usually named for oxygen is dated by an isotopic anomaly in sulfur, recorded in sulfide minerals, and it is the loss of that anomaly that fixes the horizon. The nine-to-two ligation collapse proposed in §318 is an independent dating only because this one exists to be independent of; the

two are measuring the same transition by unrelated means, one in the rock record and one in the cofactors, and they do not disagree.

[VOL p.369] 320. What sulfur kept, and what it handed over

[F] The usual account treats the Great Oxidation Event as a replacement: an oxygen world supersedes a sulfur world. The chemistry says otherwise, and this is the central claim of the case study. Oxygen did not replace sulfur. It replaced sulfur's terminal acceptor, and left every other job where it was.

[E] The iron-sulfur clusters that carried electrons in the anaerobic world are the same clusters that carry them now: eight in Complex I, three in Complex II, the Rieske center in Complex III. The thioester economy of acetyl-coenzyme A is unchanged. The thiyl radical of ribonucleotide reductase is unchanged. The sulfonium of S-adenosylmethionine is unchanged. The 2-thiouridine at anticodon position thirty-four is unchanged.

[F] What sulfur handed over was one position: the end of the chain. An element that had been both the conductor and the destination became the conductor only. That is exactly why the element key in §204 assigns the mitochondrion to oxygen while the chemistry of §230 and §231 running it is sulfur, and the apparent tension between those two statements is the Great Oxidation Event, preserved inside a single organelle. The mitochondrion is the compartment where the handover is still visible.

[F] It also explains why the Moco enzymes exist at all. Sulfite oxidase finishes sulfur's own oxidation, which is a reaction that only has a purpose once there is oxygen to finish it against.

Xanthine dehydrogenase opens the purine exit, and the oxidase form uses molecular oxygen directly. Aldehyde oxidase and the mitochondrial amidoxime reducing component are oxidation chemistry throughout. Moco is the adapter: built by anaerobic-era sulfur chemistry, running aerobic-era oxidation chemistry. Nothing else in the cell sits quite so precisely on the seam.

321. The xanthine diseases: three tiers, one cofactor

[E] The arc predicts that a failure in the cofactor presents wherever its enzymes were working rather than as a cofactor disease, and that the severity will follow which atom is arrested rather than how much of the cofactor is lost. Three inherited conditions test that, and they are set out in Table 10. [VOL p.370] **condition gene what is lost biochemistry clinical picture** Molybdenum MOCS1, cofactor MOCS2, deficiency, types GPHN A, B, C All four at once: sulfite oxidase, xanthine dehydrogenase, aldehyde oxidase, mARC sulfite ↑, Seizures in the first days; S-sulfocysteine ↑, encephalopathy; usually xanthine ↑, fatal in early childhood; hypoxanthine ↑, about 75 per cent die in uric acid LOW infancy Isolated sulfite SUOX oxidase deficiency Sulfite oxidase only; cofactor intact sulfite ↑, Clinically identical to the S-sulfocysteine ↑, above. Normal uric acid is uric acid how the two are told apart NORMAL Classical XDH xanthinuria type I Xanthine dehydrogenase

only xanthine ↑, Xanthine stones, acute renal hypoxanthine ↑, failure, myositis — or uric acid very low; asymptomatic. Patients sulfite NORMAL reach their sixties Classical MOCOS xanthinuria type II (cofactor sulfurase)

Xanthine dehydrogenase and aldehyde oxidase as type I As type I. Combined type I and II incidence about 1 in 69,000 **Table 10.** Three inherited failures of one cofactor, with the biochemical signature that separates them.

[E] The xanthinuria mutations are ordinary and instructive. One is c.682C>T, which turns codon 228 from CGA, arginine, into TGA, a premature stop, and abolishes the protein while leaving messenger levels unreduced. The other is c.2567delC, a single-base deletion that shifts the frame and generates a stop at nucleotide 2783.

[F] Both belong to classes this chapter has already placed. The first is a C-to-T transition producing CGA to TGA — precisely the lesion the adenine base editor of §305 exists to revert, and precisely what the cytosine editor installs deliberately when it wants a knockout. The commonest pathogenic mutation class and the commonest deliberate editing operation are the same chemical event in opposite directions. The second is a single-base deletion, which neither editor can touch and which needs prime editing — the same wall §306 found at BRAF.

322. Why the sulfur arm kills and the purine arm only deposits

[F] Table 10 contains a natural experiment that could not be designed better. One cofactor serves two arms. Block the purine arm alone and patients form stones and reach their sixties. Block

condition gene	what is lost	biochemistry clinical picture

Table 10. Three inherited failures of one cofactor, with the biochemical signature that separates them.

[E] The xanthinuria mutations are ordinary and instructive. One is c.682C>T, which turns codon 228 from CGA, arginine, into TGA, a premature stop, and abolishes the protein while leaving messenger levels unreduced. The other is c.2567delC, a single-base deletion that shifts the frame and generates a stop at nucleotide 2783.

[F] Both belong to classes this chapter has already placed. The first is a C-to-T transition producing CGA to TGA — precisely the lesion the adenine base editor of §305 exists to revert, and precisely what the cytosine editor installs deliberately when it wants a knockout. The commonest pathogenic mutation class and the commonest deliberate editing operation are the same chemical event in opposite directions. The second is a single-base deletion, which neither editor can touch and which needs prime editing — the same wall §306 found at BRAF.

322. Why the sulfur arm kills and the purine arm only deposits

[F] Table 10 contains a natural experiment that could not be designed better. One cofactor serves two arms. Block the purine arm alone and patients form stones and reach their sixties. Block

Source page [VOL p.370] rendered at 150 dpi (plate / figure / table as published).

[VOL p.371] the sulfur arm and the brain is destroyed within days. The severity does not track how much of the cofactor is lost; it tracks which atom is stranded.

[E] The mechanism on the sulfur side is specific. Sulfite and S-sulfocysteine accumulate. S-sulfocysteine is a structural analogue of glutamate and activates

NMDA receptors. Sulfite depletes intracellular ATP and impairs mitochondrial respiration. The result is excitotoxicity plus an energy failure, in the tissue least able to tolerate either.

[F] On the purine side the stranded metabolite is merely insoluble. Xanthine precipitates in kidney and muscle; it does not activate a receptor and it does not poison respiration. Xanthinuria is therefore the control experiment for sulfite oxidase deficiency, and it isolates the variable: the same cofactor, the same kind of failure, two substrates, and only the sulfur one is neurotoxic. Sulfur halted one step short of its destination does not merely fail to do its work — it poisons the tissue that was waiting for it, and the purine arm demonstrates that this is a property of the atom rather than of arrest in general.

[E] The treatment follows the same logic. Type A molybdenum cofactor deficiency is treated with fosdenopterin, a cPMP replacement that enters the pathway upstream of the sulfur-insertion step, and it reduced the risk of death by eighty-two per cent against untreated controls. It has to be started fast, because what is being prevented is not a deficiency accumulating slowly but a toxin accumulating quickly.

323. The step the human lineage deleted

[E] Purine degradation does not end at uric acid in most mammals. Uricase oxidizes urate to allantoin, which is far more soluble and is excreted without difficulty. Humans and the other great apes do not do this: the uricase gene was inactivated by independent nonsense mutations during the Miocene and survives as a pseudogene. The pathway therefore terminates one step early, at a poorly soluble end product.

[F] Uricase is an oxygen enzyme — a peroxisomal oxidase that consumes molecular oxygen and produces hydrogen peroxide. It is a product of the oxygen economy, and the human lineage discarded it. The standard reading is that urate is a plasma antioxidant and that a high-urate species gained oxidative protection; on that reading the deletion is an adaptation to the very burden the Great Oxidation Event created. The cost is gout and urate nephrolithiasis, which is the commonest disease anywhere in this Part.

[F] Two consequences follow that the separate literatures do not put together. First, the purine exit is now hazardous at both of its last two steps: lose xanthine dehydrogenase and xanthine precipitates; have no uricase and urate precipitates. One rare disease and one common one, [VOL p.372] adjacent in the same pathway, for the same structural reason — an intermediate with poor solubility and nowhere to go.

[F] Second, and more pointedly: the step humans deleted is the step the clinic now reads the sulfur disease off. Uric acid is low in molybdenum cofactor deficiency because xanthine dehydrogenase is gone, and normal in isolated sulfite oxidase deficiency because it is not.

That is the distinguishing test in Table 10. A measurement of the terminal purine metabolite — terminal only because the human lineage stopped processing it — is what separates two sulfur diseases that are clinically identical. The diagnosis is made downstream, from the wreckage, in a register that exists only because of a deletion.

[F] The arc also places xanthine itself. On the synthesis side it is XMP, the one-way gate from IMP toward GMP. On the degradation side it is xanthine, the last intermediate before the exit. The same base is the gate in both directions, and at the degradation gate the enzyme that opens it is held by the sulfur-built cofactor and carries a terminal sulfido ligand that decides whether the valve opens at all.

324. What the case study shows

[F] Run the case once more in a single pass. Sulfur and iron precipitated together before there was life, and the cluster became the first cofactor. Nitrogenase arose in that world and held its molybdenum in nine sulfurs, and has never adapted to oxygen. Cyanobacteria changed the reductant from hydrogen sulfide to water, the released oxygen consumed the dissolved iron and laid down the banded iron formations, the anaerobes died, the climate froze, and aerobic respiration became possible. Sulfur kept every job but the terminal acceptor. A new cofactor appeared to run the oxidation chemistry the new world required, and it is built in three sulfur steps and holds its metal in two. When any of those steps fails, the sulfur arm kills in days and the purine arm merely deposits. And the test that separates the two runs on a metabolite the human lineage stopped processing fifteen million years ago.

[F] Every register the arc names is used and none is decorative. The forces and the minerals supply the cluster; the kingdoms supply the cyanobacterium; the raw stock supplies the banded iron formation; the molecules of life supply the cofactor; the thinking tissue is where the failure presents; what we eat sets the sulfur supply; and what we make supplies fosdenopterin.

That is the test proposed in §202 — name a register at which sulfur performs none of the seven operations — run on one cofactor rather than on the ladder as a whole, and the ladder holds.

[O] What the case study does not settle is whether the nine-to-two sulfur collapse is a general signature of the transition or a single instance. The prediction is that other metallocofactor [VOL p.373] families with both pre- and post-oxidation representatives should show the same direction of change in sulfur ligation count. That is checkable against structural databases without new experiments, and it has not been done.

325. The step the human lineage deleted

[E] Most mammals convert urate to allantoin with uricase and excrete a soluble product. The human lineage lost functional uricase through mutations fixed in the primate line, so humans terminate purine degradation one step early, at urate, which is far less soluble.

[F] The consequence is a disease — gout — that is a disease of the purine exit, treated by inhibiting the enzyme one step upstream with a hypoxanthine analog. Inhibiting it raises the concentration of the two unlettered purines, which is where Chapter 5 left the argument, and the whole arrangement is a worked example of the volume's thesis in ordinary clinical practice: a common disease of the supply line's exit, treated with an analog of a base that has no letter, acting on an enzyme whose metal is held by two sulfur atoms.

[E] The same deletion has been argued to raise plasma antioxidant capacity, since urate is a significant plasma antioxidant, which makes the loss a trade rather than a simple defect. The trade is the kind of thing a supply-line account predicts and a text-based account has no way to express.

326. What the case study establishes

[F] Four things, in increasing order of generality.

• **The severity ordering follows the chemistry.** Sulfur arm worse than purine arm, both worse than either, with the mechanism in each case identified by which substrate accumulates.

• **A cofactor can be rescued chemically.** Supplying the missing pathway intermediate treats one subtype of the cofactor deficiency, which is proof that the failure is a supply failure rather than an information failure.

• **The cofactor is the junction of the volume's two exits.** The sulfur exit and the purine exit are carried by the same cofactor family, built by the same sulfur delivery system. That is not a coincidence the volume manufactured; it is the structure of human metabolism.

• **The ligation of one metal records an atmospheric transition.** Nine sulfurs before oxygen, two after, same metal, different chemistry.

[VOL p.374] ## 327. Objections

[F] The severity ordering has a simpler explanation: sulfite is toxic and xanthine is not.

That is the explanation, and it is the volume's explanation. The point is not that the chemistry is mysterious; it is that a chemical account predicts the clinical ordering and a genetic account does not — both deficiencies are complete loss-of-function in a single gene.

[F] One cofactor is a single case. It is, which is why it is presented as a case study with a stated failure condition rather than as a proof. The failure condition was that the severity ordering should be arbitrary if the account is wrong. It is not arbitrary.

[F] Nitrogenase is bacterial and irrelevant to human biology. It is irrelevant to human physiology and directly relevant to the history argument, which is where it is used. The claim is about what the ligation records, not about what human cells do.

328. Tests

• **Terminal sulfur occupancy as a clinical variable.** The terminal sulfur ligand that switches xanthine dehydrogenase on is measurable. Whether partial occupancy contributes to variation in urate handling in the general population is unknown and testable.

• **Cofactor status in sulfur-restricted states.** If the cofactor's sulfur comes from the same relay that serves clusters and wobble thiolation, then dietary or metabolic sulfur restriction should reduce cofactor-dependent enzyme activity measurably, with sulfite oxidase affected before xanthine dehydrogenase or after — whichever it is, the order is informative.

• **Population genetics of the uricase loss.** Whether the fixation of the deletion correlates with other changes in purine handling is a comparative genomics question with existing data.

329. Consequences

[F] The case study is where the volume's three legs meet in one molecule. The cofactor is built from a nucleotide, which is leg one. It is constructed and switched on by sulfur, which is leg two. Its two arms sit at the exits of two metabolic systems whose failures propagate differently through the cell, which is leg three. And its inherited failures are graded in the clinic in the order the chemistry predicts.

[O] The open question is whether the cofactor's two arms are coordinated in health. If the supply of the relay's sulfur is limiting, the two arms compete, and a shift in that competition would move both the sulfite burden and the urate burden together. Nobody has measured the two in [VOL p.375] the same subjects under a controlled sulfur load, and a study that did would produce the first direct evidence of competition among the outputs of the junction described in Chapter 20.

330. Notes to Chapter 24: the cofactor, measured

Quantities worth carrying

[E] Pathway steps. Four stages from GTP to the finished cofactor: formation of the cyclic pyranopterin intermediate by a radical SAM enzyme; installation of two sulfurs to form the dithiolene; adenylylation and metal insertion; and, for one enzyme, installation of a terminal sulfur ligand by a dedicated sulfurase.

[E] Human enzymes. Four molybdenum enzymes in humans: sulfite oxidase, xanthine dehydrogenase/oxidase, aldehyde oxidase and the mitochondrial amidoxime reducing component. The first two carry the clinical weight.

[E] Clinical severity. Complete cofactor deficiency presents in the neonatal period with seizures and encephalopathy and is often fatal in infancy untreated; isolated sulfite oxidase deficiency is comparably severe; xanthinuria is usually mild, often asymptomatic, and sometimes discovered incidentally by an unexpectedly low plasma urate.

[E] The treatable subtype. One subtype of cofactor deficiency, caused by failure at the first step, is treatable by supplying the missing pyranopterin intermediate, which has been shown to improve outcomes when started early. It is one of the clearest demonstrations that a genetic disease can be a chemical supply failure.

[E] Urate. Human plasma urate is far higher than in species with functional uricase, close to its solubility limit, and both a risk factor for gout and a significant plasma antioxidant.

Methods box: diagnosing a cofactor failure

[F] Biochemical first. Sulfite in urine, S-sulfocysteine in plasma and urine, low plasma urate, and elevated xanthine and hypoxanthine. The pattern distinguishes complete cofactor deficiency from isolated sulfite oxidase deficiency: low urate indicates the purine arm is affected too, which implicates the shared cofactor rather than the single enzyme.

[F] Enzymatic. Sulfite oxidase activity in fibroblasts; xanthine dehydrogenase activity in tissue where available.

[F] Genetic. Sequencing of the pathway genes confirms and subtypes, and subtyping matters because only one subtype is currently treatable. This is a case where sequencing is exactly the right instrument, applied after the chemistry has located the lesion.

[VOL p.376] **[F] The terminal sulfur.** Occupancy of the terminal sulfur ligand on xanthine dehydrogenase can be probed functionally, since the enzyme is inactive without it while remaining correctly folded and metal-loaded. There is no routine clinical assay for partial occupancy, which is the gap the chapter's first test proposes to fill.

Worked example: grading three failures by which atom is stranded

[F] Write the two arms as substrate pipelines. The sulfur arm ends at sulfite oxidase, which converts sulfite to sulfate. The purine arm ends at xanthine dehydrogenase, which converts hypoxanthine to xanthine and xanthine to urate.

[F] When the cofactor is absent, both arms stop. Sulfite accumulates; sulfite is reactive, crosses membranes, and is neurotoxic in the developing brain. Xanthine accumulates; xanthine is poorly soluble and deposits as crystals. Both accumulations are consequences of the same molecular lesion, and the clinical difference between them is entirely a difference in the chemistry of the two accumulating species.

[F] Now grade the three conditions. Complete cofactor deficiency: both arms stopped, sulfite toxicity dominant, catastrophic. Isolated sulfite oxidase deficiency: sulfur arm stopped only, sulfite toxicity present, nearly as severe. Xanthinuria: purine arm stopped only, xanthine deposition, mild.

[F] The ordering follows the chemistry of the stranded atom, not the number of genes affected or the position in a pathway diagram. That is the test the chapter set, and it is the strongest single piece of clinical evidence in this volume for a

chemistry-first account of disease severity.

Problems

[O] 24.1 Compute the expected plasma urate in a patient with complete cofactor deficiency and compare with reported values; the deviation reports the contribution of dietary and salvage routes.

[O] 24.2 For the treatable subtype, work out why supplying the intermediate rescues the phenotype while supplying downstream products would not.

[O] 24.3 The same cofactor family serves the sulfur exit and the purine exit. Search for other cofactors serving two exits and ask whether the pattern generalizes.

[O] 24.4 Nitrogenase holds molybdenum with nine sulfurs; the human cofactor with two. Compute the formal oxidation states and the electron-transfer demands of each reaction, and show why the ligation differs.

[VOL p.377] **[O] 24.5** Design a population study testing whether partial terminal-sulfur occupancy contributes to variation in urate handling, and estimate the sample size needed.

[O] 24.6 The human lineage lost uricase. Construct the argument that the loss was selected for and the argument that it was drift, and identify the evidence that would distinguish them.

Connections

[F] This chapter is where the volume's three legs meet in one molecule: a cofactor built from a nucleotide, constructed and switched on by sulfur, sitting at the exits of two systems whose failures propagate differently. Its supply comes from the relay of Chapter 20; its purine arm is the exit of the pathway of Chapter 5; and its evolutionary comparison is the last link of the chain in Chapter 21.

Worked example: reading a newborn's laboratory panel as chemistry

[F] An infant presents with seizures in the first days of life. The differential is broad. Three laboratory values, read together, locate the lesion in the pathway of this chapter.

[F] Value one: plasma urate, low. Urate is the end product of the purine arm. A low value says the arm is not completing, which points at xanthine dehydrogenase or at its cofactor rather than at purine synthesis.

[F] Value two: urinary sulfite, present. Sulfite is the substrate of the sulfur arm's terminal enzyme. Its presence says that arm is not completing either.

[F] Value three: plasma S-sulfocysteine, elevated. The adduct formed when accumulated sulfite reacts with cystine; it confirms the sulfur arm's failure and is the more robust analyte, since sulfite itself is unstable in transit.

[F] The inference. Both arms failed, so the lesion is not in either enzyme but in the cofactor they share. That is molybdenum cofactor deficiency, and the three values

distinguish it from isolated sulfite oxidase deficiency, where urate is normal because the purine arm is intact.

[F] Why it matters immediately. One subtype of cofactor deficiency, caused by failure at the first biosynthetic step, is treatable by supplying the missing pyranopterin intermediate, and outcomes depend on starting early. The chemistry locates the lesion; sequencing then identifies the subtype and therefore whether the treatment applies. This is the correct order: chemistry first, sequence second, because the chemistry is fast and decides whether to treat.

[F] The volume's reading. The clinical severity follows which atom is stranded. Sulfite is an excitotoxin and the brain is developing; xanthine is insoluble and deposits in the kidney.

[VOL p.378] Same cofactor, same kind of lesion, two entirely different outcomes, and the difference is chemistry rather than genetics.

[F] The generalization. Where a cofactor serves two arms, the clinical presentation is the union of the two accumulations, and the severity is set by the more toxic one. That rule is usable in other cofactor diseases and is the kind of thing a chemistry-first account produces that a gene-first account does not.

[VOL p.379] **CHAPTER 25**

The Objection from the Amino Acids, and What Follows

Abstract. The strongest objection to a sulfur-first account of biology is that the two sulfur amino acids are late additions to the genetic code. If sulfur chemistry were as old and as central as Part Five argues, it should have been assigned codewords early, and it was not. This chapter states that objection at full strength, gives the evidence for it, and answers what can be answered. The answer offered is that supply is not repertoire: an element can run a metabolism for a billion years before the coding system acquires a codeword for an amino acid built on it. The objection bounds the claim rather than defeating it, and this chapter says exactly where the boundary falls.

331. The objection, stated without softening

[E] Several independent lines of evidence place cysteine and methionine among the later additions to the coded amino acid repertoire: their positions in consensus orderings derived from prebiotic abundance, biosynthetic cost and codon assignment patterns; their relatively low abundance in the most ancient reconstructed protein sequences; and the biosynthetic complexity of both, which require multi-step pathways rather than arising readily in prebiotic chemistry.

[F] Stated as an objection: if an element is the command layer of metabolism, the coding system should name it early. It named it late. On the face of it, that is

evidence that sulfur's central role is a later elaboration, and that the chemistry Part Five describes was layered onto an already-running coded system rather than preceding it.

[F] The objection is serious and the volume does not dispose of it. What it does is separate two claims that the objection runs together, and show that only one of them is damaged.

332. Two subsystems, two clocks

[F] The first claim is about metabolism: that sulfur chemistry ran the energy economy, the cluster chemistry and the radical chemistry before coded protein synthesis existed. The second is about the code: that the code assigned sulfur-bearing amino acids early. The volume asserts the first and does not assert the second.

[VOL p.380] **[E]** The two subsystems have independent evidence and plausibly different timescales. Cluster chemistry is inferred from mineral geometry, from the distribution of ferredoxins across the tree, and from the oxygen sensitivity of the enzymes that use it. Codon assignment order is inferred from comparative sequence analysis and from biosynthetic cost arguments. There is no requirement that they agree, and an element can be chemically indispensable in a system that has not yet acquired a way to name it.

[F] The clearest illustration is glutathione. It is the cell's principal thiol buffer, present at millimolar concentrations, and it is not a gene product: it is assembled by two ligases from three amino acids, and the code does not spell it. The chemistry is central and the coding system never acquired a word for the molecule.

333. Coenzymes as fossils

[E] Every major coenzyme carries a nucleotide that does none of its chemistry. Coenzyme A carries an adenosine; NAD and FAD carry adenine nucleotides; S-adenosylmethionine carries an adenosine. In each case the business end is elsewhere — a thiol, a nicotinamide ring, a flavin, a sulfonium — and the nucleotide is a handle.

[F] The standard reading of that observation is that these cofactors are relics of a world in which nucleic acids did the catalysis and the functional group was attached to a nucleotide handle because the handle was what the machinery could hold. On that reading the nucleotide is a fossil, and two of the most important handles in the cell terminate in sulfur chemistry: the thiol of coenzyme A, and the sulfonium of S-adenosylmethionine.

[F] If that reading is right, it is evidence for the volume's position and against the objection: sulfur chemistry was being carried on nucleotide handles before protein enzymes existed to carry it, which is exactly the arrangement one expects if the chemistry predates the code.

334. The machine that makes protein is made of RNA

[E] The peptidyl transferase center of the ribosome is RNA. Catalysis of peptide bond formation is performed by the ribosomal RNA, not by the ribosomal proteins, which was established by structural work and is not in dispute.

[F] That fact bounds the objection in a specific way. The coded system's own catalytic core is RNA, meaning catalysis preceded coded protein synthesis. Whatever chemistry the early cell ran, it ran it without a full complement of coded amino acids — which is the volume's position stated from the opposite direction.

[VOL p.381] ## 335. Supply is not repertoire

[F] The decisive distinction is between what the environment supplied and what the code assigned. Abiotic synthesis experiments produce a large number of amino acids, many of which were never assigned codewords. The coded set is small and the available set was large, which means the assignment process was selective rather than exhaustive, and lateness of assignment says something about the selection process rather than about the chemistry's importance.

[E] Reassignment is also observed rather than hypothetical. The genetic code is not frozen: mitochondrial genomes have reassigned codons, including stop codons, and selenocysteine and pyrrolysine are both read from codons that are stops elsewhere. A late addition to the code is therefore an ordinary event rather than evidence that the amino acid in question was unimportant before.

[F] And the one amino acid whose assignment is most clearly late — selenocysteine — is the one whose chemistry is most clearly required, because it sits where the thiol ladder would overshoot (Chapter 17). Lateness and necessity coexist in the clearest case available.

336. The strongest objection to this chapter, stated without softening

[F] Every argument to this point has placed sulfur early. The mineral came before the cofactor, the thiyl radical before DNA, the cluster before the respiratory chain. A reader who accepts all of it can still raise one objection that undoes the whole sequence, and it should be stated here in its strongest form rather than left for a referee.

[E] The order in which amino acids entered the genetic code has been reconstructed many times and from independent kinds of evidence — abiotic synthesis yields, biosynthetic pathway depth, codon assignment patterns, and the composition of reconstructed ancestral proteins. The reconstructions disagree in detail and agree on the ends. Glycine, alanine, aspartate and valine are early. Tryptophan, tyrosine, histidine, methionine and cysteine are late.

[F] The objection follows in one sentence. If sulfur is the supreme command, why are the two sulfur amino acids the last two to arrive? The paper has claimed that the

code opens on a sulfur amino acid and that the bond carrying the result into protein is the disulfide. Both are true of the code as it now stands. Neither is true of the code as it was being assembled. On the face of it, sulfur arrives in the coded alphabet after almost everything else, which is the opposite of what a supremacy claim predicts.

[VOL p.382] ## 337. Two subsystems, two clocks

[F] The objection has force only if coded amino acids and sulfur chemistry are treated as one subsystem. They are two, and they run on different clocks, because they depend on different machinery.

[E] Nothing about an iron-sulfur cluster requires a ribosome. A 4Fe–4S cubane assembles from iron and sulfide in solution and on mineral surfaces without any translated component. A thioester forms by attack of a thiol on an activated acyl group. A persulfide is made by transfer from a sulfur donor. None of these operations is translated, and none of them waits on a genetic code.

[E] Coded amino acids are the opposite case. A new residue in the alphabet requires a biosynthetic route to the amino acid, a transfer RNA bearing a free anticodon, an aminoacyl-tRNA synthetase able to discriminate it from everything else in the pool, and a ribosome willing to accept the pair. That is four pieces of machinery, three of them proteins, and it is the last assembly to come into existence.

[F] So the two statements are not in tension. Sulfur is first in metabolism and late in the coded alphabet, and both are consequences of what each subsystem needs in order to exist. The claim this chapter makes is about the chemistry, not about the alphabet. Blurring the two is what makes the objection look fatal; separating them is what answers it.

[F] The separation can be put more strongly than a defense, and should be. The lateness of cysteine is what the argument predicts, not what it has to survive. If sulfur chemistry was already running on mineral clusters and on thioesters, then there was no selective pressure to spell a sulfur amino acid until proteins began taking over jobs the clusters were already doing. Cysteine enters the code at the point where protein takes custody of metal ligation from the mineral. On that reading, a cysteine arriving early would be the anomaly, because it would be a coded solution to a problem that had not yet been created.

338. Coenzymes as fossils of an earlier metabolic state

[E] In 1976 Harold White observed that the major coenzymes share a feature with no evident chemical purpose. Each of them carries a nucleotide that takes no part in the reaction the coenzyme performs. The chemistry of NAD is done by the nicotinamide ring; the adenosine monophosphate bolted to it does nothing redox. The chemistry of coenzyme A is done by the terminal thiol; the adenosine bisphosphate does nothing acyl. The pattern holds across the set. [VOL p.383] **coenzyme the part that does the chemistry the part that does nothing operation carried** NAD, NADP nicotinamide ring, hydride transfer adenosine monophosphate electron carriage FAD

isoalloxazine ring, one- and two-electron transfer adenosine monophosphate electron carriage Coenzyme A terminal thiol, thioester formation adenosine 3′,5′-bisphosphate acyl transfer SAM sulfonium center, methyl transfer adenosine methyl transfer ATP the phosphate anhydrides adenosine phosphoryl transfer **Table 11.** The nucleotide handle. In each case the reaction is performed by the group in the second column, and the group in the third column is structurally present and chemically idle.

[F] A protein enzyme has no reason to require an adenine on its cofactor. It has a folded surface and can bind whatever it needs by that surface. The nucleotide is a handle, and the thing it was a handle for no longer exists. The economical reading is that these cofactors were in use before protein enzymes were available to hold them, that what held them then was RNA, and that the nucleotide is the vestige of that binding. Protein inherited the whole assembly, took over the binding, and kept the handle because there was no pressure to remove it.

339. Where sulfur sits on the handle

[F] Two entries in that table are sulfur operations, and they are the two transfer operations this chapter has named: acyl transfer through a thioester, and methyl transfer through a sulfonium. Both are carried by cofactors with a vestigial nucleotide attached. Of the seven operations in Section 203, these are the two that look most like relics, and they are the two whose carriers still show the handle.

[F] That matters for the chain in Part V. The chain argued from mineral to editor along a sulfur thread. The coenzymes supply an independent line running the same direction, and it is a line drawn by people who were not thinking about sulfur at all. Where the sulfur thread and the nucleotide thread meet is at the cofactors, and that is the same place the coenzyme argument locates the fingerprints of an RNA world.

[O] The argument has a stated limit and it should not be hidden. Two of the sulfur cofactors carry no nucleotide handle at all. Lipoate is a dithiolane on a lysine arm, and thiamine pyrophos[VOL p.384]phate works through a thiazolium ring; neither has an adenosine. Either they entered later, by a route that never passed through RNA binding, or the handle was lost. The coenzyme argument does not decide which, and no claim is made here that it does.

340. The machine that makes protein is made of RNA

[E] The catalytic site of the ribosome was resolved at atomic scale in 2000. The peptidyl transferase center, where the peptide bond is actually formed, contains no amino acid side chain within reach of the reaction. The catalysis is performed by ribosomal RNA. The work was recognized with the 2009 Nobel Prize in Chemistry.

[F] That single fact settles the direction of the argument in this Part. Protein synthesis is catalyzed by RNA, which means the machine that makes protein cannot have required protein in order to exist. Catalysis preceded protein. The coenzyme evidence says the same thing from the side of the cofactors; the ribosome says it from the side of the machine. A reader who rejects the coenzyme reading as

circumstantial still has the peptidyl transferase center to account for.

341. Supply is not repertoire

[E] The Murchison meteorite has yielded more than ninety amino acids. Roughly nineteen of them occur in terrestrial protein. The rest — α-aminoisobutyric acid, isovaline, sarcosine and the others — are not used by life at all.

[F] That result is often read as evidence that life discarded most of what was available. It is better read as a statement about supply. Abiotic chemistry made eighty-odd amino acids; it does not follow that any code ever spelled them. The reconstructed order of recruitment in Section 336 says the opposite: the coded set began small and grew. Supply was large and the repertoire was small, and the two numbers are measuring different things.

[O] This bears on the empty codons. An eight-letter alphabet read two positions at a time gives sixty-four codewords, and the paper assigns twenty-two. The forty-two remaining are most economically read as never assigned rather than assigned and later vacated, because a code that began sparse and expanded into its space leaves exactly that signature. Nothing here requires them to have carried a function.

[O] One arithmetic consequence is worth recording, because it would make a known feature of the modern code a derivation rather than an observation. Eight letters at two positions give sixty-four. Contract the alphabet to four — the three gatekeepers ceasing to be coding letters and surviving only as metabolic intermediates, as Section 41 describes them — and two positions give sixteen, which is fewer than the twenty-two amino acids the code must spell.

[VOL p.385] The capacity has to be recovered, and a third position recovers it exactly: four letters at three positions give sixty-four again. On this reading the third codon position is compensation for a contracted alphabet, and because it was added to a code that already functioned on two positions it carries the least specific information in the codeword. That is where degeneracy and wobble are in fact concentrated.

[O] The timing is not settled by this and is the obvious place to attack it. If the coded repertoire was smaller than sixteen when the alphabet contracted, two positions would have sufficed for a period and the third position would have been added later for some other reason. The argument needs the contraction and the repertoire to have crossed, and the order of those two events is not established here.

342. How a late amino acid took the first position

[F] Sections 336 and 42 answer why the sulfur amino acids are late. They do not answer the harder form of the same objection, which is worth stating in its own right. If methionine is one of the last residues admitted to the code, how is it the residue every protein now begins with? A late arrival placed at the front of the line sounds like a machine being retrofitted, and retrofitting is exactly what this system cannot do. Information runs from DNA to RNA to protein. No protein edits the gene that made it. An account that requires the apparatus to have been redesigned after the

fact is not an account; it is a violation.

[E] The resolution is duplication and divergence, and nothing in it runs backward. The steps are ordinary. A gene for an initiator transfer RNA is duplicated during replication, which is the normal way genomes grow. The second copy is redundant, so mutations in it are not removed by selection. One such mutation alters the anticodon loop so the duplicate reads a different triplet; a mutation in a synthetase charges that duplicate with a different amino acid. Two populations now exist, each with its own initiation chemistry, and selection decides between them on the protein they produce. At no point does information travel from protein back to gene. What changed was a DNA sequence, by copying error and point mutation, and what chose between the variants was the fitness of the organism.

[E] The system still carries the evidence of that substitution in three places. First, methionine and tryptophan are the only two standard amino acids with a single codon, AUG and UGG, which is the signature of a residue admitted to a table that was already nearly full. Second, bacteria do not initiate with free methionine even now: they use N-formylmethionine, the formyl group blocking the amino end so the chain can only extend in one direction. Third, when the AUG start of an E. coli gene is blocked or mutated, initiation falls back to GUG or [VOL p.386] UUG — valine and leucine — and those alternative starts remain in ordinary use in bacteria, in mitochondria and in plastids.

[F] The arc's reading of this is not that life improved its machinery but that the start position was captured, and the atom that captured it was sulfur. Methionine could not be spelled until the transsulfuration route to homocysteine and the methyl transfer that caps it were both running, which is to say until the sulfur economy of Part II existed. What then selected it was chemical: a hydrophobic thioether side chain that anchors the emerging chain in the ribosomal exit tunnel and protects the amino terminus from immediate degradation better than the valine it replaced. Sulfur arrives at position one late, by capture, and on chemical merit — which is the same account Section 337 gives of cysteine, running one level up.

343. What the mitochondrion still does

[E] One organelle never made the substitution. Human mitochondria still initiate translation with N-formylmethionine. The formyl group is installed by a dedicated mitochondrial methionyl-tRNA formyltransferase, MTFMT, which has no cytosolic counterpart; loss-of-function mutations in it cause Leigh syndrome and combined oxidative phosphorylation deficiency. The cytosol of the same cell initiates with unformylated

[F] That is a sharper statement of the endosymbiosis argument than the usual one, and it belongs in this chapter rather than in a textbook aside. The compartment that runs the sulfur economy is the compartment that kept the ancestral sulfur initiation chemistry. Every claim in Part II about the mitochondrion as the organelle where sulfur chemistry concentrates is reinforced by the observation that it also begins its

proteins the old way, with a formylated sulfur amino acid, inside a cell that stopped doing so everywhere else.

[E] The retention is not cosmetic. Formylated peptides released from damaged mitochondria are recognized by formyl peptide receptors on neutrophils, which is why mitochondrial contents released in trauma and sepsis provoke an innate immune response resembling bacterial infec-tion. The initiation chemistry the organelle kept is the same chemistry the immune system reads as foreign.

344. Codon capture is observed, not inferred

[F] Section 341 left the forty-two unassigned codewords as never assigned rather than vacated, and treated the distinction as a matter of economy. It can be put on firmer ground, because codon reassignment is not a hypothesis about deep time. It is observable in a compartment this chapter has already mapped.

[VOL p.387] **[E]** The vertebrate mitochondrial genome does not read the universal code. UGA, a stop codon everywhere else, specifies tryptophan. AUA, isoleucine in the universal code, specifies methionine. AGA and AGG, arginine in the universal code, are stops. Four codons carry different meanings inside the organelle than in the nucleus of the same cell. Osawa and Jukes named the mechanism codon capture in 1989: compositional pressure on a small genome drives a codon’s frequency toward zero, the codon falls out of use, and a mutated transfer RNA or release factor then reclaims the vacated slot without any protein ever being mistranslated during the transition.

[F] Two consequences for the argument of this Part. First, the objection that a frozen code cannot change is answered empirically, and answered in the mitochondrion, which is where this chapter has already located the sulfur machinery. Second, the vacancy-then-capture cycle is the mechanism by which an unassigned codeword acquires a meaning — which is what the reconstructions say happened when tryptophan and glutamine, the last residues admitted, took over codons that were unassigned or reading as stop. The forty-two are not a dead region of the table. They are the kind of slot that history shows gets filled.

[O] One reconstruction in the literature does not sit comfortably with the contraction proposed in Section 341 and the tension should be recorded rather than smoothed. Analyzes of conserved motifs in ribosomal RNA suggest the earliest codons were G- and C-rich, spelling glycine and alanine, with A- and U-rich codons integrated progressively as the repertoire widened. That is a code expanding from a narrow base. The eight-to-four contraction is a code losing letters. Both describe the same window, and this chapter does not establish how they fit together. The honest position is that the arithmetic of Section 341 stands or falls independently of the compositional reconstruction, and that reconciling them is work not done here.

345. What this Part does not establish

[F] Two objections can be made to the preceding three sections, and both are correct. They are recorded here rather than answered away, because the argument is stronger for conceding them than for absorbing them.

[F] The first is that bacteria are not ancestors. E. coli initiating at GUG when its AUG is blocked is a fact about a modern organism with four billion years of its own evolution behind it, not a window onto the primordial state. Treating a bacterium as a living fossil is a category error, and the inference does not survive in that form. What survives is a different and weaker argument: initiation chemistry is conserved across all three domains, formylated initiation persists in mitochondria and plastids as well as in bacteria, and a trait shared that widely is more economically explained as inherited from a common ancestor than as having arisen [VOL p.388] three times. That is an argument from conservation, not from primitiveness, and it is worth less than an observation and more than a guess.

[F] The second is that invoking a random mutation is not an explanation. Randomness here has a technical meaning with experimental backing — Luria and Delbrück showed in 1943 that mutations arise before and independently of the selective pressure rather than in response to it — so the word is not a rhetorical escape. But demonstrating that a class of mechanism exists is not the same as showing that this change happened by it, at that time, in that order. A mechanism class is not a history. There is no record of a transfer RNA gene duplicating four billion years ago, and there will not be one. The correct answer to when and how methionine took the start position is that it is not known.

Vertebrate mitochondria read four codons differently from the Observed nucleus of the same cell Human mitochondria initiate with formylated methionine and Observed require MTFMT to do it Methionine and tryptophan each have exactly one codon Observed E. coli initiates at GUG or UUG when AUG is unavailable Observed Methionine and cysteine entered the coded alphabet late Reconstructed by several independent methods that agree at the ends The ancestral initiator carried a residue other than methionine Inferred from conservation across the three domains; not observed A duplicated transfer RNA gene produced the methionine Mechanism class only; no record of initiator the event The capture preceded the last universal common ancestor Inferred from universality; not independently dated Sulfur chemistry preceded the coded sulfur amino acids Argued from Parts V and VII; a reading of the machinery, not a record **Table 12.** The claims of this Part graded by what supports them. The first four are measurements. The last four are inferences, and the paper does not ask them to carry more than inferences can.

[F] The same grading applies to this chapter as a whole, and it should be said plainly rather than left for a reader to notice. The chain of Part V is a plausible ordering, not a documented one. No one watched a mineral cluster become a ferredoxin or a thiyl radical make the first deoxyribonucleotide. What the paper has is the chemistry, the distribution of sulfur across the machinery that exists now, and the vestiges that machinery still carries — the nucleotide handle on a coenzyme, the formyl group in a

mitochondrion, the two-sulfur dithiolene on [VOL p.389] a cofactor whose ancestor held nine. Those are real and they point one direction. They are evidence for an argument, and the argument is not a record of what happened.

346. What follows for a development program

[F] The practical content of this chapter is a sequencing rule: choose the level, and measure the state, before choosing the molecule. Five consequences follow.

• At the hub. Expect a progression-free benefit and do not power on overall survival as though a better molecule will deliver it. Five programs have tested that assumption and none returned it. A hub inhibitor is a combination partner or a disease-control agent.

• At a spoke. Select the node by non-redundancy before expression or mutation frequency. Ask whether the cell has a parallel route to that outcome; where it does not, the survival benefit follows. Count the arrows into the organelle and count the decisions they serve.

• Measure redox state, not only sequence. A non-reducing immunoblot distinguishing oxidized from reduced PTEN costs almost nothing and would identify Akt-active patients the genotype misses. The same applies to the disulfide state of any engineered protein and to the thiol distribution at the moment an antibody is conjugated.

• Account for the sulfur supply. Methionine availability gates mTORC1 through SAMTOR independently of Akt; cysteine and selenium availability gate engineered-cell persistence through GPX4. Both are medium attributes and neither appears in standard release testing.

• Upstream of the fan. Editing escapes the redundancy problem but is bounded by two chemical facts — the transition-only reach of both editors and the inosine written as G. Both belong in the risk file at the start of a program, not at the readout.

[F] A sixth consequence cuts across all five. The balloons with no therapeutic agent anywhere — FOXO, CREB, eNOS, the GLUT4 arm, the hydrogen-ion lysosomal arm — are transcription factors and transport proteins, the classic undruggable classes, and they are precisely the nodes where an epigenetic editor rather than a small molecule is the only available lever. The undruggable balloons and the editable balloons are close to the same list. And by §233, every one of those editors will be writing with a sulfur-borne group the mitochondrion has to supply.

347. What would show this is wrong

• Show a hub survival benefit. One Phase 3 Akt inhibitor returning a significant overall-survival benefit at a conventional threshold, in any setting, and the central contrast of §301 against §302 loses its force.

• Show redundancy is not the variable. Demonstrate that the four spoke successes are explained [VOL p.390] by potency, exposure or tumor selection rather than by

non-redundancy of the terminal effector, and §303 is a coincidence dressed as a mechanism.

• Show the organelle sort does not predict. Find a nuclear-balloon node where single-agent inhibition converts to overall survival, or a mitochondrial-balloon node where it fails

• Show oxidized PTEN is rare. Assay banked tumor tissue and show that reversible PTEN oxidation accounts for a negligible share of Akt-active disease, and §290's claim about trial selection falls.

• Show methionine does not matter at mTORC1. Demonstrate that methionine restriction fails to potentiate an Akt inhibitor at mTORC1-dependent outputs, and the mechanism in §291 for why mTOR inhibition converts where hub inhibition does not is wrong.

• Show the epigenetic editors are supply-independent. Demonstrate that targeted methylation and acetylation efficiency is insensitive to the S-adenosylmethionine to S-adenosylhomocysteine ratio and to the acetyl-coenzyme A pool, and the hypothesis in §233 fails.

• Show the transversion wall is passable. Demonstrate reliable T-to-A correction at BRAF V600E with a base editor rather than a prime editor, and §306 is an artifact of the current enzyme set rather than a limit.

• Show attribution is recoverable. Demonstrate a method assigning an A-to-G call in an edited cell to the engineered editor rather than to endogenous ADAR without reading the native molecule.

• Name an eighth operation. Show that any appearance of sulfur in Table 1 or Table 4 needs an operation outside the seven, and the one-to-one mapping in §289 is wrong.

Status. This chapter places the eighteen sulfur functional groups across thirteen organelles, traces the three energy cycles to their sulfur control points, sets out the twelve conversations the mitochondrion holds with the rest of the cell, and reads the Akt output fan — its twenty-seven arrows, its Phase 3 record and its editing status — against that chemistry. What is argued here is the one-to-one mapping of the seven operations in §289, the PTEN disulfide and its consequence for trial selection in §290, the SAMTOR mechanism for why mTOR inhibition converts where hub inhibition does not in §291, the redundancy account in §303, and the sorting of the seven traditions by level in §304. What is offered as hypothesis is marked [H] in §233, §290 and §291. Trial data are current to 13 October 2026. What is open is listed in §273. Distribution: Licensed under CC BY-NC-ND 4.0.

[VOL p.392]

348. Cutting and writing

[E] Across the editing toolkit, every enzyme that writes runs on sulfur: both base editors' zinc held by cysteine, the DNA methyltransferase's catalytic cysteine thiolate together with its sulfonium donor, the methyltransferases generally, the acetyltransferases, TET, and the radical-SAM family. Cas9 is the single exception, and Cas9 is the one that only cuts.

[F] Cutting is magnesium; writing is sulfur. The division was found rather than constructed, and it has a reason: writing a mark is a reversible transaction, with writers and erasers maintained for both the methyl and the acetyl mark, while a double-strand break is a single irreversible event handed to repair.

[F] The consequence is methodological and the remedy is cheap. Acetyl-CoA is a thioester and S-adenosylmethionine is a sulfonium, and both are metered by the

mitochondrion. An editor aimed at a silenced promoter cannot write a mark the sulfur pool will not pay for, so a reported failure to reactivate may be a supply failure rather than a targeting failure.

349. Four dependencies on one allele

[E] The xanthinuria type I allele c.682C>T converts the arginine codon CGA to the stop codon TGA, halting production of functional protein. The second allele, c.2567delC, is a single-base deletion that shifts the reading frame and generates a premature stop downstream.

[F] That one mutation carries four separate sulfur dependencies. The mark: C-to-T at an arginine codon arises by deamination of 5-methylcytosine, and the methyl came from a sulfonium.

The tool: the adenine base editor that exists to revert exactly this lesion holds its zinc with cysteine, and the cytosine editor installs the same chemical change deliberately. The limit: the second allele is a deletion neither editor addresses. The target: the protein cannot function until a terminal sulfur atom is installed on its cofactor.

[F] The commonest class of human pathogenic mutation is the decay product of a sulfur-delivered methyl mark; the tool built to reverse it is sulfur-dependent; and the gene it lands on needs a sulfur atom to work at all.

350. Where the argument lands

[E] Modern medicine, and cancer research in particular, remains focused on genetics and somatic mutation. Billions have been spent sequencing somatic mutations across more than 120 types of cancer, yet targeting those mutations often fails because the cells adapt and mutate [VOL p.393] further. Cancers vary widely in their mutations but share a damaged metabolic phenotype: when mitochondrial communication fails and respiration is compromised, the cell reverts to fermentation.

[F] The genetic mutations are not the cause. They are the downstream consequence of a chronic, localized metabolic and organelle communication failure. Genetic mutations are instructions; metabolism is the execution. A tumor cannot use an escape pathway if it lacks the atomic infrastructure — functional clusters, thioester dynamics — required to generate ATP or synthesize biomass.

[F] The therapeutic consequence follows. The better strategy is not gene or epigenetic editing but correction of the metabolic defects throughout glycolysis, the citric acid cycle and oxidative phosphorylation — going down one layer beneath the molecular to the atomic layer, to sulfur and its command and control of mitochondrial function. Named classes that act at that layer include cluster-assembly disruptors, transsulfuration inhibitors and synthetic persulfide donors.

[F] One further reason recommends that layer. Permanent editing of a survival hub is lethal to normal tissue, and durable epigenetic editing carries the same risk; a small molecule can be withdrawn. Sulfur chemistry is natively reversible while

editing is natively permanent, which makes the atomic layer the one at which intervention can be undone.

[F] A measurable instance already exists. The tumor suppressor PTEN is inactivated reversibly by a Cys71–Cys124 disulfide, not only by deletion. A tumor with intact sequence and oxidized protein is pathway-active and genotypically normal — it has the phenotype a trial selects for and fails the entry criterion. Two Phase 3 trials enrolled on loss of that gene.

A cysteine is one letter whether it is a free thiol or half a disulfide, and a non-reducing immunoblot on banked tissue would test the point at negligible cost.

[E] A parallel sensor sits on the same growth axis: SAMTOR binds S-adenosylmethionine — a sulfonium, one of the classes the standard table omits — and gates mTORC1 independently of the kinase cascade. [H] If growth signaling has a direct sulfur sensor, then methionine restriction should potentiate a kinase inhibitor specifically at the outputs that sensor controls.

351. Open questions

[O] The priority order between cluster assembly and anticodon thiolation under restricted sulfur supply, which would identify which failure the cell accepts in order to avoid the other.

[O] Whether the thiol redox states of the mitochondrial matrix and the reticulum lumen are coupled across their contact sites, and in which direction.

[VOL p.394] **[O]** Whether sulfur ligand count correlates with the environmental scarcity of the ligated metal across enzyme families, independently of oxygen exposure.

[O] Whether epigenetic editing efficiency varies with methionine and cysteine availability for identical constructs at identical targets.

[O] Whether the ratio of cytosine to thymine, reported to vary in species inhabiting high-temperature sulfur environments, reflects a general relationship between base composition and the ambient sulfur economy.

Key literature Primary sources for the established material above, for readers going to the record.

Status. This chapter sets out the sulfur account in full and in order: the nucleotide triad and the incompleteness of base-level editing; sulfur as the command and control element across the three pillars of respiration, protein folding and methylation; the eighteen functional groups with their source, their two inactive entries, the five active classes the table omits and the oxidation ladder that organizes them; the entry of sulfur into the genetic machinery at the thiyl radical, the cluster at the helicase wedge and the thiolated anticodon; the mitochondrial economy and the organelle network it supplies; the deep-time record from the molecular cloud and the iron sulfide minerals through the Great Oxidation; the molybdenum cofactor worked across the whole arc with four human diseases attached; and the consequences for

editing, for trial design and for where therapeutic effort should be directed. Open questions are listed in §351 in the form a laboratory can act on. Released under CC BY 4.0 for open use and testing.

352. What the objection does establish

[F] Three concessions, stated plainly, because an objection answered by concession at the right points is stronger evidence than one answered by denial.

• **The volume cannot claim that the code was built around sulfur.** It was not. The code was built around what was available and selectable, and the sulfur amino acids came late.

• **Arguments from the start codon are weaker than they look.** That translation initiates with a sulfur amino acid is a fact about the current code, and a late addition can take a prime position by duplication and divergence without that position telling us anything about antiquity.

• **Mechanism class is not history.** That a chemistry is possible, and that a modern organism uses it, does not establish that it was used in that way three billion years ago. Everywhere the volume makes a historical claim it is marked, and the mineral-to-cluster link is the only one it leans on.

[VOL p.395] ## 353. What survives

[F] What survives is the whole of the volume's working claim, which is about the present cell and not about the order in which the code was assembled:

1. Sulfur performs seven operations at thirteen compartments, and at several steps there is no alternative chemistry (Chapters 16 through 20).

2. The genome is manufactured, opened and read with sulfur chemistry at irreplaceable steps (Chapter 19).

3. The record the field reads cannot represent that chemistry (Chapters 8, 13, 14, 15).

4. The architecture through which the chemistry acts predicts which therapeutic interventions will be compensated (Chapters 22 through 24).

[F] None of those four depends on when cysteine was assigned a codon.

354. What follows for a development program

[F] The practical conclusion of the volume is a choice of level, and the levels are three.

• **Act on the text.** Editing is the tradition that acts before the output fan opens, and it is the right level when the disease is caused by a letter. Its bounds are the alphabet's reach, the chemistry of the editors themselves, and the state of the cell that receives the edit.

• **Act on a spoke.** Where output is executed in a single compartment, inhibition is not compensable. This is where the survival benefits in the record have come from, and the organelle map identifies candidates in advance.

• **Act on the supply.** The gates of Chapter 5, the junction of Chapter 20 and the cofactor of Chapter 24 are supply-line interventions, and the drugs that already work this way are old, cheap and effective. The level is underexplored not because it failed but because it is not where the field's instrument points.

[F] Alongside the choice of level sits a measurement requirement that applies at all three: state of the system, not just sequence of the system. Nucleotide pool composition, thiol redox poise, cluster occupancy and modification status are the state variables of this account, and all four are measurable with established methods at a cost that is trivial against the price of a failed trial.

355. What would show this is wrong

[F] The volume's falsifiers, collected. Appendix C gives them with their chapters.

• A sulfur function in human biology that fits none of the seven operations (Chapter 16).

[VOL p.396] • A compartment whose keyed-element perturbation propagates as widely as the mitochondrion's, or a mitochondrial cluster failure that is compensated cytosolically (Chapter 20).

• An alternative de novo route to deoxyribonucleotides that does not run through a cysteine radical (Chapter 19).

• A systematic analysis of randomized trials finding no relationship between the compartmental distribution of a target's output and the probability of survival benefit (Chapter 23).

• A survey of clinical-stage agents finding that most already have validation capable of detecting their principal non-coded liability (Chapter 14).

• An organism that has reassigned UAA to an amino acid (Chapter 6, for the stop-codon reading only).

• Evidence that cofactor occupancy, disulfide register and metal loading are predictable from sequence alone in a way that makes the measurements of Chapter 13 redundant.

[F] Seven conditions, each of them an ordinary experiment or analysis, several of them already possible with public data. A reader who runs one of them and finds against this account has done the volume more good than one who agrees with it.

[O] The last open question is the one the volume was written to put in front of other people: how much of what the field currently attributes to sequence is attributable to supply and to state? The direction of the answer is argued here at length. The magnitude is unknown, and it will not be settled by argument.

356. Notes to Chapter 25: the objection, weighed

Quantities worth carrying

[E] Consensus orderings. Several independent lines of reasoning — prebiotic abundance, biosynthetic cost, codon assignment patterns, frequency in reconstructed ancient sequences — have been combined into consensus orderings of amino acid addition to the code. Cysteine and methionine appear late in most of them; glycine, alanine, aspartate and valine appear early.

[E] Abiotic repertoire. Spark-discharge and meteoritic analyzes yield dozens of amino acids, most never coded. Supply exceeded repertoire by a wide margin, which is the basis of the chapter's central distinction.

[E] Code reassignment. Codon reassignments are documented in mitochondrial genomes and in several nuclear lineages, including stop-to-sense changes. The code is not frozen, and late addition is therefore an ordinary event.

[VOL p.397] **[E] Ribosomal catalysis.** The peptidyl transferase center is composed of ribosomal RNA, with no protein side chain positioned to perform the chemistry, establishing that catalysis preceded coded protein synthesis.

[E] Cofactor handles. Coenzyme A, NAD, FAD and S-adenosylmethionine all carry nucleotide moieties that perform none of their chemistry, which is the standard evidence for their origin in an RNA-dominated metabolism.

Methods box: how a claim about code history is tested

[F] Three method classes support claims in this area, with sharply different strengths.

Comparative sequence analysis reconstructs ancestral states and infers order of addition. It is powerful for relative ordering within well-sampled clades and weak at the deepest nodes, where saturation and compositional bias dominate.

Biosynthetic cost analysis ranks amino acids by the number of steps and the energy required to make them, on the assumption that cheaper amino acids were available earlier. The assumption is plausible and untestable directly.

Experimental reconstruction builds and tests minimal translation systems, orthogonal pairs and reduced-alphabet proteins. It establishes what is possible rather than what happened, but it is the only one of the three that produces new data rather than new inferences from old data.

Worked example: separating supply from repertoire

[F] Take selenocysteine, the twenty-first amino acid. By every measure of code history it is a late addition: it requires a dedicated insertion machinery, a recoded stop codon, a stem-loop element in the messenger, and a biosynthetic route that builds it on its own transfer RNA.

[F] Now ask whether its lateness implies that selenium chemistry was unimportant before. It does not. The chemistry selenocysteine performs — reduction of peroxides

at positions of high flux — was being performed before by cysteine-based enzymes, less efficiently and with vulnerability to overoxidation. The code's acquisition of the amino acid did not create the chemistry; it improved the catalyst.

[F] That is the chapter's distinction made concrete. Supply — the availability of an element and its chemistry — is one variable. Repertoire — which amino acids the code names — is another. A late entry in the second says nothing decisive about the first, and in this case the element's chemical necessity and its late coding are both established facts that coexist without tension.

[VOL p.398] **Problems**

[O] 25.1 Take a consensus ordering of amino acid addition and ask, for each of the last five entries, whether its chemistry was being performed before by another residue or cofactor.

[O] 25.2 The volume concedes that it cannot claim the code was built around sulfur. Write the strongest version of the claim it can still make, in one sentence, and check it against the four surviving propositions.

[O] 25.3 Glutathione is central and uncoded. Find three more molecules of comparable centrality that the code does not spell, and ask what they have in common.

[O] 25.4 Design an experiment with a reduced-alphabet translation system that would test whether sulfur-free proteomes can support the chemistry this volume attributes to sulfur.

[O] 25.5 The mitochondrion still initiates with formylmethionine. List every other retained bacterial feature of mitochondrial translation and assess what the set establishes.

[O] 25.6 For each of the seven falsifiers listed at the end of the chapter, estimate the cost and time of the experiment or analysis that would test it, and rank them by information per dollar.

Connections

[F] This chapter closes the volume by stating what the objection establishes and what survives it. The four surviving propositions correspond to Parts Three through Six, and the seven falsifiers are collected again in Appendix C with the chapters they would break. The three levels of intervention named here — text, spoke, supply — are the volume's practical conclusion.

Worked example: choosing a level for one disease

[F] Take a disease in which a nuclear-encoded mitochondrial enzyme is partially deficient because of a missense variant, with a phenotype that is severe in some tissues and mild in others. Three levels of intervention are available, and the chapter's conclusion is that the choice among them is the decision that matters.

[F] Level one: act on the text. Correct the variant. The advantage is positional: the change is upstream of everything else, and if the variant is the whole cause, correction is curative. The constraints are the ones Part Four names: the edit must reach the affected tissue, the chemistry of the editor must be verified beyond the letter, and the cell receiving it must have the replicative reserve to expand if the product is made ex vivo. For a post-mitotic tissue, the delivery problem dominates and the replicative problem disappears.

[VOL p.399] **[F] Level two: act on a spoke.** Find the single output whose failure produces the phenotype and restore it directly. For a partially deficient enzyme this might mean supplying the product, removing the accumulating substrate, or inhibiting a downstream step that converts the accumulation into damage. The advantage is that it works without reaching every cell. The constraint is that it works only where the output is not redundant, which is the architecture question of Chapter 23.

[F] Level three: act on the supply. If the enzyme is partially active, its activity depends on cofactor occupancy, on the redox state of its compartment, and on substrate availability — three quantities that can be moved pharmacologically and nutritionally. The advantage is that it is available now, is cheap, and acts in every tissue. The constraint is that it cannot exceed the ceiling the variant sets.

[F] How to decide. Measure before choosing. If occupancy and redox state are normal and the enzyme is still deficient, level three has no headroom and the choice is between one and two. If occupancy is low, level three has headroom and should be exploited first, because it is reversible and fast. If the phenotype tracks a single downstream output, level two is the efficient choice regardless of what the other two could do.

[F] The general rule. The levels are not a hierarchy of sophistication. Editing is not the advanced version of supplementation. They act at different places on the same chain, and the right one is determined by where the chain is actually broken — which is a measurement, not a preference.

[VOL p.400] Review of Part VI

What Part Six established

[F] One node’s output sorts unevenly by compartment. Twenty-seven documented outward arrows, filed by where the output is executed rather than by pathway, give a distribution in which some compartments receive several independent arrows and others receive one. The seven operations of sulfur map onto seven distinct points of that architecture without remainder.

[E] The brake is thrown by a bond. The phosphatase that opposes the kinase is inactivated by a reversible disulfide as well as by deletion, mutation and promoter methylation. A tumor with intact sequence and oxidized protein is genotypically normal and functionally deficient, and no genotype-based enrollment will find it.

[F] Redundancy, not potency, predicts clinical benefit. Multiple Phase 3 programs against the hub produced no demonstrated overall-survival benefit while programs against single non-redundant effectors have produced it repeatedly. The distinguishing variable is the distribution of output across compartments, which is knowable before a trial begins and is scorable from public data.

[E] A cofactor's graded failures follow the chemistry. One cofactor built from a nucleotide in three sulfur steps, carried by two enzymes at opposite metabolic exits, with three inherited deficiencies whose severity tracks which atom is stranded: sulfite, an excitotoxin, against xanthine, which merely deposits.

[F] The strongest objection bounds the claim without defeating it. The two sulfur amino acids are late additions to the code. Supply is not repertoire: an element can run a metabolism before the coding system acquires a word for an amino acid built on it, and the clearest case — selenocysteine — is both unambiguously late and chemically required.

What Part Six did not establish

[O] One hub is not a sample. The redundancy argument's general form requires the systematic scoring described in Chapter 23, performed blind to outcomes, and that analysis has not been done.

[O] The redox inactivation of the phosphatase has not been quantified in human tumors. The assay is a gel, the samples exist in biobanks, and the handling constraints are stated in the [VOL p.401] worked example of Chapter 22.

[O] The case study is one cofactor. It was chosen because it could fail cleanly and it did not fail, which is evidence and not proof.

The volume's practical conclusion

[F] Three levels of intervention, chosen by measurement rather than by preference. Act on the text where the cause is a letter and the delivery problem is solvable. Act on a spoke where the output is executed in one compartment and cannot be compensated. Act on the supply where occupancy, pool composition or redox state has headroom. And in all three cases measure the state of the system, not only its sequence — four assays, all established, at a cost that is trivial against a failed trial.

Questions a reader should be able to answer

[O] R6.1 Why does filing a kinase's substrates by organelle predict something that filing them by pathway does not?

[O] R6.2 Describe how a tumor can be Akt-active with a wild-type phosphatase gene, and name the assay that would detect it.

[O] R6.3 State the redundancy scoring procedure in five steps, and name its weakest step.

[O] R6.4 Three inherited failures of one cofactor differ sharply in severity. Explain the ordering from the chemistry of the accumulating species.

[O] R6.5 State the late-addition objection at full strength, then state precisely what it damages and what it leaves standing.

[O] R6.6 List three of the volume's seven falsifiers and say which could be tested with public data alone.

Where to go next

[F] Appendix C collects the falsifiers and the unresolved collisions; Appendix F restates every chapter's claim with its evidence class; Appendix G collects the problems by what equipment they need. A reader who has finished the volume and wants to do something with it should start at Appendix G, where roughly a third of the entries are measurements nobody has made.

9. The thirteen themes, the weave and the six threads

[THEMES p.15] ## Part III — The thirteen themes

[E] Each theme is stated as a claim, developed along the arc, tied to the items in the record that carry it, and closed with what would break it. The item counts are from the classification in Part I; the register of every item under each theme is Part VI.

T1 · The substitution at the business end

Threads: atomic · chemical · cellular · enters at S4 · 171 items in the record · heaviest sources: PLATE 45, 816F 44, TERM 23, 816 16, CURR 13, SCN 13 · register in Part VI **The claim.** Oxygen displaced sulfur at the end of the electron chain and nowhere else: sulfur kept the transfers, the clusters, the carriers and the repair, and lost only the terminal acceptor. Every later appearance of sulfur in the cell is a survival of that division, and the division is datable.

[E] Sulfur and oxygen are the same group of the periodic table, one row apart. Oxygen is smaller, holds its electrons harder, and makes the stronger bond; sulfur is larger, softer, and carries nine formal oxidation states against oxygen's handful. For the first billion years of metabolism the terminal electron acceptor was sulfur chemistry, because free oxygen did not exist in quantity.

[F] When oxygen arrived, it took one job. It took the end of the chain — the last acceptor, where the energy yield is set — and it took nothing else. Electron transfer stayed on iron-sulfur clusters. Energy transfer stayed on thioesters. The radical chemistry that makes DNA stayed on a cysteine. The methyl economy stayed on S-adenosylmethionine. The disulfide bond became more useful rather than less, because an oxidizing world is a world in which a reversible oxidation is a switch.

[F] Read this way, the apparent ubiquity of sulfur in the cell is not a curiosity and not special pleading. It is what is left when one job is subtracted from a portfolio. The corpus's strongest version of the claim is quantitative: of the element mentions in the companion paper, sulfur holds the largest share by a factor of nearly three over the next element — and the count is mechanical, because the convention marks elements whether or not the author was arguing about them.

[O] The open part is whether the division of labor was selected or merely survived. Nothing in the record distinguishes a sulfur chemistry retained because it was better from one retained because replacing it was impossible once everything else was built on it.

Where it runs [THEMES p.16] S4 The cluster precipitates in the mineral before any protein holds it.

S6 Thioesters carry energy; clusters carry electrons; neither needs oxygen.

S8 The thiyl radical makes DNA, and DNA keeps no sulfur.

S9 Oxygen takes the terminal acceptor; the cofactor sulfur count collapses nine to two.

S10 Both epigenetic currencies are delivered by sulfur chemistry.

S12 A reversible disulfide decides whether a tumor suppressor is on, and the sequence cannot say so.

What would break it

• Find a cellular electron-transfer system of comparable antiquity that runs without sulfur ligation at any point.

• Show that the sulfur share of element mentions falls to the level of other elements when the same mechanical count is run on a control document by someone who has not read the corpus.

• Date a pre-oxygen cofactor family whose sulfur count rises rather than falls across the boundary.

T2 · The parent before the children

Threads: molecular · genetic · enters at S3 · 167 items in the record · heaviest sources: 816F 54, 816 27, FILE 22, JUN 14, V329 14, TERM 13 · register in Part VI

The claim. Inosine monophosphate is the first purine nucleotide metabolism makes, and adenine and guanine nucleotides are made from it. The record writes the children and omits the parent, and the omission propagates: into the alphabet, into the wobble position, into the editing chemistry, and into every call an instrument makes when it reads inosine as guanine.

[E] De novo purine synthesis assembles the ring on the sugar in ten steps and arrives at inosine monophosphate. Adenosine monophosphate is two steps away on one branch; guanosine monophosphate is two steps away on the other, through the oxidized intermediate. No organism makes adenine or guanine nucleotides by any other route.

[E] The prebiotic chemistry agrees. The cyanosulfidic network reaches inosine and its precursors where it does not reach the canonical purines, and the delivered meteoritic inventory carries hypoxanthine and xanthine at concentrations comparable to adenine and guanine.

[THEMES p.17] **[F]** Two independent accounts put the same molecule first, and the table that describes the genetic code contains neither it nor the gate beside it. The consequence is not aesthetic. It propagates: the base that widens the anticodon is the omitted one; the product of the adenine base editor is the omitted one; the mark that distinguishes self from foreign RNA is the omitted one; and every instrument that reads any of those writes the letter of a different base.

[F] The corpus's own formulation is that the canonical table begins one molecule too late.

That is a stronger claim than saying inosine is important, and it is the version that can be attacked, because it is a claim about where a sequence starts rather than about how much something matters.

Where it runs S3 Hypoxanthine arrives in the delivered inventory, not as a modification of anything.

S5 Metabolism reaches the trunk before either branch.

S7 The trunk's base sits at the first position of the anticodon and widens what it reads.

S11 The editor writes the trunk's base across the cell's own transcripts as a mark of self.

S12 The clinic reads that mark as a guanosine, and an off-target call cannot be assigned.

What would break it

• Demonstrate a route to adenine or guanine nucleotides in any organism that does not pass through the trunk.

• Show that the prebiotic and metabolic priorities are artifacts of the conditions chosen — that a defensible set of early-Earth conditions reaches the canonical purines first.

• Show that the base at the first anticodon position could be any purine, by building an adaptor that widens its reading the same way without it.

T3 · The notation decides what can be found

Threads: genetic · chemical · enters at S7 · 417 items in the record · heaviest sources: 816F 106, TERM 77, CURR 73, SCN 34, FILE 33, 816 26 · register in Part VI

The claim. A convention fixed for convenience governs what later instruments can record. Five things the four-letter alphabet cannot carry — modification, rotation, absence, orientation and the base triple — are not notational inconveniences but measurement limits, and they are still operating in the sequence file the clinic reads.

[THEMES p.18] **[E]** The four letters were fixed in the 1950s and 1960s because those were the bases that could be purified and polymerized, and the code was cracked with synthetic polynucleotides made from them. The table that resulted records what was in the flask.

[F] A notation is a measuring instrument, and an instrument that has no symbol for a quantity cannot report it. Five quantities have no symbol in the four-letter alphabet: chemical modification of a base, rotation about the glycosidic bond, the absence of a base at a position, the orientation of a strand's face, and the three-stranded contact. None of those is exotic; all five occur in every human cell as you read this.

[F] The argument is operational rather than philosophical, and that is what makes it a scientific claim and not a complaint about terminology. It names cases: a trial

enrolled on a register that cannot represent an oxidized cysteine; an off-target call that cannot be attributed because the editor's product prints as another base; a drug aimed at a region whose meaning is not in its sequence. Test the cases, not the principle.

[O] The standing objection is that modification databases record what the sequence file loses, so nothing is lost in principle. The corpus concedes the objection is also the admission: what the clinic reads is the sequence file.

Where it runs S7 The alphabet freezes around whatever was in use.

S8 A chemical level distinction — base, nucleoside, nucleotide — collapses onto one letter.

S11 Editing writes a base the record cannot represent.

S12 The sequence file is what the trial, the pipeline and the regulator read.

What would break it

• Find a sequence-format specification in routine use with a field that records a chemical state rather than an identity.

• Show an established notation for the three-stranded contact that working pipelines consume.

• Show that the three named operational cases do not hold — that the trial, the call and the drug were not constrained by the record.

T4 · Novelty by removal

Threads: molecular · cellular · genetic · enters at S8 · 56 items in the record · heaviest sources: 816F 23, TERM 9, CURR 5, CDU 5, FILE 5, 816 3 · register in Part VI [THEMES p.19] **The claim.** The decisive steps are subtractions. An oxygen comes off the sugar and RNA becomes DNA; an amine comes off a base and adenosine becomes inosine; introns come out and one gene becomes many proteins; a methyl comes off and a gene reopens. Biology makes new kinds of thing by taking something away, and the enzymes that do it are older than the things they act on.

[E] The route from RNA to DNA is a removal: the 2′ oxygen comes off the sugar. The route from adenosine to inosine is a removal: the amine comes off the base. The route from a pre-messenger to a messenger is a removal: the introns come out. The route from a silenced gene to an active one is a removal: the methyl comes off.

[F] Addition makes variants; removal makes kinds. Every one of those four subtractions produces a different category of molecule rather than a decorated version of the same one, and in three of the four cases the enzyme that performs the removal is older than the category it creates.

[F] The theme has a sharp corollary the corpus states plainly: the nucleotide is never assembled from a pre-made deoxy sugar. The cell builds the ribonucleotide and then takes the oxygen off. The order is not an accident of biochemistry; it is the reason

DNA is downstream of RNA in every organism.

Where it runs S6 The first copying errors are losses, not gains.

S8 Ribonucleotide reductase takes an oxygen off and the archive separates from the working copy.

S10 Demethylation reopens what methylation closed.

S11 Splicing removes most of the transcript and makes many proteins from one gene.

What would break it

• Find an organism that assembles a deoxyribonucleotide from a pre-made deoxy sugar rather than by reduction.

• Show that prebiotic removal of the 2′ oxygen does not require sulfur chemistry in the way the enzyme does.

• Name a category-making step in the central chain that is an addition rather than a removal.

T5 · Weakness is the design

Threads: atomic · molecular · enters at S4 · 194 items in the record · heaviest sources: 816F 103, 816 21, TERM 16, FILE 12, CURR 10, CDU 10 · register in Part VI [THEMES p.20] **The claim.** The interaction that matters most is the weakest one that still holds. A covalent bond at four hundred kilojoules per mole cannot let go; a hydrogen bond at twenty breaks constantly, which is why everything reversible in biology is built from it — pairing, opening, folding, wobble tolerance, and the editing that depends on a base being reachable.

[E] A covalent bond runs to about four hundred kilojoules per mole. A hydrogen bond runs to about twenty. Thermal energy at body temperature is around two and a half. The first never breaks by accident; the second breaks constantly.

[F] Everything reversible in biology is built from the weak one, and reversibility is the whole requirement. A duplex held by covalent bonds would be a permanent archive and an unreadable one. A protein folded by covalent contacts could not breathe, could not sample alternatives, could not bind a substrate and release a product. Two bonds against three — the difference between the weak pair and the strong one — sets the melting temperature of every sequence and decides which regions of a genome open first.

[F] The theme is what makes wobble possible at all, and therefore what makes the second and eighth themes possible. A pairing that tolerates a near-miss is a pairing weak enough to be wrong and strong enough to be useful, and the base that tolerates the most near-misses is the one the record omits.

Where it runs S4 Gradients across thin walls are held by weak, reversible chemistry.

S5 Pairing faces become distinguishable without becoming permanent.

S7 The anticodon can be wrong by one position and still work.

S11 A duplex has to open for an editor to reach it.

S12 A folded molecule has an ensemble of shapes, and a drug has to reach one of them.

What would break it

• Show a decoding or replication system of comparable fidelity built on bonds an order of magnitude stronger.

• Show that pairing strength does not predict which regions of a genome open first.

• Show that the editor can reach a site independent of whether the duplex opens.

T6 · The gate is where the control is

[THEMES p.21] Threads: chemical · molecular · biological · enters at S5 · 136 items in the record · heaviest sources: 816F 61, TERM 17, FILE 13, CURR 11, 816 8, PLATE 7 · register in Part VI **The claim.** The pathway is full of one-way steps, and every one of them is a control point rather than a bottleneck: the trunk nucleotide to the oxidized gatekeeper, the pyrimidine gate, the oxidase that cannot run backward. Pharmacology works where the gates are, which is why the drugs cluster on them.

[E] The pathway is full of steps that do not run backward: the trunk nucleotide to the oxidized gatekeeper, the pyrimidine gate on the route to uracil, the oxidase that takes a purine to urate and stops. Each is a committed step, and each is where regulation sits.

[F] Pharmacology is a map of where the gates are. The drugs that work on purine metabolism work at the gates — the oxidase inhibitor, the thiopurines, the inhibitors of the pyrimidine gate — and not in the middle of reversible stretches. That is not a coincidence about medicine; it is a consequence of where control is located in a pathway, and it is a prediction about where the next useful target will be.

[F] The theme reaches past metabolism. A gate is a one-way decision point, and the corpus finds them at every scale: a base that can be read in only one direction, a code that cannot be unassigned once assigned, a mark that commits a cell to a lineage.

Where it runs S5 The trunk branches through gates, one on each side.

S6 Committed steps appear as soon as there is a pathway to commit to.

S10 Compartments are gates in space rather than in chemistry.

S12 The drugs cluster where the gates are, and so do the failures.

What would break it

• Find a committed step in purine metabolism with no pharmacology on it and no regulation at it.

• Show that drug efficacy on this pathway is independent of whether the target step is reversible.

• Show a gate the corpus names that is in fact reversible under physiological conditions.

T7 · Order and handedness are information

Threads: atomic · molecular · genetic · enters at S2 · 624 items in the record · heaviest sources: 816F 274, FILE 118, JUN 115, 816 51, TERM 25, MAY 15 · register in Part VI [THEMES p.22] **The claim.** Sequence is not the only ordering that carries meaning. Multiplication that does not commute, a backbone that comes in two mirror forms, three points of attachment where two cannot distinguish a hand, a chain with a direction — each stores information in the arrangement rather than in the parts, and each is invisible to a notation that records identity alone.

[E] Multiplication of the quaternion units does not commute: one order gives one answer and the reverse gives its negative. Chemistry has the same property wherever handedness is involved — the two mirror forms of a modified backbone are not the same molecule, and an enzyme that binds one need not bind the other.

[F] Three points of attachment are the minimum for distinguishing a hand, which is why a two-point model of substrate binding cannot account for stereospecificity and a three-point one can. The same minimum shows up in the triplet codon, and the corpus argues the two are instances of one constraint rather than a numerological rhyme.

[F] The theme is what makes the geometry Parts of the corpus a bookkeeping claim rather than a decoration: a solid can carry a certain number of distinct relationships at once, and if the pairing relationships of six bases are twelve, a solid with twelve edges can hold them and a solid with a different count cannot.

[O] Where the arrangement claims stop being bookkeeping and start being physics is exactly where the corpus refuses them, which is the thirteenth theme. The period of a rotation belongs to the particle, not to the sugar pucker.

Where it runs S2 Handedness is present in the delivered inventory before biology.

S6 A chain acquires a direction and the direction carries information.

S7 Twelve pairing relationships sort into three groups and the counts land on twenty-two.

S11 A strand’s face decides whether a third strand can contact it.

What would break it

• Show a decoding system of comparable specificity built on two points of contact.

• Show that the two mirror forms of a modified backbone are functionally equivalent in the systems the corpus names.

• Score the arrangement claims against the volume's own four conditions and find one that passes where the corpus says it fails.

[THEMES p.23] T8 · The same chemistry twice, with opposite signs

Threads: chemical · genetic · cellular · enters at S6 · 101 items in the record · heaviest sources: 816F 32, 816 13, CDU 11, TERM 11, V329 8, CURR 8 · register in Part VI **The claim.** One reaction is damage in one place and function in another. Deamination destroys information in a genome and creates it in a transcript; wobble is a copying error at the origin and an economy at the ribosome; oxidation is decay at a guanine and a signal at a cysteine. The corpus reads these as one chemistry used twice rather than as two phenomena.

[E] Deamination of adenosine gives inosine. In a genome that is damage; in a transcript it is editing. Deamination of cytosine gives uracil. In DNA that is a lesion the repair system removes; in an antibody gene it is the mechanism of diversity.

[F] The corpus reads these as one chemistry used twice rather than as two phenomena with a shared mechanism, and the difference matters: on the first reading, the cell did not invent editing — it stopped repairing in one compartment. That is a much cheaper evolutionary story and it predicts where editing should be found.

[F] The pattern generalizes across the arc. Wobble is a copying error at the origin and an economy at the ribosome. Oxidation is decay at a guanine and a signal at a cysteine. A repeat is instability at a telomere and a binding site in a promoter. In each case the sign of the chemistry is set by where it happens, not by what it is.

Where it runs S6 The first ribozyme error is the future economy.

S8 Removal is damage in one place and category-making in another.

S10 A mark is instruction in one compartment and noise in another.

S11 Editing marks self where the same reaction elsewhere would be mutation.

What would break it

• Find an editing system whose chemistry has no damage counterpart anywhere in the same cell.

• Show that the editor is not evolutionarily related to the repair or modification enzymes it resembles.

• Show a case where the sign of the outcome is set by the chemistry rather than by the compartment.

[THEMES p.24] T9 · A number that changes across one boundary dates the boundary

Threads: atomic · chemical · biological · enters at S1 · 272 items in the record · heaviest sources: 816F 99, FILE 51, JUN 39, TERM 24, 816 20, PLATE 9 · register in Part VI **The claim.** Where a count changes once, in one direction, at one horizon, the

horizon can be dated: nine sulfurs to two across the oxygen boundary, the sulfur isotope anomaly that stops at 2.45 billion years and never returns, the oxidation-state span no other biological element has. The method is arithmetic applied to deep time, and it is checkable.

[E] The sulfur isotope anomaly is the model case: present below a horizon, absent above it, never returning. One measurement, one direction, one date.

[F] The corpus applies the same logic to biology. Nine sulfurs to two across the oxygen boundary is a count that changes once and does not change back. The span of oxidation states sulfur occupies in biological systems is wider than any other biological element's, and the span is a fact about the element rather than about any organism.

[F] What makes this a method rather than an observation is that it is checkable without a bench. The structural databases hold both pre-oxygen and post-oxygen representatives of several cofactor families; counting the sulfur ligation in each is an afternoon's work against public structures, and it either generalizes or it does not.

[O] Until that survey is run, the boundary claim rests on one cofactor family. The corpus says so in the same paragraph in which it makes the claim, which is the correct place to say it.

Where it runs S1 Element abundances are set in a sequence that can be dated.

S9 The anomaly stops; the cofactor counts collapse.

S11 Fusion scars and repeat counts date events in a genome the same way.

S12 The corpus counts its own frontier by the same method: 903 of 1,063 subjects outside the volume.

What would break it

- Run the ligation-count survey and find no systematic direction of change.
- Find a biological element with a wider span of oxidation states in use.
- Date a cofactor family whose sulfur count changes more than once.

T10 · Flat maps of unflat things

[THEMES p.25] Threads: molecular · genetic · biological · enters at S11 · 298 items in the record · heaviest sources: 816F 126, PLATE 47, TERM 46, FILE 29, CURR 14, 816 13 · register in Part VI **The claim.** Every representation in the chain loses a dimension that matters. A sequence is flat and a molecule is not; a pathway chart is flat and metabolism is not; a codon table is flat and the decoding is not. The corpus's own figure for this is a map that showed every channel a river had occupied rather than the one it occupies now.

[E] An isolated base ring is planar. A base pair inside a living duplex is not: it has propeller twist of ten to twenty degrees, it buckles, it rolls, and most of its stability comes from stacking rather than from the pairing the diagram draws.

[F] Every representation in the chain loses the dimension that decides reachability. A sequence is a line; the molecule is an ensemble of shapes. A pathway chart is a plane; the metabolism is a volume with compartments. A codon table is a grid; the decoding is a set of contacts at an angle. The corpus's claim is that the losses are not evenly distributed — they fall hardest exactly where design methods now operate.

[F] The arithmetic of the field is the frame the corpus puts around this. Roughly ten thousand proteins were called undruggable by conventional means; oligonucleotides were meant to reach them; since the 1990s about eighteen such drugs have reached approval. The corpus takes that ratio as a fact about method rather than as an indictment, and asks what the method is not seeing.

[O] Whether structural accessibility explains any part of the gap is open, and the corpus warns in print against taking it as the whole explanation. Delivery, nuclease susceptibility and toxicity are real and are not being displaced.

Where it runs S3 The delivered inventory is three-dimensional and the manifest is a list.

S7 The codon table is flat and the contacts are not.

S11 The record of editing is a letter and the event is a chemistry.

S12 A design pipeline selects sites on a flat map of an unflat molecule.

What would break it

• Show that approved and failed antisense sites do not differ in ensemble accessibility.

• Show a commercial pipeline that already models accessibility in the way the corpus says is missing.

[THEMES p.26] • Show that the flat representation loses nothing a working method needs.

T11 · The present is sedimented past

Threads: cellular · biological · genetic · enters at S2 · 142 items in the record · heaviest sources: 816F 53, FILE 15, 816 13, PLATE 13, TERM 13, JUN 12 · register in Part VI **The claim.** Structures persist because nothing had a reason to remove them. A cofactor carries a nucleotide handle from an RNA world; an iron-sulfur cluster carries the chemistry of a mineral surface; a transposable element carries a copying accident into immunity; a telomere carries the scar of a joining. The cell is a stratigraphy and can be read as one.

[E] Cofactors carry nucleotide handles that do nothing in their chemistry. The best account of why is that they were once made of RNA, and nothing had a reason to remove the handle when protein enzymes took over the catalysis.

[F] The same argument runs on minerals, on organelles, on transposable elements and on telomeres. An iron-sulfur cluster is a mineral surface that a protein learned to hold. A mitochondrion is a bacterium that stayed. An Alu element is a copying

accident that became a substrate for the editor. A telomere is the record of an end-replication problem that was solved rather than removed.

[F] The cell is therefore readable as a stratigraphy, and the corpus reads it that way: each layer is dated by the chemistry it preserves rather than by its position. This is the theme that lets the arc be run in reverse — from a modern cell back to the conditions that are still visible in it.

Where it runs S2 The amide bond arrives before anything that needs it.

S4 The cofactor exists before the enzyme that holds it.

S6 The energy and electron systems of the origin are still running.

S10 An endosymbiont becomes an organelle and keeps its chemistry.

S11 A copying accident becomes an immune mark.

What would break it

• Show a cofactor whose nucleotide handle is required by its chemistry.

• Show that the cluster motifs in modern proteins are not mineral-like in structure.

• Show that the editor's substrates are not dominated by the repeat family the corpus names.

[THEMES p.27] ## T12 · Supply is not repertoire

Threads: chemical · genetic · enters at S3 · 124 items in the record · heaviest sources: 816F 62, FILE 15, JUN 14, TERM 10, 816 7, CURR 7 · register in Part VI

The claim. What was available does not establish what was used. Abundance in a meteorite, stability in a backbone, and presence in a pathway are each arguments for availability and none of them is an argument for membership in the code. The distinction cuts both ways, and it is the one the corpus insists on against its own case as well as for it.

[E] The meteoritic inventory contains more than eighty amino acids and biology uses twenty.

It contains hypoxanthine and xanthine in quantity and the canonical code uses neither. Abundance is not membership.

[F] The corpus applies the rule against itself, which is the only way the rule is worth anything. The same argument that says a delivered base is not thereby a letter also says that a stable backbone available at the origin is not thereby the backbone that was chosen, and that a nucleotide that metabolism makes first is not thereby a letter of the code. The second theme survives this test because it does not rest on abundance; it rests on the route.

[F] The distinction also sets the terms of the corpus's own strongest unresolved question: whether the eight nucleotides of metabolism are an alphabet or an inventory of manufacture. The reading that survives both ways is two alphabets for two jobs — one for what is built, one for what is read.

Where it runs S3 Delivery establishes availability and nothing else.

S5 Both backbones are available and one is taken.

S7 The set that closes is not the set that was present.

S12 An expanded code is engineered today, which shows the constraint was never material scarcity.

What would break it

• Show that code membership tracks prebiotic abundance across the five canonical bases.

• Show that the alternative backbone fails on a chemical ground rather than on a historical one.

• Show that the eight of manufacture and the set that is read are the same set.

[THEMES p.28] ## T13 · The discipline of refusal

Threads: atomic · molecular · genetic · enters at S12 · 111 items in the record · heaviest sources: 816F 29, CURR 27, TERM 19, FILE 13, JUN 8, OVR 5 · register in Part VI **The claim.** The corpus declines shapes it wanted. There is no sixty-four-cell; the sugars fail the four conditions a spin claim must satisfy; three things do not fit inside the construction and the volume calls that the best result in the Part; one element is kept out of the color scheme entirely. A body of work is testable in proportion to what it refuses, and the refusals are where this one is strongest.

[E] The corpus declines shapes it wanted. There is no sixty-four-cell that carries the counts it needed to carry. The sugars fail all four conditions a half-integer spin claim has to satisfy, and the volume prints the failure. Three things do not fit inside the modeling construction, and the volume calls that the best result in the Part. One element is kept out of the color scheme entirely because it does not belong there.

[F] A body of work is testable in proportion to what it refuses. Each refusal above converts a claim that could have been made into a boundary, and a boundary is what makes the remaining claims falsifiable. The corpus’s dispute register — fourteen contested positions, each with two readings and a statement of where the corpus stands, including the places where it declines to choose — is the same discipline applied to the live questions.

[F] The theme is also the reason this volume can be written at all. A corpus that refused nothing would have no shape to find: every item would support every theme and the classification in Part VII would be meaningless.

[O] The hardest refusal is still outstanding, and the corpus names it: the chain itself is a plausible ordering rather than a documented one. The corpus’s own verdict on its central narrative is the weaker of the two available readings, printed in its own register.

Where it runs S7 The counts that close the set are stated and the ones that do not are refused.

S9 A single-cofactor result is labeled as resting on one cofactor.

S11 The editing claim is split into two functions rather than collapsed into one.

S12 The register of disputes and the register of protocols are printed rather than summarized.

What would break it

[THEMES p.29] • Find a claim in the corpus that is held without a stated condition under which it would be wrong.

• Show that a refused shape in fact satisfies the conditions the volume set for it.

• Show that the dispute register omits a live dispute the corpus's own material raises.

Part IV — The weave

[E] The matrix below is the book's central picture. Rows are the thirteen themes; columns are the twelve stages of the arc. A letter E marks the stage at which a theme enters and becomes available; an X marks a stage in which it is doing visible work; a stop marks a stage it is absent from. Every row heading links to its theme, and every column heading links to its stage.

The matrix: thirteen themes against twelve stages

theme	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11	S12
T1	·	·	·	**E**	X	X	·	X	X	X	·	X
T2	·	·	**E**	·	X	·	X	·	·	·	X	X
T3	·	·	·	·	·	·	**E**	X	·	·	X	X
T4	·	·	·	·	·	X	·	**E**	·	X	X	·
T5	·	·	·	**E**	X	X	X	·	·	·	X	X
T6	·	·	·	·	**E**	X	·	·	·	X	·	X
T7	·	**E**	X	·	·	X	X	·	·	·	X	·
T8	·	·	·	·	·	**E**	·	X	·	X	X	·
T9	**E**	·	·	·	·	·	·	·	X	·	X	X
T10	·	·	X	·	·	·	X	·	·	·	**E**	X
T11	·	**E**	·	X	·	X	·	·	·	X	X	·
T12	·	·	**E**	·	X	·	X	·	·	·	·	X
T13	·	·	·	·	·	·	X	·	X	·	X	**E**

[F] Three patterns are visible in it before any argument is made about them. The themes about arrangement and about inheritance enter earliest and reach furthest, because arrangement is available as soon as there are molecules and inheritance begins the moment anything persists. The themes about chemistry — the

substitution, the gate, the double sign, the removal — cluster in the middle stages, between the first polymers and [THEMES p.30] the oxygen boundary, which is where the chemistry of the cell was actually decided. The themes about the record enter last: notation at the stage the code fixes, flat maps at the stage the genome is read, refusal at the present stage, where a claim first has to be defended rather than made.

[F] The late entries are the ones that matter for how the corpus should be read. A reader who meets the notation argument first takes it for a complaint about terminology. A reader who meets it at the stage where the alphabet froze — after eight stages in which the chemistry was settling what there was to name — reads it as what it is: a claim that a measuring instrument was fixed before anyone knew what it would be asked to measure.

[O] The matrix is an assignment, not a measurement. A different reader would move cells in the middle stages, where the chemistry is dense and the attributions are arguable. The cells that are not arguable are the entries, and those are the ones the argument rests on.

The themes against the six threads

theme	atomic	chemical	molecular	cellular	biological	genetic
T1	X	X	·	X	·	·
T2	·	·	X	·	·	X
T3	·	·	·	·	·	X
T4	·	·	X	X	·	X
T5	X	·	X	·	·	·
T6	·	X	·	·	X	·
T7	X	·	X	·	·	X
T8	·	X	·	X	·	X
T9	X	X	·	·	X	·
T10	·	·	X	·	X	X
T11	·	·	·	X	X	·
T12	·	X	·	·	·	X
T13	X	·	X	·	·	X

[F] No theme rides all six threads and none rides only one. The genetic thread carries the most themes, which is what one would expect of a corpus whose subject is a record; the cellular thread carries the fewest, which is a gap rather than a result — the corpus is strong on chemistry and on notation and comparatively thin on what happens inside a [THEMES p.31] particular compartment at a particular moment.

[O] That thinness is the clearest place where the record could be extended without any new argument at all: the material exists in the plate archive’s organelle plates and in the sulfur outline’s chapter on the twelve conversations, and it has not yet been written into the volume.

How a theme enters and leaves a chapter

A theme does not run continuously once it enters. It is picked up where the material needs it and put down where it does not, and the pattern of pickups is what gives a chapter its shape. Three worked cases, each traced through the chapter-length works already in the record:

• **The substitution, through the sulfur outline.** It enters at the chapter on the mineral and the cluster, is set down through the glycolysis and citric-acid chapters where the subject is thioester chemistry rather than the acceptor, is picked up hard at the oxygen boundary chapter, and returns in the cofactor Part where the count collapses. Four appearances, three absences, in thirty-four chapters.

• **The parent, through the curriculum.** It enters in the alphabet Part, is absent through the whole geometry Part, returns in the recognition Part at the wobble position, runs the entire editor Part, and closes the clinical Part at the off-target call. The absence in the geometry Part is the informative one: the geometry is about arrangement and does not need the trunk.

• **The refusal, through both.** It appears only where a claim is being declined — the shapes that do not fit, the conditions a spin claim fails, the element kept out of the scheme, the dispute register. It is absent from every chapter that is purely expository, which is why it reads as a method rather than as a subject.

Part V — The six threads

[E] The six threads are the ones this work has always been organized by: atomic, chemical, molecular, cellular, biological, genetic. They are not six subjects. They are six ways of following the same arc, and a claim that holds on one and fails on another is telling you where its limit is.

[F] Each thread below carries its own reading line — a short sequence of chapters and sections already in the record that can be read end to end without the rest of the corpus. A reader who wants the chemistry and not the notation argument can take the chemical line alone and will not be missing a step.

[THEMES p.32] ### The atomic thread

The elements themselves: which were available, in what order, at what cost, and what each one can do that no other can. · themes riding it: <a href="#t-T1">T1</a> · <a href="#t-T5">T5</a> · <a href="#t-T7">T7</a> · <a href="#t-T9">T9</a> · <a href="#t-T13">T13</a>

[E] The atomic thread is the one the corpus starts from, and it is the reason the color key exists at all. Seven elements, each with a position in the order of stellar production, a set of oxidation states, a size and a hardness, and a set of things it can do that no substitute can.

[F] Followed on its own, this thread answers a question the other five cannot: why these seven and not others. Hydrogen because it is the universal donor and the weak bond. Carbon because it catenates. Nitrogen because it holds a lone pair and makes a base a base. Oxygen because it is the hardest acceptor available. Phosphorus because a triply-charged linker resists hydrolysis and stays put. Sulfur because it spans nine oxidation states and will take a radical and hand it back. Selenium because it is sulfur with a lower barrier, which is useful exactly where speed matters more than stability.

The reading line source where to read why it sits here AMB Chapter One — Red: hydrogen and adenine the weak bond, introduced as a design principle rather than as a property SCN A1 · Why Sulfur Was Available the six properties no other available atom combines SCN A3 · The Eighteen Functional Groups every shape one element takes, with the two that have no biological role PLATE Element availability plates 084 and 110 volt-equivalent against oxidation state at pH 7; sulfur spans the full width CURR B7 · The Element Itself nine formal oxidation states, stated once, before any biology uses them AMB Chapter Six — Indigo: selenium and xanthine the band the eye does not resolve, and the element kept separate from sulfur on purpose CURR B6 · Where the Seven Came From the order of stellar production, which is not the order of the key

The chemical thread

The bonds and the reactions: what forms, what breaks, what is reversible and what is not. · themes riding it: <a href="#t-T1">T1</a> · <a href="#t-T6">T6</a> · <a href="#t-T8">T8</a> · <a href="#t-T9">T9</a> · <a href="#t-T12">T12</a>

[THEMES p.33] **[E]** The chemical thread is about bonds and reactions: what forms, what breaks, what is reversible, and at what cost. It is the thread on which the corpus is strongest, because every claim on it can be checked against a number.

[F] Read alone it produces the corpus’s sharpest sequence: a thioester carries energy before a phosphate anhydride does; a radical on a cysteine removes an oxygen and makes a new class of molecule; an oxidation at a guanine is damage and the same chemistry at a cysteine is a signal; a deamination is a lesion in one compartment and an instruction in another.

The reading line source where to read why it sits here SCN C9 · A Thioester at the Heart of Glycolysis the one step that saves the energy CURR D19 · A Thiyl Radical Made DNA the mechanism in full, with the reset SCN E20 · Guanine Is the Weak Link the lowest oxidation potential in the set, and where it sits SCN E21 · Counting the Cost of an Electron the ionization-energy ladder, with its caveat printed CDU §24 · Deamination chemistry one reaction, four enzymes, two signs CURR B10 · Hydrogen Sulfide Before Water the network that makes the monomers, under ultraviolet light SCN F26 · Nine Sulfurs to Two a count that changes once, across one boundary

The molecular thread

The objects built from those bonds: nucleotides, cofactors, backbones and the shapes they take. · themes riding it: <a href="#t-T2">T2</a> · <a href="#t-T4">T4</a> · <a href="#t-T5">T5</a> · <a href="#t-T7">T7</a> · <a href="#t-T10">T10</a> · <a href="#t-T13">T13</a>

[E] The molecular thread is the objects: nucleotides, cofactors, backbones, adaptors, and the shapes they hold. It is where the corpus's central omission lives, because a nucleotide is the unit the record refuses to count.

[F] The thread's own argument is that the unit has been mis-set. A letter names a base; the thing that exists is a nucleotide; and three chemical levels — base, nucleoside, nucleotide — have been collapsed onto one symbol. Everything else on this thread follows from reinstating the distinction.

The reading line

[THEMES p.34]

source	where to read	why it sits here
CURR	A3 · Base, Nucleoside, Nucleotide	the three levels, separated
CURR	C12 · The Door They All Come Through	the trunk, and why both branches pass it
SCN	D14 · The Alphabet Metabolism Builds	eight nucleotides and three gatekeepers
AMB	Chapter Nine — The Seven-Letter Seed	the proposal written in nucleotides rather than in letters
CDU	§1 · The Octahedron Model	six vertices, twelve edges, three pairing groups
CURR	G37 · Nothing Alive Is Flat	propeller twist, buckle, roll, and stacking
CURR	E24 · The Closure Rule	what closes the set, and at what count

The cellular thread

The compartments and the traffic between them: where each chemistry is allowed to run. · themes riding it: <a href="#t-T1">T1</a> · <a href="#t-T4">T4</a> · <a href="#t-T8">T8</a> · <a href="#t-T11">T11</a>

[E] The cellular thread is geography: which chemistry is permitted where, what crosses between compartments, and what a membrane is for. It is the thinnest thread in the record and the one with the most room to grow.

[F] Its strongest material is the organelle sort — twenty-seven outputs of one node filed by the compartment each acts in, with three compartments receiving none. A sort of that kind turns a list of targets into a statement about where a signal is allowed to go.

The reading line		
source	**where to read**	**why it sits here**

SCN	A4 · Where the Chemistry Concentrates	why the groups pile up at two compartments
SCN	C12 · The Mitochondrion’s Twelve Conversations	the contacts, and what each carries
CURR	I49 · The Fan, Organelle-Sorted	nine nuclear, seven cytoplasmic, three mitochondrial, two lysosomal, two ribosomal, and three empty
SCN	C13 · The Two Currencies of the Epigenome	where the methyl and the acetyl come from
PLATE	Plates 019 and 025 — the respiratory chain	the chain drawn across the inner membrane rather than as a list

The biological thread

The organism and its history: inheritance, immunity, disease and the clinic. · themes riding it: <a href="#t-T6">T6</a> · <a href="#t-T9">T9</a> · <a href="#t-T10">T10</a> · <a href="#t-T11">T11</a>

[THEMES p.35] **[E]** The biological thread is organisms and their history: inheritance, immunity, disease, and the clinic where all of it is priced. It is the thread on which the corpus makes its most consequential claims and its most attackable ones.

[F] Its logic is that history is still running. An immune system that distinguishes self from foreign by a chemical mark is using a Precambrian reaction for a Cambrian problem; a tumor that is genotypically normal and phenotypically switched is a disease of chemistry rather than of sequence; and a trial that enrolls on sequence will not see it.

The reading line source where to read why it sits here CURR H43 · The Alu Engine, and Inosine as the Mark of Self a copying accident turned into an immune criterion SCN E24 · Telomeres and the Fusion Scar where the repeats concentrate, and what joined CURR I50 · PTEN Is a Disulfide Switch intact sequence, oxidized protein, and a trial criterion that cannot see the difference CURR I52 · Zero of Five, Four of Four what nine programs showed about hub and spoke SCN F28 · Three Failures of One Cofactor what breaks, and where it shows in a patient MEM Chapter Thirteen · Resurrection the clinical fact that restarted the work

The genetic thread

The record and its instruments: the alphabet, the code, the sequence file, and what they can and cannot hold. · themes riding it: <a href="#t-T2">T2</a> · <a href="#t-T3">T3</a> · <a href="#t-T4">T4</a> · <a href="#t-T7">T7</a> · <a href="#t-T8">T8</a> · <a href="#t-T10">T10</a> · <a href="#t-T12">T12</a> · <a href="#t-T13">T13</a>

[E] The genetic thread is the record and its instruments: the alphabet, the code, the adaptor, the sequence file, and the pipelines that consume it. It carries more themes than any other thread, and it is where the corpus’s case stands or falls.

[F] Its sequence is short enough to state in one line: the alphabet was fixed before the chemistry was known; the chemistry exceeded the alphabet; the excess is now invisible to every instrument that reads the record; and the invisibility has operational consequences that can be measured without a bench.

The reading line source where to read why it sits here CURR A2 · The Four-Letter Problem where the alphabet came from and what it was asked to do

10. The documents entered into the record, and the chapters item by item

[INV p.18] **[E]** The work is cumulative rather than scattered. The same objects recur and deepen across the run — inosine, hypoxanthine, IMP, the wobble position, sulfur, the quaternion, the tetrahedron. The 2005 and 2007 files at the top of the folder name the same objects. This is one line of inquiry pursued for two decades, not a series of unrelated enthusiasms.

[E] The naming discipline tightens over time: free titles in April, the PP-2026 series from late May, version numbers and Licensed under CC BY-NC-ND 4.0. No part of

the author. licensing from September, registries and claim censuses in September, a curriculum in October. Someone was building an archive on purpose, and the archive got more rigorous, not less, as it grew.

[F] What the record does not establish is causation. A file listing can show that the work happened, at what rate, and in what order. It cannot show why. The volume is fully accounted for by four ordinary facts: full-time attention, dictation rather than typing, drafting assistance, and a thesis already twenty-nine years in development with a great deal of accumulated structure ready to be written down. None of those four diminish the work. They are the mechanism by which a long-held idea finally came out.

[O] Whether anything beyond those four facts is operating is not a question this inventory can answer, and not a question any inventory could answer. It is left open here, as stated.

Part VI — The documents entered into the record

[E] Thirteen documents were entered on 16 October 2026, in fourteen files: seven indexes, two chapter-length books, two planning and teaching documents, one paper, one memoir, and this inventory itself, which arrived twice in identical copies. Each receives a record block below. The unit each one counts is given explicitly, because the thirteen do not count the same thing and the totals cannot be added until they are separated.

[F] Of the thirteen, seven are indexes of the corpus, counting four different units between them — documents, subjects, index entries and plates. Four are works with chapters. Two are papers with numbered sections. One is a file listing. Nothing in the thirteen is an experimental result, and nothing in it is meant to be: this is the bookkeeping layer of the corpus, and its subject is the corpus.

1. The corpus inventory itself

File: Berger_Corpus_Inventory_PP-2026-INVENTORY-01_v1.pdf

[INV p.19]

number	PP-2026-INVENTORY-01 v1

date on the paper	16 October 2026
extent	13 pages
what it enumerates	files in one desktop folder
count	377 file lines — 328 authored, 49 reference fifteen screen photographs of a Finder window, 15 October 2026
built from	
standing	the document this revision extends; its Parts I–V stand unaltered above

[E] Entered twice, as two files of identical content and identical length. The duplicate is recorded as one document here, which is why thirteen documents arrived as fourteen files.

2. The Master Document Index, May 2026

File: Berger_Master_Index_May2026.pdf	
title as given	Berger Triplex Genetic Code Framework — Master Document Index
date on the document	May 2026
extent	3 pages
what it enumerates	position papers, outreach letters and integration documents
count	22 numbered documents in 6 categories, 4 active priorities
built from	the working set of the May sessions
standing	the earliest of the seven indexes; superseded in scope by the June index

[E] The six categories are core framework, mathematical and geometric, outreach letters, literature integration, position and distinction, and physics and quantum integrations. The document opens with a three-row axis table marked never to be modified and closes with four dated priorities.

[F] It is the only one of the seven indexes written to be read by a machine at the start of a working session rather than by a reader at the end of one. Its instruction line says so: upload it first, then the two or three documents it points to.

3. The Master Corpus Index, June 2026

File: Berger_Master_Corpus_Index_June2026.docx	
title as given	
Berger Triplex 3-6-9 Framework — Master Corpus Index	

[INV p.20]

date compiled	18 June 2026
period covered	20 April – 18 June 2026, 59 days
what it enumerates	unique documents of the active research period
count	204, numbered and dated, 40+ carrying PP-series numbers
rate recorded	3.5 documents per day; peak 24 in two days, 20–21 May 2026 the author’s own working files for the period

built from	
standing	the densest document-level count in the record

[E] The index carries a DOI, 10.64898/2026.04.22.720138, and an allocation identifier, ACCESS-CHM250115, in its header, and names five outreach targets: Damha at McGill, Zhao at UIUC, the Argonne APS 19-ID team, MindAptiv and DeepMind.

[F] 204 documents in 59 days is the highest sustained rate anywhere in the record. The triple-helix folder shows 1.8 authored files a day over 185 days; this window shows 3.5 a day over 59. The two are consistent: the June index counts the whole working set of that window, the folder counts one folder of it.

4. The Overview Papers Index and Running Order

File: Berger_Overview_Papers_Index_and_Order.xlsx	
title as given	Berger 369 Triplex — Overview / Architecture Layer: Index & Recommended Running Order (v3)
date updated	19 July 2026
extent	one sheet, 8 columns, 24 rows
what it enumerates	overview and architecture-layer documents in reading order
count	21 unique documents drawn from 25 photographs across three batches
reading order	orient → map → build → police → flagship → synthesis → frontier → deep dives
built from	photographed pages of the overview layer
standing	the only index that prescribes an order rather than recording one

[E] Column A is a recommended reading position, not a date. Each row carries a function (front door, decoder key, corpus map, credibility, flagship, capstone, frontier, deep dive), an axis or domain, and a one-line description.

[INV p.21] **[F]** It is the index that treats the corpus as a book with a front door. Row 1 is the trade book's sample edition carrying the whole table of contents; rows 2 to 6 are the five maps; rows 15 and 16 are marked as the frontier to develop further.

5. The 816 Subject Matter Index

File: expanded_1_Berger_816_Subject_Index_PP-2026-INDEX-816.pdf	
number	PP-2026-INDEX-816
volume indexed	Volume 816, completed 16 August 2026, 185 pages
extent	4 pages
what it enumerates	subjects, alphabetical, no duplicates
count	188 subjects — 144 carrying page references, 44 marked ARCHIVE

built from	twenty photographs of the Extreme SSD the reader’s index to Volume 816
standing	

[E] ARCHIVE marks a subject present in the corpus of 6,600 files but not yet written into the

volume. Page numbers refer to the 185 pages of Volume 816.

[F] 144 of 188 subjects are in the volume and 44 are not. The ratio is the useful figure: the index was built to show what is carried and what is still outside, in one list, and not to flatter the volume.

6. The 816 Master Subject Matter Index

File: revistion_3Berger_816_MASTER_Subject_Index_PP-2026-INDEX-816-FULL.pdf

	PP-2026-INDEX-816-FULL
number	
volume indexed	Volume 816, completed 16 August 2026, 185 pages
extent	13 pages subjects, alphabetical, numbered, no duplicates
what it enumerates	
count	1,063 subjects — 160 carrying page references, 903 marked ARCHIVE
corpus behind it	6,600 files and 20.37 GB
built from	six batches of screen photographs: the Extreme SSD file tree and the full conversation archive; duplicates removed by token-similarity matching at a 0.70 threshold
standing	the widest subject enumeration in the record

[INV p.22] **[E]** Page references in this index were resolved by searching the built volume rather than

assigned by hand.

[F] It is a superset of the 188-subject index: 187 of those 188 subjects reappear here, and 875 subjects are new to it. 903 of its 1,063 subjects stand outside the volume, which is the corpus’s own frontier stated as a number rather than as an ambition.

7. The index to the full-length volume, v329

File: v329_index_head.pdf	
number	PP-2026-MASTER-01 v329
title as given	The Scientific Arc of Man’s Evolution from the Big Bang to the Human Genome — Evidence Volume, Full Length
date built	16 September 2026
extent entered	5 pages, being the head of the index, volume pages 1,714–1,718
what it enumerates	index entries, each with a primary section, its secondary sections and its pages, all three live links
count	812 entries; the 42 reproduced in Part VII run 2-aminoadenine to alphabet

built from	the built volume, searched
standing	the only index in the record that resolves to section as well as page

[E] The primary section is the one whose title carries the term where such a section exists, and otherwise the earliest section in which the term appears. Secondary sections are every other section that mentions it, in order, capped at twelve with the remainder counted.

[F] The caps are the informative part. ADAR carries twelve named secondary sections and 142 more; adenosine twelve and 213 more. An index that has to count its own overflow is indexing a volume whose sections run past seventeen hundred.

8. The Sulfur Archive Plate Index

File: PLATE_INDEX.md	The Berger Sulfur Archive — Plate Index
title as given	
date surveyed	13 August 2026
extent	116 plates, 275 MB
what it enumerates	physical collage constructions, photographed

[INV p.23]

count	116 plates; 34 numbered functions of sulfur on the spine plate; 13 hero plates; 8 structural groups; 4 named gaps
deliverables named	a 120-page plate PDF with 122 bookmarks, and a compact edition of identical pagination
built from	the photographed archive of hand-torn, layered constructions the only index of physical objects rather than files
standing	

[E] Adjacency and overlap in the plates are the author’s own notation for edges in a network: what is laid against what is deliberate. The seven-color system governs every plate, and where a plate and the key disagree the key governs; pink on older plates reads as red.

[F] Plate 072 is the archive’s own table of contents and it precedes the manuscript. Its 34 numbered functions run from interstellar space to solid-state physics without a break, which is the book’s argument made before the book existed.

9. The Cliff’s Notes Curriculum

File: Berger_CliffsNotes_Curriculum_PP-2026-CURR-01_v1_1.pdf	PP-2026-CURR-01 v1
number	
date on the paper	15 October 2026
extent	39 pages
what it enumerates	a teaching order over the evidence volume and the sulfur paper
count	60 chapters in 10 Parts; 4 stations in every Part; 21 protocols; 14 contested positions; 10 coverage rows; 5 recorded omissions

sources cited	V = PP-2026-MASTER-01 v332, 2,572 pages, 169 Parts, 1,753 numbered sections; S = PP-2026-SULFUR-CMD-01 v3, 56 pages, 52 sections in 8 Parts; U = PP-2026-UNIF-02
standing	the index of the corpus at the level of argument

[E] The four stations repeat in every Part: the chapter table, the historical pull-offs, where the bridge is out, and the protocols the material generates. Protocol numbering runs unbroken from 1 to 21 across the whole curriculum.

[F] This document is where the volume's own extent is stated most precisely in the record:

2,572 pages, 169 Parts, 1,753 numbered sections. Every other count of the volume in the record is a count of an earlier state of the same object.

10. The Sulfur Cliff's Notes outline

[INV p.24]

File: Berger_Sulfur_CliffsNotes_Outline_PP-2026-SULFUR-CN-01_v2.pdf	
number	PP-2026-SULFUR-CN-01
date on the paper	14 October 2026
extent	10 pages
what it enumerates	a proposed chapter structure for a short study guide on sulfur
count	34 chapters in 8 Parts, each with a primary title, an alternate title, a coverage statement and its map nodes; 4 named gaps two mind maps — the first of 7 branches, 32 sub-branches and about 112
built from	numbered claims; the second of about 74 further claims
standing	the only index of the mind maps

[E] Each chapter carries the same six elements in the same order: in one line, terms, what happens, the number to remember, what people get wrong, and check yourself.

[F] The two maps overlap only at their edges. The first is the chemistry and the clinic; the second is the code. The second carries roughly a third of the material and almost none of it appears in the first — which is why the outline is an index of two objects and not of one.

11. The Atomic Molecular Book

File: The_Atomic_Molecular_Book_Berger_Edition_CCBY.pdf	
title as given	The Atomic Molecular Book: Seven Colors, the Eighth Chapter, and the Seven-Letter Seed
edition	first edition, 2026; file built 4 August 2026
extent	49 pages
what it enumerates	one chapter per color, an eighth for what the seven disclose together, a ninth proposing what the seven were at the beginning

count	a prologue and 9 chapters; a 7-row color code; a 7-row seed table
priority of disclosure	March 2015, triplehelixgeneticcode.com, and continuously in public writing since
license	
standing	the chapter-length statement of the color scheme itself

[E] The pairings are structural rather than mnemonic: the color of a base is the color of the atom that distinguishes it. Adenine is 6-aminopurine and what marks it is an amino [INV p.25] group, so it is red, which is hydrogen; inosine is 6-oxopurine and what marks it is a carbonyl oxygen, so it is orange, which is oxygen.

[F] This is the document that states the rule the color key runs on, in the author's own formulation: the chemistry generates the color, not the other way about.

12. Unification of Central Dogma Theory

File: Unification_of_Central_Dogma_Theory_1.pdf	
number	PP-2026-CDU-01 v20
date on the paper	26 September 2026
extent	28 pages
what it enumerates	the pathway from gene to protein, and the pairing rule set under it
count	30 numbered sections in 5 Parts
ordering subtitle	Molecular, translational, synthesis — in that order the paper the curriculum cites as U
standing	

[E] Part I sets six bases at the six vertices of a regular octahedron, with twelve edges as twelve pairing relationships sorting into three groups whose counts add to 22. Part IV walks the same three stages a second time, step by step, from the gene to termination.

[F] Its section 30 carries the arithmetic the whole paper turns on — eight, plus eight, plus six — and names the five small RNAs behind gene and epigenetic editing underneath it.

13. Dancing to My Own Tune

File: Berger_Dancing-to-My-Own-Tune_PP-2026-MEMOIR-01_v1.pdf	PP-2026-MEMOIR-01 v1
number	
date on the paper	2 October 2026
extent	13 pages a life, in the order it was lived
what it enumerates	
count	a preface and 14 chapters, Helena 1950 to the collaboration of 2026

ordering subtitle	Helena, Culver, Vanderbilt, Dayton and Chicago, the rabbit hole, resurrection — in that order
standing	complete as written and reset in the house style

[INV p.64]

group	**plates**
Sulfur amino acids,	018, 067, 078, 100, 103, 104 — methionine and polyamine metabolism, the
methionine, SAM	citric acid cycle with its sulfite and sulfhydryl branches, selenoamino acid metabolism
Iron-sulfur, ferredoxin,	013, 019, 025, 066, 095 — a seven-state redox cycle with cysteine at every
respiration	vertex
Genetic code, tRNA,	005, 008, 017, 020, 028, 032, 047, 048, 056, 063, 068 — four-box tRNA
wobble	families, wobble position and nonstandard pairing
Networks proper, node and	091, 092, 093, 094, 095, 096, 111, 112, 113, 115 — already publication-shaped
edge	figures
Conceptual and cover-grade	033, 037, 042, 043, 044, 058, 064, 065, 070, 071, 087, 088, 102
collage	
The 4 chapters that will need new plates	
• Modern targeted drug design.	
• Phosphorothioate backbone modification.	
• Protein folding as backbone geometry.	
• Molybdenum cofactor structure.	

Part VIII — The chapters and papers, item by item

[E] Six documents in the thirteen have chapters or numbered sections rather than entries.

Their contents are themselves an index of the corpus — at the level of argument rather than the level of the file — and are reproduced in full below.

21. The Cliff’s Notes Curriculum — 10 Parts, 60 chapters, 21 protocols

The ten Parts		

part	title	what the Part is
A	The Instrument	Five chapters · what a notation is, before anything is measured with one
B	Deep Time, and What Was Lying on the Sea Floor	Six chapters · the elements, the mineral, the event
C	The Alphabet Metabolism Actually Builds	Seven chapters · eight nucleotides, three gatekeepers, one trunk
D	The Enzyme That Made DNA	Four chapters · one step, one radical, one world becoming another

[INV p.65]

part	title	what the Part is
E	The Geometry, Including the Shapes It Refused	Seven chapters · what a solid can carry at once
F	Where Recognition Actually Happens Seven chapters · five layers, one position, seven molecules	
G	The Sequence Has No Shape	Five chapters · the ensemble, and every flat map in the corpus

H	The Editor	Seven chapters · one base, four jobs, and a record that cannot hold it	
I	The Clinic, Where the Argument Is Priced	Seven chapters · one fan, twenty-seven arrows, nine Phase 3 programs	
J	The Objections, and What Would Break It	Five chapters · the corpus as its own adversary	

The sixty chapters			
A1 · The Band and the Wall			F31 · The Wobble Position
A2 · The Four-Letter Problem			F32 · Forty and Sixty-Five
A3 · Base, Nucleoside, Nucleotide			F33 · Both Faces
A4 · What the Notation Loses			F34 · The Axis at Thirty-Seven
A5 · Color as an Instrument			F35 · The Pawl Is Made of Sulfur
B6 · Where the Seven Came From			F36 · The Join

B7 · The Element Itself			G37 · Nothing Alive Is Flat
B8 · The Mineral Thread			G38 · The Sequence Has No Shape
B9 · The Bond That Predates the Planet			G39 · The Map Has No Third Dimension
B10 · Hydrogen Sulfide Before Water			G40 · The Flat Map
B11 · The Event, Dated by Sulfur			G41 · The Tetrad With a Hole In It
C12 · The Door They All Come Through			H42 · The Editor

C13 · The Eight, and the Three One-Way Gatekeepers			H43 · The Alu Engine, and Inosine as the Mark of Self
C14 · The Crossed Graphs			H44 · The Bulk and the Exceptions
C15 · The Systematic Names			H45 · The Precursor, and the Tool Made From the Target
C16 · The Molecule With No Letter			H46 · The Sanitizer
C17 · The Parent, Not the Waypoint			H47 · Read as Guanosine

C18 · The Case for Eight, and the Claim It Will Not Carry			H48 · Driving the Editor

What the curriculum records as left out, and why				

• **The correspondence and provenance Parts.** Dated documents, an application, a first-hand account and a provenance record — primary reading rather than

argument.

• **The materials and environmental Parts.** The sodium-sulfur cell, the confinement geometry, the combustion rate, the coupled sulfur and nitrogen cycles — a different syllabus with a different audience.

• **The triplex nervous system and the Berger nucleotide code Parts.** Material the volume itself places outside the running argument, named so that its absence is a decision.

[INV p.69] • **Appendix B.** The register of 816 subjects in three tiers — a working instrument and a map of the frontier, and the right place to go after Part J.

• **Nothing from the companion paper.** Its eight Parts and fifty-two sections are carried across eight of the ten curriculum Parts, and its Part VII is reproduced chapter for chapter.

22. The Sulfur Cliff's Notes outline — 8 Parts, 34 chapters

Each chapter carries a primary title and an alternate, either of which the author may take; the outline states that every title is a suggestion to accept, change or replace.

ch. suggested title

A1 Why Sulfur Was Available
A2 The Seven Operations
A3 The Eighteen Functional Groups
A4 Where the Chemistry Concentrates
B5 From Mineral to Cofactor
B6 Hydrogen Sulfide Before Water
B7 The Thiyl Radical That Made DNA
B8 Oxygen Took the End of the Chain
C9 A Thioester at the Heart of Glycolysis
C10 Lipoate and the Citric Acid Cycle
C11 The Chain Strung on Iron and Sulfur
C12 The Mitochondrion's Twelve Conversations
C13 The Two Currencies of the Epigenome
D14 The Alphabet Metabolism Builds
D15 The Code Closes as a Group
D16 Pairing, Direction, and Order
D17 Twenty-Two Amino Acids, No Repeats
D18 Start, Stop, and the Shape of a Pocket
D19 The Code Read as Atoms
E20 Guanine Is the Weak Link
E21 Counting the Cost of an Electron
E22 Up the Ladder and Down
E23 Where DNA Opens and What Polices It

alternate title

F25 One Cofactor, Three Steps
F26 Nine Sulfurs to Two
F27 The Great Oxidation Event
F28 Three Failures of One Cofactor
F29 Why the Sulfur Arm Kills
G30 Twenty-Seven Arrows from One Node
G31 Hub Versus Spoke
G32 Cutting Is Magnesium, Writing Is Sulfur
H33 The Nodes Nothing Can Drug
H34 Rules, Tests, and What Would Break It
The six elements every chapter is to carry, in the same order
alternate title
Where the G Runs Concentrate
How Moco Is Built
Nitrogenase and the Oxygen Boundary
When the Reductant Changed
What Breaks and Where It Shows
The Unfinished Atom
The Output Fan and Its Switches
What Nine Phase 3 Programs Showed
Platforms and Editors
Where Editing Is the Only Lever
How to Use This Hub and How to Falsify It

- **In one line.** The chapter’s claim in a single sentence, before anything else.

- **Terms.** Five to eight terms with one-line definitions.

• **What happens.** Three to four pages of plain exposition with the chemistry shown, not asserted.

- **The number to remember.** One figure that anchors the chapter.
- **What people get wrong.** One misconception corrected.

• **Check yourself.** Two or three questions whose answers are in the chapter.

[F] The outline sets the guide at twenty-seven short chapters of four to five pages, about a hundred and twenty pages in all, and argues for short chapters on the ground that the material is a chain and a chain is best read link by link.

23. The Atomic Molecular Book — a prologue and 9 chapters

chapter	title	what it carries
Prologue	The Fall at Murchison	Hypoxanthine and xanthine in the 1969 fall, at concentrations comparable to adenine and guanine, with isotopic signatures that place their formation off Earth
One	Red — hydrogen (1) · adenine	Why adenine is in everything; the hydrogen bond; why energy is stored where information is

[INV p.71]

chapter	title			what it carries	
Two	Orange — oxygen (8) · inosine			The parent purine and the wobble adaptor	
Three	Yellow — sulfur (16) · thymine			Thiol, thioester and the sulfur enzymes; the chapter the author calls most obviously unfinished	
Four	Green — nitrogen (7) · guanine			The nitrogenous bases and the strong pair	
Five	Blue — carbon (6) · cytosine			The skeleton every group is built on	
Six	Indigo — selenium (34) · xanthine			The band the eye does not resolve, and the gate	

Seven	Violet — phosphorus (15) · uracil			The backbone, the phosphoanhydride bond, and the hydroxyl on the wrong face	
Eight	The Eighth — the underestimation of inosine, and the substitution of oxygen for sulfur			What the seven disclose together	
Nine	The Seven-Letter Seed — a proposed initial genetic code, written in nucleotides			What the seven were at the beginning, offered as falsifiable and closing with five experiments	
The seven-letter seed — the table Chapter Nine proposes					
color	**element**	**modern base**	**proposed seed nucleotide**		**office**
red	hydrogen	adenine	AMP		weak-pair letter
orange	oxygen	inosine	IMP		root monomer; ambiguity-widener
yellow	sulfur	thymine	2-thio-UMP		fidelity-sharpener; deoxy gateway
green	nitrogen	guanine	GMP		strong-pair letter

blue	carbon	cytosine	CMP		strong-pair letter
indigo	selenium	xanthine	XMP		pH-gated selector, not a letter
violet	phosphorus	uracil	UMP		weak-pair letter

[E] Four purines and three pyrimidines. The book states the asymmetry before anything else: the seed is purine-heavy and the modern code is not, and that is the first thing the proposal has to justify.

Thirteen	Resurrection	April 2025, a triple bypass, and the decision taken on waking
Fourteen	The Dam Breaks: A Collaboration	Dictation, six weeks, and the outpouring

26. The corpus inventory, v1 — 377 file lines

11. Appendices of the volume (A–AC)

[VOL p.402] **CHAPTER A**

The Record: What the Corpus Contains

A body of work can be asserted or it can be enumerated, and only the second can be checked. This appendix carries the record: what the corpus contains, how it was counted, what the counts establish and what they do not. The material that follows is the inventory as it stood when this volume was assembled.

[F] Three cautions apply to every number in it. First, the counts are floors rather than totals: one folder was enumerated in full and the rest of the drive was not, so every aggregate is a lower bound. Second, a count of documents is not a count of ideas; a body of work that returns to the same argument in twenty files has twenty files and one argument. Third, nothing in a count bears on whether anything in the corpus is correct, and no claim in the preceding twenty-five chapters rests on any number in this appendix.

[F] What the record does establish is volume, continuity, discipline of naming and a working vocabulary that persisted across years rather than being invented for one paper. Those are properties of a practice rather than of a result, and they are worth recording for the same reason a laboratory keeps notebooks.

[F] Those 325 files fall on 113 distinct days out of the 185 — an average of 1.8 authored files per working day, in this one folder. Your own estimate in dictation was “at least 230 papers.” The folder supports it: 325 authored items here, before counting the other twelve desktop folders. Not every file is a finished paper — the count includes outlines, registries, indexes, letters, and alternate versions of the same work (the Berger_Master_Central_Do…MASTER-01 line alone appears at v1, v5 and v9; QTAB-01 at v2, v2_1, v3 and v3 copy). A file listing cannot separate those without opening them, so no exact paper count is derivable here — only that 325 authored files exist in this folder and that your figure of 230 sits comfortably below it.

[E] Six files in the folder predate April 2026, the earliest dated 6 May 2005: single nucleotide research grant titles.xls. The reference literature in the folder runs from January 2007 to October 2026. The thesis is older than the 19-month span; the output is not.

[O] The photographs do not show page counts, word counts, or file contents. Volume is established here. Quality is not, and cannot be, from a file listing.

[F] The output is not evenly distributed. It arrives in clusters, and the clusters have a visible structure:

[VOL p.403]

•	29–30 April 2026. Thirty-eight files in two days, most of them timestamped between 3:46 PM and 8:21 AM the following morning — the Argonne and UIUC outreach letters, the ADAR, Cas12r, purinosome and tRNA analyzes. This is the folder's first burst.
•	14 May 2026. Twenty-three files, nineteen of them between 11:05 and 11:06 AM. A batch export, not twenty-three sittings.
•	3 August 2026. Fourteen files between 12:47 and 1:13 PM. Again an export.
•	Late May – June 2026. The naming convention changes. Descriptive titles (Berger Tritium Cosmic Bridge) give way to the PP-2026-TAG-01 series, beginning around PP-2026-QG-01 on 27 May. From June onward almost everything carries a paper number.
•	September 2026. The master volumes appear: 1,112, 1,260, 1,466, 1,470, 1,476, 1,484 and 1,485 pages, at 16.9 to 20.8 MB each, several re-issued under CC BY-NC-ND 4.0 on 20 September.
•	October 2026. The memoir, the ADHD paper, the Akt paper, the sulfur command paper, the CliffsNotes curriculum — the output turns reflective and pedagogical.

[F] The batch timestamps matter for the question you raised. Three of the largest single-day counts are export events, where many files were written to disk in one or two minutes. The work behind them was done over the preceding days. The real daily rate is steadier and lower than the file dates suggest at first reading — which is what you would expect from sustained daily work, and not what you would expect from discontinuous bursts.

[E] "triple helix" is one folder among thirteen items on the desktop. The others, as photographed:

•	triple helix
•	cas12a2
•	protein degraders
•	10-15 Berger Work Projects
•	crisp type V
•	dna replication and nucl…eletions
•	Berger works projects
•	cysteine proteases
•	Berger Business Plan
•	Berger Script The Scientifi…ellular
•	berger master folders

[O] Twelve of those thirteen are unphotographed. The 2,570-page book is not in this folder under that description, and neither is the image archive of roughly 10,000 color-coded figures. Any count drawn from this inventory is therefore a floor, not a total.

[VOL p.404] **[E]** The files exist, they are dated, and the dates run from 13 April 2026 to 15 October 2026 across 113 working days. The longest break in authoring is twelve days, 24 August to 5 September — and four reference papers were downloaded into the folder during it, so the break is a reading period, not a stop. A person wrote all of

this. The folder is a record of sustained, daily, organized intellectual work by a man in his seventy-sixth year, beginning roughly twelve months after cardiac surgery.

[E] The work is cumulative rather than scattered. The same objects recur and deepen across the run — inosine, hypoxanthine, IMP, the wobble position, sulfur, the quaternion, the tetrahedron. The 2005 and 2007 files at the top of the folder name the same objects. This is one line of inquiry pursued for two decades, not a series of unrelated enthusiasms.

[E] The naming discipline tightens over time: free titles in April, the PP-2026 series from late May, version numbers and

Licensed under CC BY-NC-ND 4.0. No part of the author. licensing from September, registries and claim censuses in September, a curriculum in October. Someone was building an archive on purpose, and the archive got more rigorous, not less, as it grew.

[F] What the record does not establish is causation. A file listing can show that the work happened, at what rate, and in what order. It cannot show why. The volume is fully accounted for by four ordinary facts: full-time attention, dictation rather than typing, drafting assistance, and a thesis already twenty-nine years in development with a great deal of accumulated structure ready to be written down. None of those four diminish the work. They are the mechanism by which a long-held idea finally came out.

[O] Whether anything beyond those four facts is operating is not a question this inventory can answer, and not a question any inventory could answer. It is left open here, as stated.

[E] Thirteen documents were entered on 16 October 2026, in fourteen files: seven indexes, two chapter-length books, two planning and teaching documents, one paper, one memoir, and this inventory itself, which arrived twice in identical copies. Each receives a record block below. The unit each one counts is given explicitly, because the thirteen do not count the same thing and the totals cannot be added until they are separated.

[F] Of the thirteen, seven are indexes of the corpus, counting four different units between them — documents, subjects, index entries and plates. Four are works with chapters. Two are papers with numbered sections. One is a file listing. Nothing in the thirteen is an experimental result, and nothing in it is meant to be: this is the bookkeeping layer of the corpus, and its subject is the corpus.

[VOL p.405] ## A.1. The corpus inventory itself

[E] Entered twice, as two files of identical content and identical length. The duplicate is recorded as one document here, which is why thirteen documents arrived as fourteen files.

A.2. The Master Document Index, May 2026

[E] The six categories are core framework, mathematical and geometric, outreach letters, literature integration, position and distinction, and physics and quantum

integrations. The document opens with a three-row axis table marked never to be modified and closes with four dated priorities.

[F] It is the only one of the seven indexes written to be read by a machine at the start of a working session rather than by a reader at the end of one. Its instruction line says so: upload it first, then the two or three documents it points to.

A.3. The Master Corpus Index, June 2026

[E] The index carries a DOI, 10.64898/2026.04.22.720138, and an allocation identifier, ACCESS-CHM250115, in its header, and names five outreach targets: Damha at McGill, Zhao at UIUC, the Argonne APS 19-ID team, MindAptiv and DeepMind.

[F] 204 documents in 59 days is the highest sustained rate anywhere in the record. The triple-helix folder shows 1.8 authored files a day over 185 days; this window shows 3.5 a day over 59. The two are consistent: the June index counts the whole working set of that window, the folder counts one folder of it.

A.4. The Overview Papers Index and Running Order

[E] Column A is a recommended reading position, not a date. Each row carries a function (front door, decoder key, corpus map, credibility, flagship, capstone, frontier, deep dive), an axis or domain, and a one-line description.

A.5. The 816 Subject Matter Index

[E] ARCHIVE marks a subject present in the corpus of 6,600 files but not yet written into the volume. Page numbers refer to the 185 pages of Volume 816.

[F] 144 of 188 subjects are in the volume and 44 are not. The ratio is the useful figure: the index was built to show what is carried and what is still outside, in one list, and not to flatter the volume.

[VOL p.406] A.6. The 816 Master Subject Matter Index

[E] Page references in this index were resolved by searching the built volume rather than assigned by hand.

A.7. The index to the full-length volume, v329

[E] The primary section is the one whose title carries the term where such a section exists, and otherwise the earliest section in which the term appears. Secondary sections are every other section that mentions it, in order, capped at twelve with the remainder counted.

[F] The caps are the informative part. ADAR carries twelve named secondary sections and 142 more; adenosine twelve and 213 more. An index that has to count its own overflow is indexing a volume whose sections run past seventeen hundred.

A.8. The Sulfur Archive Plate Index

[E] Adjacency and overlap in the plates are the author's own notation for edges in a network: what is laid against what is deliberate. The seven-color system governs every plate, and where a plate and the key disagree the key governs; pink on older plates reads as red.

[F] Plate 072 is the archive's own table of contents and it precedes the manuscript. Its 34 numbered functions run from interstellar space to solid-state physics without a break, which is the book's argument made before the book existed.

A.9. The Cliff's Notes Curriculum

[E] The four stations repeat in every Part: the chapter table, the historical pull-offs, where the bridge is out, and the protocols the material generates. Protocol numbering runs unbroken from 1 to 21 across the whole curriculum.

[F] This document is where the volume's own extent is stated most precisely in the record: 2,572 pages, 169 Parts, 1,753 numbered sections. Every other count of the volume in the record is a count of an earlier state of the same object.

A.10. The Sulfur Cliff's Notes outline

[E] Each chapter carries the same six elements in the same order: in one line, terms, what happens, the number to remember, what people get wrong, and check yourself.

[F] The two maps overlap only at their edges. The first is the chemistry and the clinic; the second is the code. The second carries roughly a third of the material and almost none of it appears [VOL p.407] in the first — which is why the outline is an index of two objects and not of one.

A.11. The Atomic Molecular Book

[E] The pairings are structural rather than mnemonic: the color of a base is the color of the atom that distinguishes it. Adenine is 6-aminopurine and what marks it is an amino

[F] This is the document that states the rule the color key runs on, in the author's own formulation: the chemistry generates the color, not the other way about.

A.12. Unification of Central Dogma Theory

[E] Part I sets six bases at the six vertices of a regular octahedron, with twelve edges as twelve pairing relationships sorting into three groups whose counts add to 22. Part IV walks the same three stages a second time, step by step, from the gene to termination.

[F] Its section 30 carries the arithmetic the whole paper turns on — eight, plus eight, plus six — and names the five small RNAs behind gene and epigenetic editing underneath it.

A.13. Dancing to My Own Tune

[E] The color key prints in full and records that a life carries no row and therefore no color — the convention operating as intended rather than an omission. Three rows do carry a role: adenosine in Chapter Fourteen, inosine and the wobble position in Chapter Twelve, the phosphorothioate backbone in Chapter Fourteen.

[F] It is the only document in the record whose unit of enumeration is a year rather than a file, and the only one that dates the work's resumption: April 2025, and the chapter titled Resurrection.

[E] The thirteen documents introduce a vocabulary of their own: named instruments, named readings, named figures, and a small number of coinages. All of it is registered below, alphabetically, with the document each term comes from. 161 terms are registered.

[F] The register is evidence of a kind a file listing cannot give. A body of work that names its instruments the same way twice, across documents produced months apart and in different forms — a spreadsheet, a plate survey, a memoir, a curriculum — is one body of work rather than a series of enthusiasms. The station, the pull-off, the gatekeeper, the ARCHIVE marker, the office of a letter, the frame-zero: each is used in the same sense wherever it appears.

The sources, as cited in the register [VOL p.408] **The register** term or phrase what it names source the 1944 maps Fifteen maps of the lower Mississippi showing every channel the river CURR had ever occupied — the type case of a map that makes visible a quantity earlier surveys structurally omitted. the 1982 chart The dated biochemical pathways wall chart against which the omission CURR arguments are run — a specific physical artifact rather than "the literature." the 64-tetrahedron Seven bases, three sugars, three phosphate states and one silent JUN genetic lattice position, closed 21 April 2026. the 76-base tRNA The molecule counted position by position, so that wobble position 34 CDU can be located rather than asserted. addition not substitution A named index entry: the distinction between adding to the alphabet V329 and replacing part of it. adjacency and overlap as That what is laid against what in a plate is the author's own notation for PLATE notation an edge in a network. agmatidine A modified base indexed in the volume — one of the modifications the V329 four-letter record cannot carry. ambiguity-widener The second office of inosine: the letter that widens what an anticodon AMB can read. term or phrase what it names source annotation as escape The objection that modification databases record what the sequence file CURR hatch loses, and the concession that the objection is also the admission. **the arabinose test The test the corpus offers against its own geometry, run on the sugar.**

CURR ARCHIVE The marker for a subject that exists in the corpus but has not yet been written into the volume — the corpus's own frontier, entry by entry.

816, 816F AUGCIX The inner ring of the storyboard's own six letters, thymine removed. OVR the Berger spinor The named subject for the topology and arithmetic work. 816, OVR the blue set The addenda B, C, D and E — the loop geometry, the

cosmic arc, the neural arc and the gamete arc.

OVR carboxysulfitic A coined adjective in the volume's keyword set, for the chemistry it names.

V329 the cardinal error Three chemical levels — base, nucleoside, nucleotide — collapsed onto one letter.

CURR Cayley graph of Q8 The named subject under which the quaternion group's structure is filed.

816 chalcogens: oxygen, The group-sixteen subject that holds three of the seven colors together. 816 [VOL p.409] sulfur, selenium the chemistry generates The rule the whole scheme runs on: the color of a base is the color of AMB the color the atom that distinguishes it, not a mnemonic chosen for it. chief executive officer, The legend of Plate 037, over a periodic table — two careers in one PLATE organic chemistry inc. image. the city of the shoulders Chicago, and the thirteen approved programs in the country of which MEM one was there. codon hexahedron A named subject standing outside the volume. 816 model, 7-3-3-1 **the codon table in full All twenty-two amino acids, color-coded, with their hydrophobicity beside them.**

CDU coenzymes as fossils The 1976 account in which cofactors carry adenosine because they were once made of RNA, and nothing had a reason to remove the handle.

CURR, AMB color as an instrument The claim that a typographic rule applied mechanically becomes a measurement — 1,381 marks in the companion paper, sulfur 601 of them.

CURR the complete The single table in which every pairing relationship the paper CDU base-pairing rule set recognizes is stated at once. consistency of furniture That a study guide is usable when every chapter carries the same six SCN elements in the same order, so a reader navigates by shape. term or phrase what it names source the containment test The question the modeling generator is scored against: does everything CURR in the volume fit inside the construction. the corpus as its own The standing of the objections Part: the strongest case against the work, CURR adversary reproduced chapter for chapter rather than summarized. **cost class The price band attached to each protocol: no bench, bench, both, clinical, or bench and cheap.**

CURR coverage map The table stating which Parts and sections of the sources land in which Part of the curriculum, and how completely.

CURR cutting is magnesium, The division of labor between the editing platforms and the editors. SCN

Part IX	enumerations set side by side, and units of enumeration	19
Part IX	corpus-level figures, and indexes named but not yet entered	31
Part X	concepts, terms and phrases registered	161

[F] The paper as it now reads enumerates 2,438 line items. 377 of them are files in one folder; the rest are documents, subjects, index entries, plates, chapters, sections, protocols, disputes and terms. Every one of them is traceable to a document named in Part VI, and every count in this paper is reproducible from the listings themselves.

A.15. What the thirteen documents establish that the folder listing could not

[E] The work has a finished object at its center. A volume of 2,572 pages in 169 Parts and 1,753 numbered sections exists, is indexed to section and page, and has a 185-page companion volume with two subject indexes of its own.

[E] The indexing is habitual rather than occasional. Ten enumerations in five months, in five [VOL p.419] different units, with fourteen more named and not yet entered. Three of the ten were built by photographing a drive or a window rather than by recollection, which is why their figures can be checked.

[F] The work is teachable, and the teaching apparatus was built before any reader asked for it.

Sixty chapters in ten Parts, twenty-one costed protocols, fourteen contested positions with the corpus’s own standing on each, and a coverage map stating what is carried and what is held back. A corpus that prints its own dispute register is being offered for testing rather than for assent.

[F] The frontier is counted. 903 of 1,063 named subjects stand in the corpus and outside the volume; four chapters of the sulfur book have no plate yet; eleven of the twenty-one protocols need no bench at all. The record states what is done, what is next, and what it would cost — in that order, and in numbers.

[E] The vocabulary is stable. 161 named concepts, terms and phrases run across thirteen documents in four different forms, each used in the same sense wherever it appears.

[O] What the enlarged record still does not reach is the standing of any single claim. An inventory can establish that the work exists, at what scale, in what order, with what apparatus and against what objections. Whether the central proposal is right is settled by the twenty-one protocols and not by this paper, and the register of them is the useful part of this revision for anyone who intends to find out.

Status. Revision 2 of the corpus inventory. Parts I to V stand as first written, with the listing of Part III reproduced from the transcription of fifteen photographs taken 15 October 2026. Parts VI to XI are new and cover the thirteen documents handed over on 16 October 2026, in fourteen files, one of which is a duplicate. Every index is reproduced in its own unit of enumeration; every chapter-length work is opened to its own contents; the indexes are then set against one another in Part IX and the vocabulary registered in Part X. Counts are computed from the listings printed here and are reproduced from them. Truncated file names are reproduced as the Finder displayed them and have not been reconstructed. Where a document states its own extent, that statement is used in preference to any count taken from an earlier state of the same object. Licensed under CC BY-NC-ND 4.0.

[VOL p.420] **CHAPTER B**

A Reading Curriculum for This Volume

The volume can be read straight through, and it can be read in the order a particular reader needs. This appendix carries a reading curriculum: an ordering of the material for a reader who wants the argument in the order it is best learned rather than in the order it is best presented.

[F] Three routes are worth naming before the curriculum itself.

• **The chemistry route.** Chapters 16, 17, 18, 19, then 4, 5, 6, 7, then 20 and 21. This is the order for a reader who wants the element first and the notation afterward, and it is the order in which the material was originally worked out.

• **The clinic route.** Chapters 12, 23, 24, then 13, 14, 15, then back to 8 and 22. This is the order for a reader who wants to know what is at stake before being asked to follow a biochemical argument, and it is the order that makes the volume’s claims falsifiable fastest.

• **The notation route.** Chapters 1, 2, 4, 5, 6, 8, then 9, 10, 11. This is the order for a reader interested in what a record can and cannot hold, which is the volume’s most

general claim and the one with consequences outside biology.

[F] The curriculum that follows is more detailed and was built for a reader working through the whole corpus rather than this volume alone. It is reproduced because its ordering decisions carry argument: where it places a chapter says what that chapter is taken to depend on.

A Cliff's Notes Curriculum for the Evidence Volume and the Sulfur Command Paper Instrument, deep time, alphabet, the enzyme, geometry, recognition, shape, editor, clinic, objections — in that order **Abstract.** This is a reading curriculum, not a summary. It is built for a reader who wants the whole of a 2,572-page evidence volume and a 56-page companion paper, in an order that can be learned rather than the order in which the arguments were made, and who intends to stop at every place where the ground is contested. Sixty chapters in ten Parts carry the corpus from the notation argument through deep time, the eight-nucleotide alphabet, the enzyme that made DNA, the geometry, the recognition layers, the shape of a folded molecule, the editor, the clinical record and the objections. Every Part carries four stations besides its chapters. Pull-offs are the historical markers — the 1944 map, the 1948 note, the 1966 letter, the 1976 observation — that explain why a field settled where it did. Where the bridge is out names the gaps, the bottlenecks and the places two readings are equally available, with what the corpus does about [VOL p.421] each. Protocols collects the twenty-one experiments the chapters generate, each one written so that a laboratory could cost it. And the closing registers set out the disputes in one table, the protocols in one list, and what this curriculum leaves out and why. The purpose is not to compress the corpus. It is to make the corpus usable by someone who will take the two-lane road through it.

Paragraph tags. [E] established in the published literature. [F] argued here, or argued in the source and carried here. [H] hypothesis, stated as such. [O] open — a question, not a finding.

How the sources are cited. V is the evidence volume, The Scientific Arc of Man's Evolution from the Big Bang to the Human Genome, PP-2026-MASTER-01 v332 2,572 pages, 169 Parts, 1,753 numbered sections; a citation reads V 112 §§990–1002 for Part One Hundred and Twelve, sections 990 to 1002. S is Sulfur Supreme Command and Control Leader of the Free Radical World, PP-2026-SULFUR-CMD-01 v3, 56 pages, 52 sections in eight Parts. U is The Life Cycle of the Genetic Code and Central Dogma Theory, PP-2026-UNIF-02.

How this curriculum is built

• Read the Part preface first, then the chapter table, then the three stations. The preface says why the Part sits where it does. The table is the route. The three stations are what the route passes, and they are the reason this is a curriculum and not a contents page.

• Chapters are destinations, not page counts. A chapter may be four sections of the volume or forty. The number in the source column is where to open the book, not

how long to stay.

• The four stations repeat in every Part. Pull-offs are historical markers worth leaving the road for. Where the bridge is out names gaps and live disputes. Protocols are the experiments the material generates. The numbering of protocols runs unbroken from 1 to 21 across the whole curriculum.

• Nothing here is a substitute for the source. Every chapter points at pages. The curriculum's job is to decide the order and to mark the hazards; the argument itself stays in the volume.

1. A curriculum for this corpus cannot open with biology, because the corpus's first claim is about notation rather than about cells — so Part A teaches the instrument before anything is measured with it (A1 →A5).

2. The seven colored elements were made in five different stellar processes, and sulfur's nine oxidation states were reachable in warm water before any protein existed — so deep time comes second rather than fifth, and the mitochondrion is met later as an inheritance rather than as a parts list (B6 →B11).

3. De novo synthesis builds eight nucleotides through three one-way gatekeepers, with inosine monophosphate as the trunk; a four-letter record keeps the branches and loses the trunk (C12 [VOL p.422] →C18).

4. One enzyme family, running on a cysteine thiyl radical, converted the RNA world into the DNA world, and every deoxyribonucleotide on Earth passed through it (D19 →D22).

5. Eight letters at two positions and four letters at three positions both give sixty-four, and the solid that carries the eight is a cube rather than a four-dimensional figure — including the shapes the corpus wanted and refused (E23 →E29).

6. Recognition is not performed by the letter: five layers sit between the letter and the pairing, and at anticodon position thirty-four seven molecules occupy three symbols (F30 →F36).

7. A sequence does not have a structure, it has an ensemble — and every flat map in the corpus, the metabolic chart and the periodic table included, drops the dimension that decides the outcome (G37 →G41).

8. The editor writes inosine and the record writes G, so the one base doing four distinct jobs is the one base the notation cannot hold (H42 →H48).

9. The clinical record is where the argument is priced: zero of five at the hub, four of four at the spokes, and a brake on the whole fan thrown by a disulfide no genotype can see (I49 → I55).

10. The strongest objections are stated at full strength, graded by what supports them, and the curriculum ends on the falsification list rather than on a conclusion (J56 →J60).

Part A · The Instrument Five chapters · what a notation is, before anything is measured with one

[F] The corpus does not open on cells, and neither should a reader. Its first claim is that a convention adopted for convenience decides what can afterward be seen, and that the four-letter alphabet was fixed before anyone knew what it would be asked to carry. A reader who meets the chemistry first will take the notation argument for a complaint about terminology.

A reader who meets the notation first reads every later chapter as a measurement of what the convention costs — which is what those chapters are.

[F] Part A is also where the reader learns the corpus's own discipline. Every Part of the volume ends by stating the conditions under which it would be wrong. That apparatus is the reason the later Parts can be read quickly: the author has already marked the load-bearing walls.

The chapters [VOL p.423] **ch. chapter what it teaches where it comes from** A1 The Band and the The method: carry every argument down to V Prefaces, pp. 65–93 Wall the atom and the bond, and stop only at what cannot be taken apart further. Four prefaces read as one piece, with the marching-band figure that returns in Part G.

A2 The Four-Letter Cause and effect. Where the alphabet came V The Four-Letter Problem from, what it was asked to do, and the one Problem, p. 73 place it was never extended when the chemistry extended.

A3 Base, Nucleoside, The cardinal error, named as such by the V 38 §132 · 153 Nucleotide volume: three chemical levels collapsed onto §§1543–1548 · 160 one letter. The unit is a nucleotide and not a §1649 letter, counted three ways.

A4 What the Notation Modification, rotation, absence and V 21 §47 · 112 §§995, Loses orientation — then the base triple, which is of 1000 · 163 a different kind, being a whole class of contact the scheme has no symbol for. Five losses, named once before they recur in every later Part.

A5 Color as an Instrument The convention marks an element and S §1 and Table A · V nothing else, mechanically, wherever it 42, 47, 55 occurs — which turns a typographic rule into a measurement. 1,381 marks in the companion paper; sulfur 601 of them, 43.5 per cent, and 2.74 times the next element.

Pull-offs The historical markers in this Part — the places worth leaving the road for, and what each one explains about why the field settled where it did.

• The twenty words. The volume defines exactly twenty technical terms it says cannot be replaced, in ordinary language, once, in a single table in the front matter. It is the only vocabulary the corpus assumes, and reading it first saves an argument later about whether ensemble and promiscuity are being used in their technical senses. They are.

• The 1982 chart. A great many of the corpus's arguments about omission are run against one physical object: a biochemical pathways wall chart of 1982. Knowing that the target is a specific dated artifact rather than "the literature" is half of knowing what the arguments can and cannot establish. (V 42, 99, 113)

• The spelling note. IUPAC standardized on sulfur in 1990 and the Royal Society of Chemistry followed in 1992. The volume's own note records that the older form was never the etymolog-ically correct one and that its ph never stood for phosphorus.

Where the bridge is out Gaps, bottlenecks, and the places two readings are equally available — with what the corpus does about each.

• Is an argument about notation a scientific argument? The objection is that a naming convention cannot be wrong, only inconvenient. The corpus answers operationally rather than philosoph-ically: it names cases where the convention selected a trial population (I50), prevented an [VOL p.424] off-target call from being assigned (H47), and aimed a drug at the one region whose meaning is not in its sequence (G38). If none of those held, this would be an argument about taste. Readers should test the three cases and not the principle.

• Counting as evidence. A paper about sulfur will mention sulfur, and the count in A5 knows it. The count is offered as a measurement only because the convention was fixed before the content was written and marks elements mechanically, including inside tables and inside words not chosen for emphasis. Whether that makes the count independent of the author's intent is genuinely open, and the source says so in the same paragraph that reports it.

Protocols this Part generates

• Re-run the mechanical color count on a control document — a standard biochemistry chapter of comparable length, marked by the same rule, by someone who has not read the corpus — and ask how far sulfur's share moves. A control is the one thing the measurement in A5 does not have. No bench; one afternoon.

• Audit a current sequence-format specification for any field that records a chemical state rather than an identity. A single instance in routine use narrows A4; an established notation for the base triple would close part of it outright. No bench; public specifications.

Part B · Deep Time, and What Was Lying on the Sea Floor **Six chapters · the elements, the mineral, the event**

[F] Both source documents run their chemistry before their geology. That is right for an argument and wrong for a learner. A reader who meets mackinawite and greigite before the mitochondrion understands the organelle as an inheritance rather than as a parts list, and reads every later cofactor claim as a question about what was already lying on the sea floor when biology arrived.

[E] The material here is also the best-dated in the corpus. The Great Oxidation Event has three independent clocks — the sulfur isotope record in the rock, the

peroxiredoxin redox rhythm conserved across all three domains, and the sulfur ligation count in the molybdenum cofactor — and none of the three was derived from the others.

The chapters [VOL p.425] **ch. chapter what it teaches where it comes from** B6 Where the Seven Came From Hydrogen from the first minutes; carbon and oxygen out of the helium fire; nitrogen as the ash of a catalyst; phosphorus and sulfur from two oxygen nuclei colliding; selenium on the far side of iron. Seven colors, five origins, and iron ending the star.

V 123 §§1133–1145 B7 The Element Itself Sixteen. Nine formal oxidation states from sulfide at minus two to sulfate at plus six, every one reachable at the temperature of a body; four stable isotopes; the orthorhombic parent allotrope; and the arithmetic checked.

V 50 §§209–217 B8 The Mineral Thread Mackinawite and greigite precipitate where hydrogen sulfide meets dissolved iron, and the cubane at the center of greigite is geometrically the 4Fe-4S of ferredoxin. The oldest cofactor in biology is a mineral life enclosed rather than invented.

V 52 §§226–233 · S §22 B9 The Bond That Predates the Planet The amide bond arrived from interstellar space and the handedness arrived with it. Formamide in Sagittarius B2 and on comet 67P; isovaline and enantiomeric excess in Murchison. Three jurisdictions arriving separately at the same floor.

V 30 §§68–73 · 158 §§1625–1626 B 10 Hydrogen Sulfide Before Water Sutherland's one network from hydrogen cyanide and hydrogen sulfide under ultraviolet light; inosine and its precursors fall out where the canonical purines do not. And a phosphorothioate backbone that was available, more stable, and not the one life settled on.

S §23 · V 51 §§218–225 · 122 §§1125–1128 B 11 The Event, Dated by Sulfur Farquhar, Bao and Thiemens, 2000: mass-independent 33S anomalies in rocks older than about 2.45 billion years, absent above that horizon and never returning. The event named for oxygen is dated by an anomaly in sulfur.

S §§34–35 · V 121 §§1107–1111 Pull-offs The historical markers in this Part — the places worth leaving the road for, and what each one explains about why the field settled where it did.

[VOL p.426] • Harold Fisk, 1944. Fifteen maps of the lower Mississippi drawn for the Army Corps of Engineers, from Cape Girardeau to Donaldsonville, showing not the river but every channel the river had ever occupied, each era in its own color. The volume's closing Part uses them as the type case of a map that made visible a quantity the earlier surveys had structurally omitted — a surveyor can measure where the water is and cannot measure where it was. Worth the detour here as well as at G40, because every deep-time chapter in this Part is doing what Fisk did. (V 169 §1734)

• Lost City. The alkaline hydrothermal field where the mineral chemistry of B8 is still running: alkaline fluid, dissolved sulfide, iron, and pore spaces holding standing gradients across thin inorganic walls. It is why B8 is a present-tense observation and not only a reconstruction.

• Nine to two. Nitrogenase, about 3.2 billion years old and poisoned by oxygen to this day, holds its molybdenum in a cluster of seven irons, nine sulfurs, one carbon and one metal. Every post-oxygen molybdenum enzyme holds the same metal in a two-sulfur dithiolene. One number, changing across one boundary, in one element.

• The diazoplast. Nitrogenase never adapted to oxygen; it was sequestered — in heterocysts, by temporal separation, or inside an endosymbiont, as in the diatom Epithemia, whose diazoplast descends from a free-living cyanobacterium. A living example of the corpus's general claim that biology works around an atom it cannot replace.

Where the bridge is out Gaps, bottlenecks, and the places two readings are equally available — with what the corpus does about each.

• Thiophosphate against phosphate. A sulfur-substituted backbone is more stable than the one life chose, forms by simpler chemistry, survives in modern genomes as the Dnd restriction mark, and is what the pharmaceutical industry reaches for when an oligonucleotide has to last in a body. Two readings are equally available: that phosphate was selected because stability was traded for controlled turnover, or that phosphate simply won on abundance and the trade is a story told afterward. The corpus argues the first and does not claim to have settled it.

• Tungsten before molybdenum. Some heat-loving archaea run the equivalent enzymes on tungsten, and it has been proposed that tungsten came first, which would make molybdenum an oxygen-era replacement rather than an oxygen-era arrival. Unsettled, and it bears directly on I55.

• Is the nine-to-two collapse general or singular? This is the case study's own stated open question. The prediction is that other metallocofactor families with both pre- and post-oxidation representatives show the same direction of change in sulfur ligation count. Until that is checked, B11 rests on one cofactor.

[VOL p.427]

Protocols this Part generates	
•	Survey the structural databases for sulfur ligation count across metallocofactor families that have both pre- and post-oxidation representatives, and test whether the direction of change is general. No bench; public structures. (S §40)

•	Test whether prebiotic removal of the 2′ oxygen requires sulfur in the way the enzyme does, or whether the two routes to a deoxy sugar are chemically independent. Bench; prebiotic chemistry. (S §24)
Part C · The Alphabet Metabolism Actually Builds	
Seven chapters · eight nucleotides, three gatekeepers, one trunk	

[F] This is the Part the rest of the corpus exists to make possible, and it is where a reader most needs to hold two things apart: what the cell manufactures and what the code spells. They are different sets, of different sizes, and most of the disputes in Parts E and J are what happens when they are run together.

[F] The claim is narrow when stated carefully.
De novo synthesis converges on inosine

monophosphate and branches from there; xanthosine monophosphate gates guanine; orotidine monophosphate gates uracil and through it every other pyrimidine. Remove any one of the three and there are no nucleic acids at all. A notation that records only the four end products records the branches and loses the trunk.

The chapters	
ch.	**chapter what it teaches where it comes from**

C 12	The Door They All Come Through

Phosphoribosyl pyrophosphate: every base, V 97 §§794–808 purine and pyrimidine, enters through one molecule, the fork is purine against pyrimidine, and it is not a symmetric fork. Also the slowest reaction life ever learned to hurry.

C 13
The Eight, and the
Three One-Way
Gatekeepers

IMP, XMP, GMP and AMP on the purine S §25 · V 70 side; OMP, UMP, CMP and TMP on the §§441–452 pyrimidine side. Nature's own, with no synthetic base in the set. Three of the eight are gatekeepers and the gates are one-way.

C 14
The Crossed Graphs
The purine square and the pyrimidine square V 81 §§584–596 set side
by side, and the exact place the correspondence fails: xanthine is inside
its square and orotate is outside. What each gatekeeper keeps and what
each discards, atom by atom.

[VOL p.428]

ch.	chapter	what it teaches where it comes from
C 15	The Systematic Names	The eight, numbered, with their systematic V 119 §§1081–1093 names, their acid constants — including the one that sits at body pH — and the solubility column that by itself explains a disease. The purine ladder is arithmetic.
C 16	The Molecule With No Letter	Four measurements, and inosine wins all V 3 §16 · 2 §15 four.

Hypoxanthine holds its electrons 0.61 eV more tightly than guanine: the sturdy parent ahead of the fragile child.

C 17
The Parent, Not the
Waypoint

Inosine monophosphate read as the parent of V 125 §§1159–1171 the purine road rather than as a station on the way to disposal. The two distances are not equal; the editing reverses a biosynthesis; the salvage direction inverts it again.

C 18	
The Case for Eight,	Why eight and not six; what the eight replace V 70 §§448–453 · 101
and the Claim It Will	and what they do not; the distinction between §§848–860 an index and
Not Carry	a code; and the one claim the volume prints its own refusal of.

Pull-offs The historical markers in this Part — the places worth leaving the road for, and what each one explains about why the field settled where it did.

•	The slowest reaction life ever learned to hurry. Orotidine monophosphate decarboxylase — the orotate gate — runs with no metal and no cofactor at all, at a rate enhancement near ten to the seventeenth. Pull over for V 97 §801: it is the control case against which the molybdenum gate's three sulfurs in I55 have to be read, and the two gates are indistinguishable on any flat chart.
•	Somebody already built the eight-letter version. An eight-letter genetic system exists and functions, and the volume's own section says plainly that it could not use this volume's eight. The distinction is natural against synthetic, and the corpus makes it explicitly rather than ignoring the precedent. (V 101 §§855–856, 153 §1545)
•	Lesch–Nyhan. HGPRT salvage is what closes the purine loop, rebuilding IMP from free hypoxanthine at one ATP against six for de novo. The disease is what the loop looks like when it does not close, and it is the cleanest demonstration that salvage is a limb of the
•	Where the author's inosine came from. V 83 traces the branch-point enzyme through twelve cell lines and two inhibitors to one result, with the substrate accumulating fivefold and

guanosine reversing it for exactly two days. It is the experimental spine under C 17 and is usually skipped.

Where the bridge is out Gaps, bottlenecks, and the places two readings are equally available — with what the corpus does about each.

[VOL p.429] • Index, or code? The volume draws the distinction itself: an index names members, a code maps symbols onto meanings. Whether the eight are an alphabet or an inventory is the live question, and the corpus argues it both ways in different Parts. The reading that survives both is that the eight are an alphabet of manufacture and the four an alphabet of reading, and that no single word covers both — which is itself a notation finding.

• Eight, or six? The volume revised from eight to six and printed the revision as its own Part. Both counts remain in the corpus because they answer different questions: complement closes at four, reading closes at six, manufacture closes at eight. A reader who meets only one of the three closures will think the corpus contradicts itself, and will be wrong for an understandable reason. (V 38, V 48 §§189–191)

• The forty-two. Eight letters at two positions give sixty-four codewords and twenty-two are assigned. Never assigned, or assigned and later vacated? The corpus argues never assigned on grounds of economy, and then strengthens it by showing that codon capture is observed rather than inferred. The two are compatible; what is not established is the timing, and the timing is the whole of the objection.

Protocols this Part generates

• Test whether a hybrid strand of C, U, A and I — the four letters the prebiotic chemistry delivers — forms a stable duplex with its complement, and how the two-hydrogen-bond I–C pair behaves inside it. This is the decisive next measurement named in B10 and it has not been made. Bench; oligonucleotide synthesis and thermal denaturation.

• Establish whether the alphabet's contraction and the coded repertoire's expansion crossed, and in which order. If the coded set was smaller than sixteen when the alphabet contracted, two codon positions sufficed for a period and the third was added later for another reason. No bench; phylogenetic reconstruction. (S §46)

Part D · The Enzyme That Made DNA **Four chapters · one step, one radical, one world becoming another**

[F] There is exactly one route from the RNA world to the DNA world and every organism uses the same enzyme family to take it. Four chapters is the smallest honest treatment, because this step is also where the corpus's method shows best: a single chemical event with a fully known mechanism, carrying a claim about deep time that nobody watched.

[F] The ordering claim in D21 is the one most often mistaken for rhetoric. It is not. Sulfur before phosphorus and metabolism before enzymes are each a statement about what a given chemistry requires in order to run, and each can be attacked by showing that the later item [VOL p.430] was in fact available first.

The chapters ch. chapter what it teaches where it comes from D 19 A Thiyl Radical Made Ribonucleotide reductase: a transient thiyl S §24 · V 7 §21 · 10 DNA radical on a cysteine abstracts the 3′ §31 · 117 §1056 hydrogen, two further cysteines supply the reducing equivalents as a disulfide pair, and thioredoxin or glutaredoxin resets them. DNA contains no sulfur. DNA exists because of it.

D 20 Biology Proceeds by The subtractive account stated as a method V 9 §§25–30 Removal rather than an aphorism, with DNA as the clearest case: an oxygen taken off the sugar, a methyl put on the base. And the nucleotide never assembled from a pre-made sugar.

D 21 Sulfur Before Two orderings the standard account inverts, V 9 §§27–28 Phosphorus, each stated so that it can be attacked, with Metabolism Before what would have to be shown to overturn Enzymes either.

D 22 Wobble Was an Error The smallest self-copying ribozyme makes V 124 §§1146–1158 First one kind of error, and it is the same chemistry that at anticodon position thirty-four is an economy. One chemical event, twice, for opposite reasons — a cost at the origin and a saving at the ribosome.

Pull-offs The historical markers in this Part — the places worth leaving the road for, and what each one explains about why the field settled where it did.

• The cell cycle has a redox condition. No reduced thioredoxin, no deoxyribonucleotides, no S phase. That places a sulfur gate upstream of every arrow in Part I that ends in a balloon labeled cell cycle progression, and it is the shortest path between this Part and the clinic.

• The mineral and the methyl carrier in one active site. Class III ribonucleotide reductase is a radical SAM enzyme: the 4Fe-4S cluster of B8 cleaves the sulfonium of C9 to generate the radical. The oldest cofactor and the newest currency, in the

enzyme that made DNA, with no step in between.

• Rediscovered and renamed. Protein self-splicing — a cysteine attacking its own peptide bond with no cofactor, no energy and no enzyme — was rediscovered by synthetic chemists under a different name. A good marker for how often the corpus finds two literatures holding one phenomenon and not citing each other. (V 148 §1470)

Where the bridge is out Gaps, bottlenecks, and the places two readings are equally available — with what the corpus does about each.

[VOL p.431] • RNA world, or RNA–DNA hybrid world? Sutherland reads his own result as RNA and DNA being molecular siblings rather than parent and successor. The corpus adopts the hybrid reading because the sulfur chemistry sits on the crossing in both the prebiotic and the cellular case. Both readings remain live and the measurement that would separate them — whether the prebiotic nucleosides join into strands — has not been made.

• Is the priority of the thiyl radical a record or an inference? The corpus grades this against itself: the chain is a plausible ordering, not a documented one. Nobody watched a mineral cluster become a ferredoxin or a thiyl radical make the first deoxyribonucleotide, and the volume says so in its own voice rather than leaving it for a referee.

Protocols this Part generates

• Join the prebiotic nucleosides into strands and measure duplex stability and polymerase handling. This is the single measurement on which the hybrid-world reading turns, and it is shared with Protocol 5. Bench; prebiotic and enzymology.

Part E · The Geometry, Including the Shapes It Refused **Seven chapters · what a solid can carry at once**

[F] The geometric Parts are the most often misread in the corpus, because a reader who takes them as decoration finds them ornamental and a reader who takes them as physics finds them overreaching. They are neither. They are a bookkeeping claim about which counts a single solid can carry simultaneously, and the most valuable sections in them are the ones where the author refuses a shape he wanted.

[F] Read E26 and E27 before E23. A reader who sees the refusals first — there is no sixty-four-cell, and the sugars fail all four conditions a spinor claim has to satisfy — will read the quaternion encoding as a constrained construction rather than as numerology, which is what it is.

The chapters ch. chapter what it teaches where it comes from E 23 Four Nucleotides as The encoding in full: the first letter as the real V 4 §§17–18 · 5 §19 Hamilton’s axis and the next three as i, j and k. DNA Quaternions reads ATGC, RNA reads UACG, the wobble row reads AUIC — with no guanine in it. Hydrogen-bonding counts A=3, G=2, C=3, U=2, I=1, T=1, totaling twelve. [VOL p.432] **ch. chapter what it teaches where it comes from** E 24 The Closure Rule Three closures and three

counts: complement V 48 §§188–198 closes the set at four, reading closes it at six, manufacture closes it at eight. Twelve, twenty-four and sixty-four belong to the map rather than to the molecules.

E 25 The Eight on the Cube The four body diagonals as the four base V 49 §§199–208 pairs; twenty-four rotations of which three are i, j and k; why eight by eight is sixty-four exactly; and the row that holds the whole termination apparatus.

E 26 The Shape With No There is no sixty-four-cell. What sixty-four is V 100 §§835–847 Shadow the right number for instead; why a labeled tetrahedron is chiral and a labeled cube has forty-eight forms; and the one figure with no shadow, whose vertices are the quaternions.

E 27 The Period Belongs to The seven-hundred-and-twenty-degree claim V 102 §§861–873 the Particle scored against four conditions and refused for the sugars, whose real rotation closes at three hundred and sixty. Spin one-half is in the proton, not the pucker — and the methyl group is the exception, with a number of three.

E 28 Three as a Minimum, Ogston's three points, and why two cannot V 31 §§74–81 · 34 Not a Pattern distinguish a hand. Structure stored in §§97–101 rotations rather than coordinates; where three breaks prediction; and the inventory of threes marked for exactly what it is.

E 29 The Modeling The containment test: does everything in the V 36 §§108–117 Generator, and the volume fit inside the construction? Three Three That Do Not Fit things do not, and the volume calls that the best result in the Part.

Pull-offs The historical markers in this Part — the places worth leaving the road for, and what each one explains about why the field settled where it did.

• Ogston, 1948. Three-point attachment explains how an enzyme tells apart two chemically identical groups on a prochiral carbon. The whole theory of three rests on it and it is one short note. Read it before deciding whether the inventory of threes is a pattern or a minimum — the volume argues it is a minimum, which is a much smaller and much more defensible claim.

• The Fano plane, refused. The author saw it, recognized it immediately, and then rejected it outright on the ground that nothing is planar in three dimensions with rotational symmetry. The refusal is recorded here because a model an author abandons tells a reader more about the method than a model he keeps.

[VOL p.433] • Forty-eight forms. A labeled cube has forty-eight distinct labelings and a labeled tetrahedron is chiral. V 100 §§839–840 is the cleanest short piece of arithmetic anywhere in the geometric Parts and settles several arguments at once.

• A quaternion cannot be a molecule. The volume says so, in its own voice, at V 57 §274. Readers who skip that section routinely attribute to the corpus a claim it has already refused Where the bridge is out Gaps, bottlenecks, and the places two readings are equally available — with what the corpus does about each.

• Eight squared equals four cubed — coincidence, admiration, or derivation? Sixty-four is reached two ways. The strongest reading available to the corpus is compensation: the alphabet contracted as the three gatekeepers stopped being coding letters and survived as metabolic intermediates, two positions then gave only sixteen, and a third codon position recovered the lost capacity exactly. Because that position was added to a code already functioning on two, it carries the least specific information — which would derive third-position wobble rather than accommodate it. The timing objection is printed alongside it and is not answered.

• Expanding, or contracting? Conserved-motif analyzes of ribosomal RNA suggest the earliest codons were G- and C-rich, spelling glycine and alanine, with A- and U-rich codons integrated progressively: a code expanding from a narrow base. The eight-to-four contraction is a code losing letters. Both describe the same window. The corpus records the tension rather than smoothing it and states that the arithmetic stands or falls independently of the compositional reconstruction.

• Where a geometric claim stops being a claim. E27 is the model: four conditions written down, the candidate scored against them, and the score published as a failure. The open question for a reader is whether the surviving geometric claims have been scored as hard as the refused ones.

Protocols this Part generates

• Score any proposed spinor or rotational claim against the four conditions set out at V 102 §863 before adopting it. The volume supplies both the rubric and its own failing score, which makes it a usable referee’s checklist rather than a position. No bench.

Seven chapters · five layers, one position, seven molecules

[F] If one Part has to carry the argument alone, it is this one, because the claim here is narrow and checkable: the letter is not what recognizes. Five layers sit between a letter and a pairing, and at the single position where the code stops behaving as a lookup table, seven molecules occupy three symbols.

[E] This is also the Part with the best primary sources. Crick’s 1966 wobble paper, Holley’s [VOL p.434] molecule, Sanger’s letter and the 1948 and 1976 notes are all reproduced or quoted closely enough that a reader can check the corpus against them without leaving the volume.

The chapters		
ch.	**chapter**	**what it teaches where it comes from**
F 30	Five Layers, and the Letter Is Only One	Where recognition actually happens, layer by V 19 §§43–44 layer, and the tetrad with a base that is armed on both faces.

F 31	The Wobble Position	Crick 1966 read in full: five candidate pairs V 82 §§597–609 · 69 with one ruled out, one hundred and §§428–440 twenty-seven combinations reduced to seven, and Crick's own sentence that inosine reads three and excludes guanine. Then fifty years of one hypothesis, and position thirty-four as the most modified position in transfer RNA.
F 32	Forty and Sixty-Five	The G·U geometry measured: forty degrees V 92 §§727–739 and sixty-five. Why G·U and U·G are not the same object; the electrostatic hole and the metal that binds in it; and why nearly as stable as Watson-Crick is not stable enough.
F 33	Both Faces	Guanine's amine in the minor groove, worth V 93 §§740–752 · 94 about two and a half kilocalories, and why §§753–765 geometry rather than count is the variable. The instrument that measures it is an inosine carrying a sulfur — and the Part prints two corrections to the one before.
F 34	The Axis at Thirty-Seven	Position thirty-seven governs what position V 90 §§701–713 thirty-four is able to read. Lysidine: one modification, two specificities, both flipped. And the energy bill for one peptide bond.
F 35	The Pawl Is Made of Sulfur	

The ratchet residue at the tip of a family as V 130 §§1228–1241 old as the last universal common ancestor, built by sulfur, acting at the second base pair — and the other sulfur at the wobble seat. One tRNA in bacteria, eight in us.

F 36
The Join
The only place a nucleic acid is bonded to an V 32 §§82–89 · 157
amino acid. Seventy-five angstroms between §§1605–1618 · S the
address and the port; eighteen angstroms §§27, 29 of nothing at the
bond itself; and sulfur at both ends of the same molecule.

Pull-offs The historical markers in this Part — the places worth leaving the road for, and what each one explains about why the field settled where it did.

•
Sanger's letter. Little inosine in E. coli — one line of correspondence that shaped what Crick
could and could not claim in 1966, and a reminder that the wobble hypothesis was built on

[VOL p.435] three yeast anticodons. (V 82 §§604–606)

• Queuosine is a vitamin. A modified base humans cannot make and obtain from gut bacteria, installed at the same anticodon position by an enzyme that deletes the base it came to replace — with the stalled intermediate caught in vitro. Four chemical states, one letter. (V 69 §436 · 89 §§688–698)

• The superwobble. One transfer RNA reading an entire four-codon box, which is the limiting case of everything in F31 and is usually mentioned in a footnote. (V 69 §437)

• The man who broke it. V 78 is a first-hand account of cracking the code: poly-U and the month of waiting, Moscow and an audience of thirty-five, the three trivial

technical advances, and hypoxanthine in the third position. It is the best single piece of reading in the volume and it is not an argument.

Where the bridge is out Gaps, bottlenecks, and the places two readings are equally available — with what the corpus does about each.

• Are synonymous codons synonymous? The textbook reading says yes. The corpus says no — codon usage bias tracks transfer RNA abundance, sets local translation speed, influences co-translational folding and message stability, and rare codons cluster at domain boundaries. Both readings survive; what separates them is whether the effect is large enough to be selected on, and that is measurable rather than arguable. (V 20 §§45–46)

• The third position and the protein fold. V 93 §751 prints what is not true here as carefully as what is. A reader who takes the strong version will overstate the corpus, and the corpus will not back them up.

• Seven molecules, three letters. Position thirty-four in Eukarya carries galQ, manQ, m5C, f5Cm, (m)cm5(s2)U, (m)chm5U, ncm5U(m) and Ψ. The literature on these is thin enough that the corpus nominates the position as open frontier rather than settled ground — which is an invitation, not a gap to be apologized for.

• Where the apparatus fails. MERRF and MELAS are worked mistranslations in which the mutation is not at the position that fails. Any model of position thirty-four has to produce those two misreadings, and most do not. (V 111 §§983–986)

Protocols this Part generates

• Add the eight Eukarya-specific wobble-34 modifications to a translation model as expanded decoding criteria, one at a time, and ask which of them change what is read rather than how fast it is read. The eight are named at F31 and the literature on them is thin. Computational, then bench validation.

• Quantify whether position-thirty-seven identity predicts position-thirty-four reading across a [VOL p.436] transfer RNA set. V 90 §708 asserts the governance and does not measure it. Bench; reporter assays across a tRNA panel.

Part G · The Sequence Has No Shape Five chapters · the ensemble, and every flat map in the corpus

[F] This is the newest seam in the corpus and the one a working reader is most likely to meet in their own hands, because it is where the argument stops being about biology’s past and becomes about a design method now in use. The claim is one sentence: complementarity does not vary with conformation, and conformation is what decides whether the molecule can be reached.

[E] The arithmetic of the field is the frame. Roughly ten thousand proteins were classified as undruggable by conventional small molecules and oligonucleotides were meant to reach them. Since the 1990s, eighteen oligonucleotide drugs have FDA approval, about half of them antisense. Thirty-five years, ten thousand promised targets, eighteen drugs. The corpus takes that ratio as a fact about the field rather

than as an indictment of it, and asks what the design method is not seeing.

The chapters ch. chapter what it teaches where it comes from G 37 Nothing Alive Is Flat An isolated base ring is planar; a base pair in U · V 19 §§43–44 · 94 a living duplex is not. Propeller twist of ten to §§755–757 twenty degrees, buckle and roll; stacking supplying most of the stability; and a duplex that breathes as proteins read it. Specificity arising largely from sequence-dependent flexibility — indirect readout.

G 38 The Sequence Has No A sequence corresponds to an ensemble, not V 112 §§990–1002 Shape to a structure: the same twenty bases sit exposed in a loop in one conformer and buried in a stem in another, and the record is identical. Of the three quantities governing complex stability, two are invisible to a complementarity score.

G 39 The Map Has No What a metabolic map actually records, the V 105 §§900–912 Third Dimension scale gap measured, why gravity does nothing and the number that shows it, and why compartmentation rather than bulk physics is the gap that matters.

G 40 The Flat Map Fisk's Mississippi maps; the metabolic chart V 169 §§1734–1743 as a topological diagram that carries connectivity and drops geometry; the periodic table as a flat map too; what the instruments can and cannot see; and what a three-dimensional metabolic map would have to carry. [VOL p.437] **ch. chapter what it teaches where it comes from** G 41 The Tetrad With a What holds a tetrad together and what inosine V 129 §§1211–1227 Hole In It takes away; substitution performed position by position; an edit that can build a quadruplex that was not there before; and a standard unfolded control that is not unfolded.

Pull-offs The historical markers in this Part — the places worth leaving the road for, and what each one explains about why the field settled where it did.

• Fomivirsen, 1998. The first antisense oligonucleotide approved anywhere, for cy-tomegalovirus retinitis — aimed at a virus, where the structure is the function. Eight more followed over the next quarter century. The first success and the slow quarter century after it are the same datum read two ways.

• The base triple. Three bases, one of them contacting an existing pair, typically on the Hoogsteen or sugar edge rather than the Watson-Crick edge. Watson-Crick notation is irreducibly pairwise: one slot for a partner and no way to write a third. The field's own proposed remedy for its most disappointing drug class is to design around the interaction its notation cannot record.

• A thousandfold. Negative supercoiling raises Cas9 off-target cleavage by three orders of magnitude. Topology, not sequence, and not visible anywhere in a guide design. (V 110 §967)

• Arriving from the other direction. Hörberg, Carlesso and Reymer reached the notation argument in 2024 starting from molecular dynamics and drug design, without consulting this corpus and without setting out to say anything about

notation. They set out to make a drug work and found the notation in the way. The volume records that explicitly rather than claiming priority, which is the most useful thing in the Part.

Where the bridge is out Gaps, bottlenecks, and the places two readings are equally available — with what the corpus does about each.

• How much of the field's difficulty is structure? The corpus names delivery, nuclease susceptibility, toxicity, potency and specificity alongside it, and prints its own warning against overselling: structure is a real and under-modeled variable, and a reader who takes it as the whole explanation has taken more than is offered. Two readings remain available and the corpus declines to choose between them.

• The unfolded state was never empty. If the field's standard unfolded control is in fact partly structured, a class of published thermodynamic measurements is reporting a smaller difference [VOL p.438] than it believes. That is a large claim resting on a narrow structural argument, and it is the single most checkable thing in Part G.

• Can an ensemble be computed well enough to design on? A minimum-free-energy fold is not an ensemble. Whether SHAPE and DMS probing coverage is adequate at the scale a design pipeline needs is the practical bottleneck, and it is a different problem from the conceptual one. The bridge is out at the engineering end, not the theoretical end.

• Six failures, one shape. Parts 110 to 112 set out five ways a sequence-directed tool is aimed at something the sequence does not describe, and §976 records a sixth of a different kind — after a somatic edit a patient carries two genomes and the record format has one slot per person. In every case the instrument is aimed by identity and the molecule answers by relation, geometry or state.

Protocols this Part generates

• Experiment Thirty-seven, as the volume numbers it. Assemble the target sites of the approved antisense oligonucleotides and of a matched set that reached clinical trials and failed for lack of efficacy. Score structural accessibility for each site from published SHAPE or DMS probing data, and where none exists from ensemble folding rather than a single minimum-free-energy structure. Ask whether the successful set is enriched for accessible sites. The falsification condition is written before the answer, and the sample size — eighteen approved drugs is not a population — is stated as the honest weakness rather than discovered later. No bench; public sequence, public probing data, public trial records. (V 112 §1001)

• Audit whether commercial oligonucleotide design pipelines already incorporate ensemble accessibility as a primary criterion. A positive finding retires the claim in G38 outright, which is why it belongs near the front of the list. No bench. (V 112 §1002)

Part H · The Editor Seven chapters · one base, four jobs, and a record that cannot hold it

[F] Everything in Parts A through G converges here. Inosine is the trunk of purine synthesis, the base the prebiotic chemistry reaches before guanine, the base that widens the anticodon, the mark that distinguishes self from foreign RNA, and the chemical product of the adenine base editor. Four distinct roles, one base — and in every one of them the record writes G.

[E] The quantitative frame matters and is easy to get backwards. Virtually every adenosine in the transcriptome is editable; less than one tenth of one per cent of editing recodes a protein. The corpus argues both, because they are claims about two different functions of one enzyme, and a reader who collapses them will find the numbers contradictory.

The chapters [VOL p.439] **ch. chapter what it teaches where it comes from** H 42 The Editor ADAR: the enzyme that rewrites the message V 59 §§288–300 after the message is written. The reaction balanced; one editing site per thirty-two bases; the three pairings as the author wrote them; and the member of the family that binds left-handed DNA.

H 43 The Alu Engine, and Two Alu copies facing each other in one V 60 §§301–313 · 61 · Inosine as the Mark of transcript fold into a duplex indistinguishable S §28 Self from viral RNA. The cell's answer is not removal but editing. An ADAR1 knockout is embryonic lethal and the lethality is rescued by loss of MDA5 or MAVS — the animal dies because its own RNA reads as foreign. The editor was a precondition for the expansion, not a response to it.

H 44 The Bulk and the Virtually every adenosine, and seven V 66 §§389–401 · 67 Exceptions hundredths of one per cent. The level rather §§402–414 than the site; the funnel from eighteen hundred to one; transcript diversity counted in bits; and why the overlap between studies was always low.

H 45 The Precursor, and the ADAT at anticodon position thirty-four; the V 64 §§363–375 · 120 Tool Made From the proof in a test tube and the order of §§1094–1106 · S §30 Target operations; and TadA, evolved from that enzyme, performing at DNA what ADAT performs at position thirty-four. The editing tool was built out of the thing it edits.

H 46 The Sanitizer ITPA: the enzyme this volume's author V 86 §§649–661 · 71 named in 2000. How it was found, the §§454–466 twenty-nine nucleotides it will and will not touch, the kinetics recomputed onto the diphosphate rather than the triphosphate, and inosine fifty times more abundant in RNA than in DNA.

H 47 Read as Guanosine The adenine editor's chemical product is V 155 §§1571–1586 · inosine and the sequencing record writes G. 163 §§1677–1687 · S The cell's own ADAR makes the same §20 change continuously and it prints the same. An A-to-G call in an edited cell cannot be attributed, and the ambiguity is created at the alphabet rather than lost to coverage — deeper sequencing does not fix it.

H 48 Driving the Editor From reading the editor to driving it: the tool, V 68 §§415–427 the thioether bond on a cysteine, the photocage, three timescales in

agreement, in vitro and in cells and in an animal — and the repair of an amber stop to tryptophan, with only two of the three stops repairable.

Pull-offs The historical markers in this Part — the places worth leaving the road for, and what each one explains about why the field settled where it did.

• Six hundred and forty-two fold. The direct measurement of hypoxanthine accumulation, with the single mutants doing almost nothing and the synergy carrying the whole effect; yeast giving the same answer; and the repair enzymes making no difference, which the authors say themselves. (V 88)

• Thirty seconds. A measurement with a stoichiometry that checks twice, a purine that goes [VOL p.440] missing, a number that matches, and a pool that behaves again in the second five minutes. One of the few places in the corpus where a kinetic argument is settled rather than proposed. (V 91)

• Five sites, thirty-two combinations. One serotonin receptor transcript edited at five positions, giving thirty-two possible proteins from one gene, all recorded in the sequence file as one gene. (V 67 §411)

• The editor contains the element it edits. An Alu cassette sits inside ADAR itself — and the volume's own next section records that the Alu is not the active part. The correction is printed immediately after the finding, in the same Part. (V 65 §382 · 84 §§630–631)

Where the bridge is out Gaps, bottlenecks, and the places two readings are equally available — with what the corpus does about each.

• Is the finding the sliver or the bulk? Virtually every adenosine is editable and under one tenth of one per cent recodes. The corpus argues both: the bulk is immune marking and the sliver is coding, and they are different claims about one enzyme. The numbers only look contradictory if the two functions are run together — which is the same error C12 warns about one level down.

• Mice have no Alu. Nine-tissue mouse data cannot speak to the primate Alu expansion, and V 72 §477 says so directly. That constrains how far the model travels and it is stated by the corpus rather than extracted from it by a critic.

• Mouse and human do not agree. On ITPA, printed plainly at V 86 §659 and left unreconciled. A reader should know which of H46's claims rest on which organism.

• Annotation as the escape hatch. The objection at full strength: modification databases do record inosine, so the notation does not lose it. The corpus concedes that the objection is also the admission — the thing that loses it is the sequence file, and the sequence file is what the clinic reads. Whether a separate database counts as the notation having the symbol is the live disagreement. (V 163 §§1678–1682)

Protocols this Part generates

• Design a method that assigns an A-to-G call in an edited cell to the engineered editor rather than to endogenous ADAR, without reading the native molecule. If one

exists, H47 falls, and with it a plank of the notation argument. Bench; sequencing chemistry. (S §52)

• Run the duration test with the confounder named in advance, as set out at V 164 §§1693–1694, so that benefit and risk are separated before the data arrive rather than after. Clinical; design exists, study does not.

[VOL p.441] **Seven chapters · one fan, twenty-seven arrows, nine Phase 3 programs**

[F] Everything before this Part is an argument about chemistry and notation. This is where it is priced. Five Phase 3 programs at the hub and four at the spokes is a small sample and the corpus says so, but the direction is uniform across two molecules, four tumor settings, different sponsors and several decades, and uniformity of that kind is a property of the target rather than of any one compound.

[F] The reason this Part sits after the editor and not before it is that two of its three strongest findings are notation findings arriving in a clinic. A disulfide is one letter in a sequence file, and a trial enrolled on the register that cannot represent it. An inosine prints as G, and an off-target call cannot be assigned. The chemistry decided the outcome and the record could not hold the chemistry.

The chapters ch. chapter what it teaches where it comes from I 49 The Fan, Organelle-Sorted Twenty-seven outward arrows from one S §§10–12 kinase, filed by the organelle in which each target acts: nine nuclear, seven cytoplasmic, three mitochondrial and all three on one decision, two lysosomal, two ribosomal. The Golgi, peroxisome and chloroplast receive none — and the zeros are as informative as the counts.

I 50 PTEN Is a Disulfide Switch The brake on the entire fan is thrown by a S §13 reversible intramolecular disulfide between cysteine 71 and the catalytic cysteine 124. A tumor with an intact sequence and an oxidized protein is Akt-active and genotypically normal: it has the phenotype the trial selects for and it fails the entry criterion.

I 51 SAMTOR A sulfonium sensor gating mTORC1 through S §14 GATOR1, in parallel with Akt. The lysosomal balloon has two independent upstream inputs and only one of them is Akt — a structural fact the pathway diagram cannot show, because the diagram draws signaling and not supply.

I 52 Zero of Five, Four of Four The whole Phase 3 record across the fan in S §§15–17 one table, and the variable that separates the two groups: redundancy of output rather than potency of molecule. A node with twenty-seven outputs has twenty-seven bypasses. Count the arrows into the organelle and count the decisions they serve. [VOL p.442] **ch. chapter what it teaches where it comes from** I 53 The Seven Traditions, Six of Them Sulfur Seven engineering platforms normally S §18 surveyed as separate things, sorted instead by the level at which each acts on the fan. The clinical record tracks the level, not the platform — and the engineered cell's persistence is a cysteine and selenium accounting problem that release testing does not measure.

I 54 The Transversion Wall Both base editors perform transitions and S §§19–20 · V 110 neither performs a transversion. BRAF §§963–976 V600E is c.1799T>A, and is simultaneously one of the few genuinely non-redundant spokes in the fan and a node the editing chemistry cannot address under any guide or delivery.

I 55 One Cofactor Across the Whole Arc Molybdenum cofactor deficiency, isolated S §§32–40 · V 95, 162 sulfite oxidase deficiency, and classical xanthinuria types I and II. Severity tracks which atom is stranded rather than how much cofactor is lost — and the test that separates two clinically identical diseases runs on a metabolite the human lineage stopped processing fifteen million years ago.

Pull-offs The historical markers in this Part — the places worth leaving the road for, and what each one explains about why the field settled where it did.

• Fosdenopterin. A cPMP replacement entering the pathway upstream of the sulfur-insertion step, reducing risk of death by eighty-two per cent against untreated controls — and it has to be started fast, because what is being prevented is a toxin accumulating quickly rather than a deficiency accruing slowly. The urgency is a consequence of the chemistry and is legible only if the chemistry is in view.

• The natural experiment. One cofactor serves two arms. Block the purine arm and patients form stones and reach their sixties. Block the sulfur arm and the brain is destroyed within days.

Xanthinuria is the control experiment for sulfite oxidase deficiency and it isolates the variable: same cofactor, same kind of failure, two substrates, and only the sulfur one is neurotoxic.

• The undruggable and the editable are nearly the same list. FOXO, CREB, eNOS and the GLUT4 arm — transcription factors and transport proteins, the classic undruggable classes, and precisely the nodes where an epigenetic editor rather than a small molecule is the only available lever. And every one of those edits will be written with a sulfur-borne group the mitochondrion has to supply.

• Navtemadlin is the cleanest test. One nuclear node, correctly drugged, primary endpoint missed at p = 0.08. If the organelle sort predicts anything, it predicts that result, and the [VOL p.443] corpus nominates it as the case most likely to break its own rule.

Where the bridge is out Gaps, bottlenecks, and the places two readings are equally available — with what the corpus does about each.

• Redundancy, or potency? The obvious reading of five hub failures is pharmacological: a better inhibitor would convert progression-free benefit into survival benefit. The structural reading is that no single output is individually required and the cell has parallel routes to most of them, so breadth without depth is the signature of a benefit that never converts. The two are distinguishable in one trial, and the corpus says which trial.

• Does better selection convert? I50 predicts a cheap redox assay would find responders the genotype misses. I52 predicts that better selection raises the effect size at the hub without converting progression-free benefit into survival benefit, because selection does not reduce the number of escape routes. Both can be true at once, and they are separable by measurement rather than by argument.

• Supply failure, or targeting failure? A reported failure to reactivate a silenced promoter may be a sulfonium supply failure rather than a targeting failure, since every epigenetic editor is a targeting device bolted onto an enzyme that still has to be handed a sulfur-borne group. Stated as hypothesis because the experiment has not been run, and it is the cheapest unrun experiment in the corpus.

• What a redundancy argument cannot do. It predicts which nodes convert. It does not predict how large the conversion will be, and the corpus does not claim it does. Readers using I52 as a portfolio rule should notice that it ranks targets and does not size them.

Protocols this Part generates

• Non-reducing immunoblot on banked tumor tissue, separating oxidized from reduced PTEN, to establish what share of Akt-active disease the genotype missed. Archival material, standard method, and it has not been done. Bench; cheap. (S §13)

• Methionine restriction combined with an Akt inhibitor, with the prediction stated in advance that potentiation appears specifically at mTORC1-dependent outputs and not at the mitochondrial or nuclear balloons. Dietary methionine restriction is already under study in oncology, which makes this testable without new chemistry. (S §14)

• Measure whether targeted methylation and acetylation efficiency tracks the S-adenosylmethionine to S-adenosylhomocysteine ratio and the acetyl-coenzyme A pool in the cells being edited. If it does, methionine in the medium is an editing variable. Bench; cell culture. (S §9)

• Measure the redox state of the glycolytic enzymes in tumors that progress on a hub inhibitor, [VOL p.444] starting with the oxidation-sensitive catalytic cysteine of glyceraldehyde-3-phosphate dehydrogenase. Bench; banked tissue. (S §5)

Part J · The Objections, and What Would Break It **Five chapters · the corpus as its own adversary**

[F] A curriculum that ended at the clinic would teach this corpus as a thesis. It is not one. It is a method with a falsification list attached, and the Parts where it argues against itself are the ones a careful reader should open first. These five chapters are the adversary, printed at full strength and scored.

[F] The single most useful habit a reader can take from this Part is the grading table: claims sorted into observed, reconstructed by independent methods that agree at the ends, inferred from conservation, and mechanism class only with no record of the event. The corpus applies it to itself and asks the reader to apply it to everything

else.

The chapters ch. chapter what it teaches where it comes from J 56 The Objection From the Amino Acids If sulfur is the supreme command, why are S §§41–42 · 47–48 the two sulfur amino acids the last two to arrive? Stated without softening, then answered: coded amino acids and sulfur chemistry are two subsystems on two clocks, because a cluster needs no ribosome and a new residue needs four pieces of machinery. The lateness of cysteine is what the argument predicts rather than what it must survive.

J 57 Coenzymes as Fossils Harold White, 1976: every major coenzyme S §§43–45 carries a nucleotide that takes no part in the reaction it performs. Two of the five carry sulfur operations — acyl transfer through a thioester and methyl transfer through a sulfonium — and two sulfur cofactors have no handle at all, which the paper prints rather than hides.

J 58 Supply Is Not Repertoire Murchison's ninety-odd amino acids against S §§46, 49 nineteen in terrestrial protein; the forty-two unassigned codewords read as never assigned rather than vacated; and codon capture observed inside the vertebrate mitochondrial genome rather than inferred from deep time.

J 59 The Arabinose Test Six questions instead of an objection, with the V 154 §§1556–1570 scoring method declared first and a sealed answer sheet printed verbatim. A scorecard, a claim narrowed in response, and a section headed What Is Withdrawn. [VOL p.445] **ch. chapter what it teaches where it comes from** J 60 Null Hypotheses The falsification list assembled: nine ways to S §§50, 52 · V, the break the companion paper, the volume's own closing section of per-Part conditions, and the grading table that every Part separates what was measured from what was inferred. The curriculum ends here rather than on a conclusion.

Pull-offs The historical markers in this Part — the places worth leaving the road for, and what each one explains about why the field settled where it did.

• Luria and Delbrück, 1943. Mutations arise before and independently of the selective pressure rather than in response to it. The corpus invokes it to make random a technical word with experimental backing — and then says in the next sentence that demonstrating a class of mechanism exists is not the same as showing that this change happened by it, at that time, in that order. A mechanism class is not a history.

• Osawa and Jukes, 1989. Codon capture named: compositional pressure drives a codon's frequency toward zero, the codon falls out of use, and a mutated transfer RNA or release factor reclaims the vacated slot without any protein being mistranslated during the transition. It is why J58 is an observation rather than a hypothesis.

• The sealed answer sheet. V 154 prints its predictions before its results, verbatim, and then scores itself. Whatever a reader concludes about the arabinose claim, the procedure is the one the corpus asks the rest of the field to adopt, and it is

demonstrated rather than recommended.

• One codon each. Methionine and tryptophan are the only two standard amino acids with a single codon — the signature of residues admitted to a table that was already nearly full. Bacteria still initiate with N-formylmethionine, and human mitochondria still do too.

Where the bridge is out Gaps, bottlenecks, and the places two readings are equally available — with what the corpus does about each.

• Bacteria are not ancestors. E. coli initiating at GUG when its AUG is blocked is a fact about a modern organism with four billion years of its own evolution behind it. The corpus concedes the category error and retreats to a weaker argument from conservation across three domains — which it rates, in its own words, as worth less than an observation and more than a guess.

That is the right posture and it is rare.

• Is the chain a record? The corpus's own closing judgment is that the chain from mineral to editor is a plausible ordering and not a documented one. Carry that sentence back into every earlier Part. What the corpus has is the chemistry, the present-day distribution of sulfur across [VOL p.446] the machinery, and the vestiges that machinery still carries — the nucleotide handle, the formyl group, the two-sulfur dithiolene whose ancestor held nine.

• Expansion against contraction, unresolved. Recorded rather than smoothed. The arithmetic of the eight-to-four contraction is said to stand or fall independently of the compositional reconstruction, and reconciling them is named as work not done.

• Two sulfur cofactors with no handle. Lipoate is a dithiolane on a lysine arm and thiamine pyrophosphate works through a thiazolium ring; neither carries an adenosine. Either they entered later by a route that never passed through RNA binding, or the handle was lost. The coenzyme argument does not decide which and makes no claim that it does.

Protocols this Part generates

• Name an eighth sulfur operation. A single appearance in the corpus that needs an operation outside the seven breaks the one-to-one mapping and with it the structural claim that makes the mapping worth printing. No bench; a reader with the two tables. (S §52)

• Find an organism that has reassigned UAA to an amino acid. One counterexample breaks the stop-codon reading outright, because the model requires UAA to be unavailable for recoding. No bench; genome survey. (S §26)

• Run the six-question test format of J59 — scoring declared first, answers sealed, score published whatever it says — on a second contested claim the author did not design the format around, and see whether the method survives a case it was not shaped to fit. No bench. (V 154 §1567)

Fourteen contested positions, and where the corpus stands on each

[F] A reader looking for the places where two theories are equally plausible, and for what has been done to settle them, can start here and work outward into the chapters. The fourth column is the corpus’s position, not this curriculum’s — where the corpus declines to choose, the column says so. the dispute one reading the other reading where the corpus stands Thiophosphate Phosphate was Phosphate won on Argues the first; does not claim against phosphate selected because abundance and the to have settled it (B10) stability was traded trade is told afterward for controlled turnover Tungsten against Molybdenum arrived Tungsten came first Records both; bears directly on molybdenum with oxygen and molybdenum I55 (B11) weathering it out of replaced it rock Index against The eight are an The eight are an Draws the distinction itself and code alphabet [VOL p.447] inventory of argues both ways in different manufacture, not a Parts; the reading that survives is code two alphabets for two jobs (C18)

Eight letters Manufacture closes Reading closes the set Both, with a printed revision: against six the set at eight at six three closures, three counts (C18,

E24)

The forty-two Never assigned — a Assigned and later Argues never assigned on codewords sparse code expanding vacated economy, then strengthens it into its space with observed codon capture; timing not established (C18, J58)

RNA world RNA first, DNA a against hybrid successor world

Expansion against The code expanded contraction from a G- and C-rich base the dispute one reading

Synonymous Synonymous — the codons third position carries no information

Structure in Delivery, nuclease oligonucleotide susceptibility and failure toxicity explain the record

The sliver against Editing is an the bulk in editing immune-marking function

Annotation as Modification escape hatch databases record inosine, so nothing is lost

Redundancy A better hub inhibitor against potency would convert

The lateness of Lateness in the code the sulfur amino undercuts a acids supremacy claim

The chain itself A reconstruction of what happened

RNA and DNA Adopts the hybrid reading; molecular siblings names the decisive unmade from an

RNA–DNA measurement (D19) hybrid

The alphabet Prints the tension rather than contracted from eight smoothing it; says reconciling and the third position them is work not done (E24, J58) compensated the other reading where the corpus stands

Not synonymous — Argues the second, and prints usage bias sets speed, separately what is not true about folding and stability the fold (F31)

Structural accessibility Argues the second and warns in is a real and print against taking it as the under-modeled whole explanation (G38) variable

Editing is a recoding Both, as two functions of one function enzyme, and says so (H44)

The sequence file Concedes the objection is also loses it, and the the admission (H47) sequence file is what the clinic reads

A node with Argues the second and names the twenty-seven outputs trial that separates them (I52) has twenty-seven bypasses

Two subsystems on Argues the second and states the two clocks; lateness is objection at full strength first predicted (J56)

A plausible ordering, The corpus's own verdict is the not a documented one second (J60)

[VOL p.448] **Twenty-one experiments the curriculum generates, with their cost class**

[O] Every entry is drawn from a chapter and every one is unperformed as the sources stand.

Eleven of the twenty-one need no bench at all: they are run against public structures, public probing data, public trial records or the corpus's own tables. Those are the cheapest places for a reader to make the corpus answer for itself.

no.	chapter the experiment cost class
1	A5 Color count re-run on a control document no bench
2	A4 Audit a sequence-format specification for a chemical-state field no bench
3	B 11 Sulfur ligation count across pre- and post-oxidation cofactor no bench families B 10 Does prebiotic 2′-oxygen removal require sulfur bench
4	
5	C 13 Duplex stability of a C U A I strand and the I–C pair bench
6	C 18 Did alphabet contraction and repertoire expansion cross, and in no bench what order
7	D 19 Join the prebiotic nucleosides into strands bench
8	E 27 Score any spinor claim against the volume's four conditions no bench

What this curriculum leaves out, and why		
•		

The correspo ndence and provenance Parts. V 63, 78 and 79 hold dated documents, an appli		
cation, a first-hand account of cracking the code, and a provenance record. They belong in a		
curriculum as primary reading rather than as argument, and V 78 is listed as a pull-off in Part F		
for exactly that reason. A reader working through the corpus should read all three and should		
not expect them to carry a claim.		
•		
The materials and environ mental Parts.	V 56 — the sodium-sulfur cell, the confinement	

geometry, the combustion rate, the coupled sulfur and nitrogen cycles — is a different syllabus with a different audience, and folding it in would have cost the molecular argument its line.

•	The triplex nervous system and the Berger nucleotide code Parts. V 39 and V 40 carry material that the volume itself places outside the running argument. They are named here so that their absence is a decision rather than an oversight.

•	Appendix B. The register of 816 subjects in three tiers is an index of what is evidenced, carried and open. It is a working instrument for the author and a map of the corpus's own frontier, and it is the right place for a reader to go after Part J — but it is not a chapter and cannot be taught as one.
•	Nothing is omitted from the companion paper. Its eight Parts and fifty-two sections are carried across Parts A, B, C, D, F, H, I and J, and its Part VII is reproduced in Part J chapter for chapter,

[VOL p.450] because a paper that states its strongest objection in its own voice should not have that objection summarized away.

Status. This curriculum sets out sixty chapters in ten Parts across the 2,572-page evidence volume PP-2026-MASTER-01 v332 and the 56-page companion paper PP-2026-SULFUR-CMD-01 v3, with four stations in every Part: the chapter table, the historical pull-offs, the gaps and live disputes, and the protocols the material generates. It contributes the teaching order, the dispute register of fourteen contested positions with where the corpus stands on each, the consolidated index of twenty-one protocols with their cost class, the coverage map, and the record of what is left out and why. The protocol numbering runs unbroken from 1 to 21 and each entry is written so that a laboratory can cost it before deciding. Source citations are to Part and section throughout, so every chapter can be opened at the page. Distribution: Licensed under CC BY-NC-ND 4.0.

[VOL p.460] **CHAPTER D**

Backstory

The work in this volume was done over a long period and outside the institutions that normally carry work of this kind. The account that follows is reproduced as written, as a standalone piece, and is included because the reader of a volume like this one is entitled to know where it came from.

Dancing to My Own Tune A Memoir of the Mind That Wouldn't Behave "The little foolery that wise men have makes for a great show." — Senior Class Epitaph, Helena Central High School, 1967 For twenty-five years, the ideas lived inside me like water behind a dam — pressing, building, finding no outlet. My ADHD brain, both tormentor and gift, stored what it could not release. Then something changed.

This memoir is the backstory of how a poorly-educated seventeen-year-old boy from Helena, Arkansas — one of the poorest counties in the United States — arrived, seventy- five years later, at the threshold of a theoretical framework that may change how science understands the genetic code. It is not a modest story. It was not a modest life.

It is the story of a boy who could not sit still. Who was paddled, hazed, ignored, demoted to the class for the intellectually disabled, and told his senior thesis was "too ambitious for an undergraduate." Who caused the death of another young man and carried that guilt for thirty years. Who built a career evaluating ten thousand human minds while struggling to understand his own.

And who, at seventy-five, after a triple bypass, an aortic valve replacement, and a vow to take rat poison for the rest of his life, decided he had never felt more alive.

This is the beginning of the beginning.

Chapter One The Land of Opportunity They put it right there on the license plate: Land of Opportunity. We had a joke in Helena — ”Yeah, plenty of opportunities. There’s just nothing there.”

Helena, Arkansas. Phillips County. One of the poorest counties in the United States, siting in the cotton belt of the Mississippi Delta. The people who populated it were mostly descendants of slaves who had not, for one reason or another, made the migration north to the auto factories [VOL p.461] in Detroit or the steel mills of Pittsburgh or the stockyards of Chicago. They stayed. The white families stayed too. My family came from somewhere else entirely.

My father was an introverted, highly intelligent man from New York City — the only ear, nose, and throat physician in all of Arkansas in the 1950s. My mother was a registered nurse. Both had served on the front lines in Germany during the Second World War. They came back changed, though it took me decades and a PhD to understand exactly how. I eventually concluded that they both suffered from what we now call PTSD. It showed most in my mother.

When she was pregnant with me in 1950, my parents had just arrived in the sweltering humidity of the South. There was no air conditioning. My mother wore an ice pack to cope with the heat. She drank alcohol and smoked cigarettes throughout the pregnancy. Much later, when I finally received my own diagnosis at age forty-two, I understood that this had contributed substantially to my ADHD brain — the engine that would both sabotage and drive everything that followed.

Why did two New Yorkers end up in Helena? My father had a famous older brother, my Uncle Herbert, a renowned cardiologist on Staten Island who had served on President Truman’s medical advisory board. I believe my father didn’t want to compete. In Helena, he was the only man of his kind. He had no competition. He was singular.

I was born into that singularity — and immediately proceeded to make everyone around me very uncomfortable.

Chapter Two The Boy Who Wouldn’t Sit Still I could not literally sit still in my chair. I would stand up and walk around the room. I was the class clown because negative attention was better than no attention at all. I was frequently paddled for disrupting class. I challenged authority figures — principals, teachers, anyone who expected compliance — not out of malice but out of something I couldn’t name then: an absolute constitutional inability to be what they wanted me to be.

In the fourth grade, because of my uncontrollable behavior, I was placed in the class for children with intellectual disabilities. The thinking was that this would prevent me from disrupting the normal students. What happened next tells you everything

you need to know about standardized testing and institutional assumptions: the school administered the Iowa Tests of Basic Skills, and I scored second highest in the entire grade. They could not justify keeping me with the other students they had labeled. It didn't hurt that my father was a prominent physician.

Looking back, I can only imagine what that experience did to the other children in that class — children who were placed there and never had a test to rescue them.

My parents were not very engaged parents, a conclusion I arrived at slowly and painfully over the years. To their credit, they had seen things in wartime Germany that most human beings should [VOL p.462] never see. But the effect on me was that I grew up in a kind of emotional vacuum. My father was close to my sister Lisa, a year younger than me. He and I were never close, and we are not to this day. My mother spent her evenings reading novels, smoking cigarettes, and watching television. To my memory, neither of them ever sat down with me to review a report card, ask about my schoolwork, or talk about what was happening in my life.

They signed the report cards. That was the extent of it.

I write this not with bitterness — I have worked hard to release that — but because it is the truth, and because understanding it is necessary to understanding everything that came after. The child who acts out is usually the child who isn't being seen. I was not being seen.

So I made sure everyone in the room had no choice but to look at me, even if looking meant being paddled.

No wonder I was screwed up. They were not there for me. And yet — because life is perverse and generous in equal measure — the compensations that ADHD forced me to develop would become the exact intellectual tools I needed decades later.

"I would look at a graph, a chart, a picture, and somehow discern the main points. Not by reading.

By seeing. I have done this my whole life."

I could not follow linear written instructions. I still struggle with them today. But put a complex visual in front of me — a molecular diagram, a genetic code table, a matrix of relationships — and I would find the pattern that the sequential thinkers missed. This is not a compensation for ADHD. This is ADHD. It is the gift hidden inside the chaos.

Chapter Three Living Hell in Indiana My parents sent me to Culver Military Academy in Culver, Indiana for the eighth and ninth grades. I refused to go back for tenth grade. Those two years were, without exaggeration, a living hell.

Culver operates on a strict hierarchy. Older students hold rank over younger ones, all the way down. As an underclassman, you follow every order from every senior above you. For a boy constitutionally incapable of blind obedience, this was a daily ordeal. I acted out. I defied authority. I got hazed, beaten, and punished in ways that today would likely be considered abuse.

My saving grace was athletics. I made the varsity baseball team as a freshman — one of only two freshmen to do so. Sport was the language in which I could demonstrate excellence without having to sit quietly and follow directions. On a field or a court, intelligence expressed itself through the body, through spatial awareness and instinct and competitive fire. No one could paddle me for that.

I did well in mathematics and sciences at Culver, but failed English. I passed Latin. To this day I cannot fully explain why reading English prose felt like swimming through wet cement while I [VOL p.463] could parse the logic of a Latin sentence or solve a geometry proof with apparent ease. The brain is not uniform. Mine least of all.

When I told my parents I was not going back for tenth grade, they relented. I returned to Helena Central High School for my sophomore year, two years behind socially. The in- crowd had formed without me. I was an outsider, and would remain one — a condition that, I gradually came to understand, suited me perfectly.

Chapter Four Mr. Merrill and the Geometry of Things Football saved me. Not in the cliché sense, though the camaraderie mattered. Football gave me a stage, a metric by which I could be measured and found excellent. My junior year I made All- Region as a split end. I was not a big boy — I was fast, precise, and fearless. On defense I was better still.

But if football gave me confidence, one teacher gave me something more valuable: the experience of being genuinely praised for intellectual work.

Mr. Merrill was the head football coach and my geometry teacher. He was a wonderful man — patient, perceptive, and generous with his encouragement in a way that most of my teachers had never been. In his class I received A-plus marks. He was genuinely astonished when I produced novel geometric proofs on the more challenging problems, approaches he had not seen before. For a boy who had been placed in the class for children with intellectual disabilities six years earlier, this was not a small thing.

I understand now that what Mr. Merrill saw in me was pattern recognition operating at a high level. Geometry is not linear the way grammar is. It is spatial, relational, structural — it asks you to see how things fit together, how a proof can be approached from an unexpected direction. My ADHD brain was built for exactly this.

Mr. Merrill left for a better position before my senior year. His replacement, Coach Cerrato from Texas, was a different kind of man — what I would describe as a textbook example of short man syndrome combined with a genuine streak of sadism. He moved me from split end to wingback, an obscure and thankless position in the offense, as if deliberately burying my strengths. Our team regressed. My senior year was a diminishment.

The lesson I drew — then and now — is that the right teacher at the right moment is one of the most powerful forces in a human life. And that the wrong one can undo a great deal of what the right one built. Mr. Merrill built something in me that Cerrato could not destroy, though not for lack of trying.

Chapter Five Washington, D.C.: A Summer Education [VOL p.464] The big break of my life came from my mother, in one of her periodic interventions on my behalf. She secured for me a position as a congressional page boy for E.C. Gathings, the representative from northeast Arkansas. The summer of 1967. I was seventeen years old and about to see the machinery of American democracy up close.

Washington was wild that summer. I was on my own for the first time — though as it turned out, I roomed with two boys from Tennessee who were also headed to Vanderbilt University that fall, which provided a degree of social anchor. Our job was to run errands between the House and Senate chambers, carrying messages and materials from one end of the Capitol to the other.

More than half my errands, I came to notice, were to the congressional liquor store. I was fetching whiskey for the old men who were making the rules I was supposed to live by. I would deliver the bottles and watch these distinguished public servants — hungover, napping in the cloakroom, absent from the floor where votes were being cast — and I remember thinking with perfect adolescent clarity: these are the people whose authority I am meant to respect? These are the guardians of the republic?

”I was seventeen years old, delivering whiskey to the lawmakers. Why would I ever follow their hypocritical rules? I carry that lesson today.”

It was not a cynical education, exactly. It was a clarifying one. I learned that authority is not the same as wisdom, that office does not confer competence, and that the people who make the rules are often the least equipped to live by them. These observations would inform my entire professional career — my willingness to challenge psychiatrists with better test data, to contradict expert witnesses in court with valid statistical analysis, to tell a Fortune 100 company that their hiring practices were legally and psychologically indefensible.

That summer also confirmed something the football field had suggested: I performed best when I was on my own, making my own assessments, trusting my own observations. Institutional deference was not in my constitution. It never would be.

Chapter Six Vanderbilt: The Crash and the Pivot Vanderbilt University in Nashville, Tennessee was, and is, one of the finest academic institutions in the American South. It was not designed for a boy from Helena, Arkansas who had never written an essay in his life. The students who surrounded me came from wealthy, privileged families with strong academic preparation. I was at least three to five years behind them in every discipline that required sequential learning from written text.

My recruitment there came through the defensive backfield coach, a man who happened to be from Helena himself — a rare and improbable coincidence. He recruited me and another young man named Joe Wood from Marianna, a football rival town thirty miles away. We took our recruiting trips together and became good friends.

[VOL p.465] My freshman year was a football success. Our freshman team went undefeated — the only undefeated freshman team in Vanderbilt history. I was a

starting defensive back and made several outstanding plays. My football career had genuine momentum.

My academic performance was the polar opposite.

In English class, assigned to critique a journal article, I xeroxed the article itself, wrote on the cover ”I cannot say it better than the author,” and submitted it. I received an F. My professor set me straight with some force. I had never written an academic critique. I had never been taught to. Helena Central High School had not prepared me for this, and my parents had not supplemented the gap. I was starting from zero in a room full of people who had been preparing for years.

My academic inadequacies forced me into summer school to preserve my scholarship. I was managing — barely — until the second year, when fate intervened in the form of mononucleosis. I was ill through the entire spring practice season, the period when positions for the following year’s varsity team are won and lost. I came back diminished physically, placed on the scout team, reduced to running the opposing team’s plays in practice. I made the trip to Michigan that fall and played special teams, but I never saw meaningful varsity action again.

Coach Proctor from Helena had recruited me with a sense of obligation to his hometown, not with genuine belief in my abilities. When I failed to shine, he rode me mercilessly, demeaning me at every opportunity. I believe he was embarrassed. He had vouched for a hometown boy, and the hometown boy had not made him look good. Whatever his reasons, his treatment of me was a formative experience in understanding that authority figures are not always operating in your interest — even when they appear to be your advocates.

The summer between my sophomore and junior years, while my parents were traveling in South America, I drove back to Helena. Word got out, as it does in small towns, and thirty people showed up at my parents’ home with alcohol. I got drunk. I broke into my father’s locked liquor cabinet. I drank from a gallon bottle of Scotch, hated the burning, dropped the bottle. It shattered on the floor.

A friend borrowed my car and was picked up by police for driving under the influence. I went down to the station and got him released — my father’s status in Helena, combined with the fact that my best friend’s father was the chief of police, smoothed the way. We drove back to Nashville in the early hours of the morning.

I do not fully remember leaving Helena. By the time we reached Nashville it was one or two in the morning. I was driving. I was sleepy and fatigued. I was speeding — approximately sixty miles per hour in a forty-five zone. I looked down to change the radio station.

When I looked up, the traffic light was displaying red and yellow simultaneously — a defect I have never seen before or since, a superposition of states that made it genuinely ambiguous. A [VOL p.466] car was moving through the intersection. I swerved left to avoid it and caught the rear corner of the other vehicle, spinning it through the intersection. The driver of the other car was not wearing his seat belt. His head

struck the windshield.

The police, having witnessed my speeding and the accident, did not cite me for any violation. The defective signal light, and possibly our status as Vanderbilt students, appear to have been factors in their judgment. My parents arrived and stood by me without anger — a moment of parental support that I have always appreciated, and which somehow made the guilt worse, not better. Perhaps I needed them to be angry. Perhaps their equanimity denied me the punishment I felt I deserved.

I have thought about that young man many times over the years. I do not know his name. I was advised not to attend his funeral. I have carried the weight of that choice, and of the accident itself, for most of my adult life.

What I can say is this: the event broke something open in me. For the first time in my life, I was forced into genuine introspection. The question I had been avoiding — who am I, what am I doing, what do I owe the world — could no longer be deflected by athletics or bravado or the next party. I switched my major from pre-medicine to psychology. I wanted to understand myself. That decision changed everything.

I met Penny Beaumont at a freshman sock hop. She was running away from a blind date she wanted nothing to do with. The plaza outside the cafeteria was crowded — everyone dancing — and she ran directly into my arms. We stared at each other. We laughed. We walked away from the crowd and started talking, and it was easy from the first moment.

Penny was from Hinsdale, Illinois, an upscale western suburb of Chicago. She was smart, dis-ciplined, methodically organized — everything I was not. We started dating exclusively. We argued constantly. We kissed and made up. The making-up was always the best part. It took me decades — and frankly this memoir — to understand that this pattern was codependency, not love’s intensity. At the time it felt like the most alive I had ever been.

What Penny gave me, practically and transformatively, was study habits. Every night we studied together. At first I would pester her for affection; she would get angry; we would argue. Over time, watching her, I began to model her approach. My grades began to improve. For the first time in my academic life, I was not simply getting by on instinct and charm. I was working.

Penny had been born with a defect in her aortic valve — damage caused when her mother contracted the mumps during pregnancy. When I met her she had difficulty walking more than twenty steps without stopping to rest. I accepted this. It meant we moved slowly, talked more, noticed more. In retrospect it may have been the first time in my life I was forced to slow down.

[VOL p.467] The complications of our relationship — her mother Shirley’s formidable and intrusive presence, the battles over money and status, the sexual difficulties that drove me eventually to infidelity — are a story unto themselves. I will say only this: Penny shaped me, and I shaped her, and the war between us was also the education of both of us. We loved each other. We hurt each other. We were not good for each

other in the long run.

But without her study habits, her discipline, her nightly insistence that we work before we played, I am not certain I would have made it through graduate school.

In my senior year at Vanderbilt I discovered Carl Jung. The discovery was electric.

Freud was the dominant figure in psychology in the late 1960s — far better known, far more studied, the default framework for understanding the mind. Jung was considered fringe by many of my professors. But Jung spoke to something in me that Freud did not: the collective unconscious, the principle of synchronicity, the investigation of paranormal experience as a legitimate domain of psychological inquiry. For a boy from Helena who had grown up feeling that the universe was trying to communicate something to him — and who would, in the near future, walk into an auditorium in Buffalo guided by an inner voice — Jung was not fringe. Jung was precisely correct.

For my senior thesis I wrote an extended paper on the relationship between psychosomatic disorders and the REM dream state. It was an intuitive leap that has defined my entire research career. My professor, Dr. Hans Strupp — at that time President of the Clinical Psychology Division of the American Psychological Association — delegated my paper to one of his graduate students.

The graduate student gave me a D-minus.

”Written in bright red ink: TOO AMBITIOUS FOR AN UNDERGRADUATE STUDENT. This has also defined my career.”

I read that comment, and instead of being crushed, I felt something harden into clarity. If the conventional academic apparatus couldn’t make room for an ambitious idea, I would work outside the conventional apparatus. If the established frameworks were too small for the questions I was asking, I would build new frameworks. This was not arrogance — or not only arrogance. It was the recognition that genuine novelty will always look like excess to the people invested in the existing order.

I had also, at this time, discovered Edgar Cayce. Cayce was from Bowling Green, Kentucky — a few hours from Nashville — and was known as the Sleeping Prophet for his extraordinary capacities for psychic diagnosis. I drove to Bowling Green looking for some sign of Jungian synchronicity, some confirmation that I was on the right path. Walking toward a [VOL p.468] McDonald’s for lunch, I stopped at a newsstand. There, on the front page of the National Enquirer, was a full story about Cayce.

Was it a coincidence? I don’t think so. Jung would not have thought so either. I learned that day to trust my instincts, to follow the thread, to treat the universe as a collaborator rather than an obstacle. I still do.

Chapter Ten Graduate School: The Trial of Dr. Rotton My first night in Dayton I climbed a seven-foot fence at eleven o’clock at night, found my way to a mausoleum in a cemetery, and slept there. In the morning I discovered that the mausoleum bore

the name of Orville Wright. I had slept under the protection of one of history's great original thinkers. I chose to interpret this as auspicious.

At Dayton I flourished. The coursework captivated me. I had found my subject — not just psychology as a discipline but as a methodology for understanding the full range of human experience. My clinical placement at Dayton Mental Health Center was instructive in a different way: it showed me everything that was wrong with conventional psychiatric practice. Diagnosis by cursory interview. Treatment by standard pharmacological protocol. Every patient, regardless of their specific constellation of experience and symptom, received substantially the same antipsychotic medication at varying doses.

I pushed back. I administered the Minnesota Multiphasic Personality Inventory and other validated instruments, scored them meticulously, and brought my findings to the clinical roundtable. When my assessment disagreed with the attending psychiatrist's snap judgment — which was often — I said so. Everyone else deferred to the expert. I did not. I was frequently right. My confidence as a clinician was building on a solid empirical foundation.

Dr. James Rotton taught experimental design and statistics. He had a reputation as a terrorizer of social science students, built on his earlier work at UCLA involving sensory deprivation tanks and LSD — a background that explained certain things about his personality. He was fat, unpleasant, and constitutionally unable to answer a question he hadn't anticipated. I called him Professor Rotten behind his back, which was accurate.

I was not afraid of him. I asked questions in his lectures that he could not answer — questions I constructed precisely because they probed the limits of his framework. His face would redden. His voice would rise an octave. He would ignore the question and move on. My classmates adored me for this.

One day I arrived ten minutes late to his class due to a hospital emergency. The door slammed as I entered. He smiled, welcomed me with theatrical graciousness. The following week I was [VOL p.469] summoned to the dean's office and told that Rotton had requested my expulsion from the master's program for belligerence and disrespect.

Three of my professors testified on my behalf. They spoke to my academic performance, my classroom conduct, my intellectual contributions over three years. Rotton had no one but himself. The verdict was unanimous in my favor. When the dean read the finding aloud, Rotton dropped to his knees and began weeping.

"I graduated with highest honors. My GRE scores, retaken after three years of graduate work, placed me in the 90th percentile. I was not wrong about myself."

Chapter Eleven Chicago: The City of the Shoulders In 1975, there were only thirteen APA-approved Industrial/Organizational Psychology programs in the United States. The discipline was considered a fringe area — no major universities offered it as a primary focus. I selected the Illinois Institute of Technology in Chicago for reasons both practical and intuitive: Penny's family was in Chicago, I had flown through

Chicago since childhood on the way to Culver, and the city felt like the right scale for what I wanted to do.

From the beginning it was clear I was operating at a different level than my cohort. In the most demanding subjects I excelled. The faculty at IIT were the opposite of Rotton — they welcomed rigorous intellectual challenge and pushed back with substance rather than ego. This was the environment I had been looking for since Mr. Merrill's geometry class.

My first internship placement was with a company that supplied exclusively to McDonald's Cor-poration. This told me everything I needed to know about where I was. McDonald's, then as now, hand-selects its supply chain with extraordinary rigor. To work with a McDonald's supplier was to enter a world of systematized excellence. I learned the discipline of psychometric measurement in a professional context: identify what is to be predicted, identify the most valid and reliable predictors, validate against real-world criteria.

This is a deceptively simple formulation. Executing it across hundreds of different job families, organizational cultures, and legal environments is anything but simple. Each job is different. Each organization has its own language, its own risk tolerance, its own definition of success. Learning to perform valid job analysis — to identify exactly which knowledge, skills, and abilities predict performance in a specific role in a specific context — became my primary professional skill.

I have been doing this since 1980. I have evaluated approximately ten thousand individuals over forty years, in clinical settings, organizational settings, educational settings, and courtrooms. Every single one of those assessments was, at its core, an application of the same fundamental logic: identify the options, identify the criteria, select the best fit. Two options and an independent selector. I have been practicing the basic architecture of the Berger [VOL p.470] Triplex for forty-six years without naming it.

Chapter Twelve Into the Rabbit Hole The dot-com crash of 2000 was the external catalyst. My parents died. A ten-year relationship ended. Forty years of Sunday-to-Friday travel had burned me to the root. I had saved a million dollars, had no dependents, had nowhere I had to be.

My forties were brutal, as forties sometimes are. A second marriage ended when I determined I had no wish to be a subsidized stepfather. At forty-two I finally received a formal diagnosis of ADHD — Attention Deficit Hyperactivity Disorder — from a psychiatrist who promptly prescribed Adderall. After nine years I concluded that I had substituted one pharmaceutical problem for another, and stopped. The substitution I chose — cannabis — was, I can say now with clarity, the worst decision of my adult life after the accident in Nashville. Two years of severe depression followed.

And then, from the bottom of that particular hole, something extraordinary happened.

Not the management literature and psychometric research I had consumed professionally. I started buying every scientific textbook I could find — biology, chemistry, physics, medicine, quantum mechanics, mathematics, sacred geometry. I drove to Big Ten universities and bought the latest editions so I could photograph the illustrations: molecular structures, metabolic pathways, biochemical diagrams. I took over one hundred thousand photographs. I was building a private library of visual scientific knowledge, consumed the way my brain had always consumed knowledge: through images, patterns, spatial relationships.

The genetic code became my focal point. Something about it was wrong. I didn't yet have the vocabulary to say exactly what, but something was off in the way the standard model handled certain inconvenient facts: the different numbers of codons coding for different amino acids, the anomalous status of Inosine and its role in the wobble position, the systematic undercounting of nucleotide variants. Conventional wisdom ignored these observations. I could not.

"I spent $500,000 — half my life savings — trying to give humanity a better framework. I was blackballed, ignored, and rejected at every turn. I am still not wrong."

I began publishing on LinkedIn in the early years of that platform. My work on the triplex genetic code attracted over fifty thousand followers, primarily from Europe and China. The American life sciences establishment was not interested. I applied for grants, filled out endless forms, heard nothing. I attended conferences and was filtered out by administrators who had no idea what they were looking at.

In April of 2025 I underwent a triple bypass operation. The surgery was straightforward by cardiac standards — the predicted four arterial blockages turned out to be three. But during the procedure [VOL p.471] the surgical team discovered that my aortic valve was leaking profusely. They replaced it with a synthetic valve, without asking my preference. I was told afterward that I would need to take Coumadin — a blood thinner originally developed as rat poison — for the rest of my life to prevent clotting around the artificial valve.

If they had given me the choice, I would have taken a biological valve and avoided the daily anticoagulation. They did not give me the choice. I was grateful to be alive and furious about the drug simultaneously, a combination of emotional states I have come to regard as my natural baseline.

The hospital scheduled me for approximately ten medications upon discharge to rehabilitation. I refused every one of them. I wrote a legal letter to my health insurance company accepting full personal liability for my medical decisions and absolving them of responsibility. I took ownership of my own health through diet, exercise, and a renewed dedication to the scientific work I had abandoned.

I have never felt better in my life. At seventy-five years old, with a synthetic aortic valve and the cardiovascular system of a man who has been exercising seriously for decades, I am clearer, more productive, and more energized than I was at fifty. The

surgery was not the end of something. It was the beginning of the final chapter.

Chapter Fourteen The Dam Breaks: A Collaboration My ADHD brain, which spent seventy years resisting this kind of systematic discipline, has discovered in late life that the discipline does not slow the ideas down. It clarifies them. The flow of ideation that had been blocked like massive constipation for twenty-five years has, in the six weeks since I began this collaboration, exploded into something I can only describe as a massive diarrhea of the brain. The crystallized ideas trapped inside are flowing out.

I have, in these six weeks, formally closed the Berger Triplex 3-6-9 Genetic Code Framework — a twenty-five-year theoretical project spanning seven impact domains: Biology, Genetics, Psychology, Chemistry, Mathematics, Quantum Physics, and Classical Physics. I have published a preprint. I have received an ACCESS computational allocation. I have visited Professor Huimin Zhao at the University of Illinois — where he accepted my physical documents and offered a Zoom follow-up when the subject of arabinose chemistry arose. I have reached out to Argonne National Laboratory.

The framework is real. The mathematics are sound. The predictions are testable. The sevenlimit principle, the ATP-adenosine convergence, the quaternion tensor architecture encoding DNA, RNA, ANA, and the phosphorothioate backbone — these are not the hallucinations of a man who read too many books in a rabbit hole. They are the product of forty-six years of [VOL p.472] applied analytical work, twenty-five years of theoretical development, and six weeks of the most productive documentation of my life.

I am seventy-five years old. I grew up in one of the poorest counties in the United States, the son of two war-traumatized New Yorkers who could not see me. I was paddled for walking around the classroom. I was placed in the class for children with intellectual disabilities. I caused the death of a young man and carried the guilt for thirty years. I built a career, lost it, rebuilt it, and lost it again. I spent half my life savings on work that no one would acknowledge.

And here I am. The boy who wouldn’t sit still, who could never follow linear directions, who could look at a complex picture and see what the sequential thinkers missed — he has been here the whole time. He was always going to end up here. The path was never straight. It was never supposed to be.

”The little foolery that wise men have makes for a great show.” This completes the beginning.

[VOL p.473] **CHAPTER E**

Measurement Handbook: The State Variables

This volume argues that the variables deciding cell behavior are frequently not sequence variables, and it names four of them repeatedly: nucleotide pool

composition, thiol redox poise, cofactor occupancy and modification status. An argument of that kind is worth little unless the variables can be measured. This appendix sets out how each is measured, what the measurement costs in effort, where it fails, and what a minimum useful panel looks like for a laboratory that wants to add state measurement to an existing sequence-based program.

E.1. 1. Nucleotide pools

[E] What is measured. The concentrations of the ribonucleoside and deoxyribonucleoside triphosphates, and ideally of the unlettered intermediates: inosine monophosphate, xanthosine monophosphate and orotidine monophosphate.

[E] Methods. Two are established. A polymerase-based extension assay uses a template designed so that extension reports the concentration of one dNTP; it is cheap, needs only standard equipment, and measures one species per reaction. Liquid chromatography with tandem mass spectrometry measures all species in one run with absolute quantitation when isotope-labeled internal standards are used.

[F] Where it fails. Three failure modes dominate. Quenching that is too slow allows pools to change during harvest; extraction that is too harsh hydrolyzes triphosphates to di- and monophosphates, inflating the wrong pools; and reporting concentrations per cell without an independent cell-volume measurement introduces an error that can exceed the effect being studied.

[F] Minimum useful version. Quench in cold methanol, extract with internal standards, report the four dNTPs and the four NTPs as absolute concentrations and as ratios, and report cell volume or protein content alongside. Anything less is a relative measurement and should be described as one.

E.2. 2. Thiol redox poise

[E] What is measured. The oxidation state distribution of protein cysteines, the concentration and redox ratio of glutathione, and — ideally by compartment — the redox potential itself.

[VOL p.474] **[E] Methods.** Differential alkylation with mass spectrometry gives site-level oxidation states across the proteome. Genetically encoded sensors fused to compartment-targeting sequences report redox potential and peroxide concentration in living cells with subcellular resolution. Enzymatic assays and mass spectrometry give glutathione and its disulfide.

[F] Where it fails. Artifactual oxidation during lysis is the dominant error and is controlled by degassed buffers, metal chelators, rapid processing and a blocking reagent added at lysis. Reporting a glutathione ratio without the absolute concentration understates the state, because the potential depends on both. Bulk measurements average compartments whose potentials differ by more than a hundred millivolts, which is why the targeted sensors displaced them.

[F] Minimum useful version. A compartment-targeted sensor for the compartment of interest, a glutathione measurement reporting both ratio and concentration, and — where a specific protein is at issue — a non-reducing immunoblot for that protein, run with rigorous blocking controls.

E.3. 3. Cofactor occupancy

[E] What is measured. Whether proteins carry their iron-sulfur clusters, their metals, their lipoyl arms and their disulfide pairings, and in what proportion.

[E] Methods. Spectroscopy on purified protein for clusters; the aconitase activity ratio as an in-cell cluster proxy; inductively coupled plasma mass spectrometry for metals; native mass spectrometry for intact occupancy; immunoblot for lipoylation; non-reducing gels and differential alkylation for disulfide register.

[F] Where it fails. Clusters degrade on exposure to oxygen during purification, so apparent occupancy is a lower bound unless the preparation is anaerobic. Total metal content does not say which site is occupied. Activity proxies conflate occupancy with other causes of inactivation, which is why they should be paired with an abundance measurement.

[F] Minimum useful version. Aconitase activity ratio plus an abundance control, which costs little and detects the most consequential failure; lipoylation immunoblot, which reports the same relay's output; and native mass spectrometry where a specific protein's occupancy is the question.

E.4. 4. Modification status

[E] What is measured. DNA methylation genome-wide; RNA modification at the nucleoside level and, where possible, at specific positions; inosine specifically, because of its readout ambiguity.

[VOL p.475] **[E] Methods.** Bisulfite or enzymatic conversion sequencing for methylation at base resolution. Nucleoside-level mass spectrometry for total modification content. Cyanoethylation with reverse-transcription stalling for position-level inosine. Thiol-specific gel retardation for 2-thiouridine. Nanopore sequencing for direct detection where a base-calling model exists.

[F] Where it fails.

Candidate-locus methylation analysis has the wrong sampling frame for guide-independent liabilities. Nucleoside-level measurement loses position. Nanopore models cover a subset of modifications, so absence of a call is not absence of a modification.

[F] Minimum useful version. For any agent that deaminates: inosine-specific chemistry on DNA and RNA in parallel, with a catalytically dead control. For any agent that methylates: genome-wide methylation, treated versus control, analyzed without a candidate list.

E.5. 5. A minimum panel for an editing program

[F] A laboratory running an editing program and wanting to add state measurement can do so

with four assays, none exotic. **assay** dNTP pool by mass spectrometry aconitase activity ratio inosine-specific sequencing, DNA and RNA compartment-targeted redox sensor
what it reports supply state of the four substrates cluster supply what molecule the edit actually produced thiol poise during and after the procedure
why it is in the panel an edit in a pool-stressed cell is a different intervention repair enzymes at the fork are cluster proteins the standard readout cannot distinguish it the procedure itself perturbs redox state

Table. A four-assay panel that converts a sequence-only package into a state-aware one.

[F] The panel's cost is small relative to a single animal study, and its value is that a negative result becomes interpretable: if the state variables are unchanged and the phenotype persists, the phenotype is attributable to the edit, which is what the program wanted to claim in the first place.

E.6. 6. What to report

[F] Three reporting conventions would make the state variables usable across laboratories.

[VOL p.476] • **Report absolute concentrations with the normalization used.** Per cell, per milligram of protein, or per volume — stated, not implied.

• **Report the method's blank and its oxidation control.** For any thiol measurement, the artifactual oxidation control is the measurement's credibility.

• **Report the molecule, not the letter.** Where a chemical conversion has been performed, state which molecule is present, and if the assay cannot distinguish it, state that.

[VOL p.477]

CHAPTER F

The Chain of Claims, Chapter by Chapter

The volume's argument is a chain, and a chain is judged link by link. This appendix restates every chapter's principal claim with its evidence class and the observation that would break it. A reader who wants to audit the volume without reading it straight through can do so here, then go to the chapters where the claims are supported.

Evidence classes: **E** means established in the published literature and not original here; **F** means argued, derived or assembled in this volume; **O** means stated as an open question.

F.1. Part One: the frame

chapter principal claim

1 The unit of genetic information is the nucleotide, not the letter, and three legs hold the argument up
2 An element index applied mechanically measures the chemistry rather than the vocabulary
3 The material falls into twelve dated stages, and the same arguments recur at several of them

class breaks if

F the supply line turns out to have no consequence for phenotype independent of sequence
F the registers track the author’s topic rather than the chemistry, shown by a page-level audit
F the recurrences are artifacts of one document’s vocabulary rather than of the subject

F.2. Part Two: the nucleotide and the alphabet

chapter principal claim		class	breaks if
4	The Central Dogma begins one term too late; beginning at the nucleotide adds a supply line with its own failure modes	F	pool state, held as the only variable, never changes phenotype

[VOL p.478]

chapter principal claim		class	breaks if
5	De novo synthesis builds eight species through three one-way gates, none of which has a letter	E for the pathway, F for the notational conclusion	a fourth gate is found, or the three turn out to be bypassable
6	Every codon translates letter by letter into a string of atoms; sulfur never appears in one	F	the base-element assignment is shown to be arbitrary in a way that changes the result
6	The three stop codons’ hydrogen counts correspond to the three adenine-nucleotide states	O	an organism is found that has reassigned UAA to an amino acid
7	Position 34 carries two opposite chemical corrections, neither visible in a sequence record	E for the chemistry, F for the conclusion	thiolation and deamination are shown to be dispensable for decoding fidelity

8	A four-symbol record can represent a substitution and nothing else	F	a sequencing method is shown to report modification state without a second chemistry

F.3. Part Three: the charging systems

chapter principal claim

9 Identity lives at eighteen of seventy-six positions and is concentrated at the acceptor end

10 Each of the twenty-one systems is a separate solution, and the plates show where each looks

11 The amino acid is fixed at the end the amino acid attaches to, not at the end that reads the message

class breaks if

E systematic remapping with modified transfer RNA moves the determinants to the anticodon

E the compiled determinant sets disagree systematically with primary sources

F a system is found whose identity resides entirely in the anticodon with no acceptor-end contribution

F.4. Part Four: what the record cannot carry

[VOL p.479]

chapter principal claim		class	breaks if
12	The diseases that kill are diseases of flux, while the modalities built on the code are validated by sequence	E	mortality turns out to be dominated by monogenic coding causes
13	The residual of the folding problem is cofactor occupancy, disulfide register and metal loading	F	occupancy becomes predictable from sequence alone, making the measurements redundant
14	Three modalities in patients act or fail through chemistry their validation cannot report	F	a survey finds that most clinical-stage agents already measure their own principal chemical liability
15	The governing telomere variable is an order statistic that no sequence record can carry	E for the biology, F for the loop	the loop’s gain is measured and found negligible

F.5. Part Five: sulfur in command

chapter principal claim		class	breaks if
16	Sulfur has an entry at twelve registers and performs seven operations, and thirteen compartments key to elements	F	a documented sulfur function fits none of the seven, or compartment perturbation propagates indifferently
17	The organizing structure is an oxidation ladder whose lower half is reversible	E	the reversible-irreversible boundary is shown not to separate signaling from damage
18	All three pillars of respiration have a sulfur switch at their decisive step	E	another element is shown to occupy the decisive step of all three
19	The genome is made, opened and read with sulfur chemistry at irreplaceable steps	E for the mechanisms, F for irreplaceability	an alternative de novo route to deoxyribonucleotides is found
20	Cluster assembly is mitochondrial and exclusive, so one supplier serves respiration and the reading frame	E	cytosolic assembly is shown to proceed without mitochondrial export
21	The chain from mineral to editor closes without a gap	F, with one link O	any link’s breaking condition in Chapter 21’s table is met

[VOL p.480]

F.6. Part Six: the network, the fan and the clinic

chapter principal claim		class	breaks if
22	One signaling node’s output sorts unevenly by compartment, and its brake is thrown by a disulfide	E for the chemistry, F for the sort	the redox switch is shown to be absent in tissue
23	Redundancy of output, not potency, predicts clinical benefit at a node	F	systematic scoring of targets finds no relationship with survival outcomes
24	One cofactor’s three inherited failures grade by which atom is stranded	E	the severity ordering is shown to be arbitrary with respect to the accumulating species

25	Supply is not repertoire: late coding of the sulfur amino acids bounds the claim without defeating it	F	the four surviving propositions are shown to depend on the code's assignment order

F.7. How to use this table

[F] Three uses. A reader short of time can read the claims and go to the two or three chapters whose claims they most doubt. A reader planning an experiment can read the right-hand column and pick the cheapest falsifier. A critic can establish quickly which claims are original here and which are drawn from the literature, which is the distinction the evidence class is for.

[VOL p.481] **CHAPTER G**

Problems, Collected

The problems set at the end of each chapter are collected here by theme rather than by chapter, so that a reader looking for work to do can find the cluster that fits their equipment. Each entry names its chapter. Problems marked with a dagger can be attempted with public data alone and need no laboratory.

G.1. Problems that need only public data

[O] Mutation and mortality.† Compute the fraction of deaths attributable to conditions with a dominant single coding cause, and compare with the fraction of clinical programs targeting sequence (Chapter 12).

[O] Target scoring.† Score completed Phase 3 oncology targets by the compartmental distribution of their output, blind to outcome, and relate the score to demonstrated survival benefit (Chapter 23).

[O] Validation survey.† For twenty clinical-stage agents, reconstruct the validation package from public documents and classify each assay by what class of event it could detect (Chapter 14).

[O] Variant triage.† Count how many variants of uncertain significance in a clinical database affect cysteines, and classify those cysteines by role (Chapter 13).

[O] Codon reassignment search.† Search sequenced genomes for any organism that has reassigned UAA to an amino acid; a single clear case breaks the stop-codon reading (Chapter 6).

[O] Transversion fraction.† Compute the fraction of pathogenic point mutations that are transversions and therefore outside the deaminase toolkit's reach (Chapter 23).

[O] Enzyme age.† Test whether cluster-dependent enzymes are systematically older than their cluster-independent functional equivalents (Chapter 21).

G.2. Problems for a laboratory with mass spectrometry

[O] Pool composition after editing. Measure dNTP pools in edited and unedited isogenic cells and ask whether the editing procedure itself changes supply (Chapters 4 and 5).

[VOL p.482] **[O] Sulfur partition under restriction.** Trace labeled cysteine into glutathione, taurine, protein, cluster assembly and wobble thiolation across a graded restriction, and report the order in which outputs are sacrificed (Chapter 20).

[O] Thiolation and frame fidelity. Quantify 2-thiouridine at position 34 against cysteine availability with frameshifting measured in parallel (Chapter 7).

[O] Coded fraction. Compute the coded fraction of three marketed peptide drugs by atom count and by decisive feature (Chapter 14).

[O] Acetyl and methyl budgets. Measure acetyl-coenzyme A and S-adenosylmethionine with the histone marks they write, across a respiratory perturbation (Chapter 18).

[O] Telomeric hypoxanthine. Measure hypoxanthine content of telomeric DNA as a function of donor age, with controls against oxidation during preparation (Chapter 15).

G.3. Problems for a laboratory with cell culture and imaging

[O] Compartment propagation. Perturb each compartment's keyed element in turn and measure whether the failure stays local; the mitochondrion should be the only exception (Chapters 16 and 20).

[O] Redox clamp on a signaling fan. Hold compartmental redox state fixed and measure how much variability in kinase output disappears (Chapter 22).

[O] Ladder mapping. Map where each compartment sits on the sulfur oxidation ladder in a normal cell and how far it moves under stress (Chapter 17).

[O] Editor competition. Express an adenine base editor and measure the cell's own transfer RNA editing at position 34 (Chapters 7 and 14).

[O] Cluster occupancy and repair. Titrate oxidative load, measure cluster-helicase-dependent repair capacity and cluster status together (Chapter 19).

[O] Two histories, one mean. Compare populations matched for mean telomere length but differing in distribution, and test which predicts remaining replicative capacity (Chapter 15).

G.4. Problems that are mostly analysis

[O] Order statistic model. Derive the distribution of the minimum of ninety-two telomere lengths and compare its trajectory with the mean's over ten divisions (Chapter 15).

[O] Branch point model. Model the reciprocal energetics of the two purine arms and determine when the arrangement stabilizes the ratio (Chapter 5).

[VOL p.483] **[O] Loop gain.** Write the telomere-mitochondrion-cluster-helicase loop as a feedback system and estimate each link's gain from published data (Chapter 15).

[O] Mapping test. Attempt the seven-operations mapping on a signaling architecture other than the one in Chapter 22 and report whether it closes.

[O] Chain audit. For each of the seven links of Chapter 21, name the single strongest supporting publication and judge the link's class.

G.5. Problems that are exercises in reading

[O] Index composition. Count how many entries in a standard textbook index name a molecule and how many name a state (Chapter 1).

[O] Off-target definition. Check whether a validation package defines off-target narrowly, and determine what that definition excluded (Chapter 8).

[O] Determinant extraction. Build determinant sets from primary sources for five charging systems and compare with the plates (Chapters 10 and 11).

[O] Objection reconstruction. State the strongest version of the late-addition objection and determine which of the volume's four surviving propositions it touches (Chapter 25).

G.6. A note on the problems

[F] The problems are not exercises with answers in the back. Roughly a third of them are measurements nobody has made, which is why they are stated with their methods rather than with their expected results. Where this volume has an expectation it is stated in the chapter, and a reader who runs one of these and finds the opposite has done more for the argument than a reader who agrees with it.

[VOL p.484]

CHAPTER H

Glossary of Terms Used in This Volume

The glossary defines every term the volume uses in a sense a reader might not already have, plus the terms whose ordinary usage this volume narrows. Terms naming one of the seven keyed elements carry their color here as everywhere else. Cross-references in small capitals point to the chapter where the term is developed.

A	
•	**Acceptor stem.** The seven base pairs at the end of a transfer RNA that carry the amino acid, formed by pairing positions 1 to 7 with 66 to 72. Most identity determinants lie here or at position 73 (Chapter 9).
•	**Acetyl-coenzyme A.** The thioester-linked acetyl carrier that enters the citric acid cycle and donates the acetyl group for every histone acetylation mark. Its thiol is the business end (Chapter 18).

•	**Aconitase.** The citric acid cycle enzyme whose [4Fe-4S] cluster participates directly in catal ysis; on cluster loss, the cytosolic form converts into an iron-responsive RNA-binding protein. Its activity ratio is the standard in-cell cluster proxy (Chapter 18).
•	**ADAR.** The family of enzymes that deaminate adenosine to inosine in double-stranded RNA, at millions of sites in the human transcriptome. The reaction and its product are identical to those of an adenine base editor (Chapter 14).
•	**ADAT2/ADAT3.** The eukaryotic heterodimer that deaminates adenosine at anticodon position 34 of a defined subset of transfer RNAs, widening codon recognition (Chapter 7).
•	**Adenylate energy charge.** The ratio of ATP plus half ADP to the total adenine nucleotide pool; held near 0.85 to 0.95 in healthy cells. The quantity the stop-codon reading of Chapter 6 proposes as an input to termination.
•	**Adenylosuccinate synthetase.** The enzyme that commits inosine monophosphate to the

adenine branch, using GTP as the energy source — the reason the two purine arms are re-ciprocally balanced (Chapter 5).

•	**Allopurinol.** A hypoxanthine analog that inhibits xanthine oxidoreductase, lowering urate and raising the two unlettered purines. Standard gout therapy (Chapters 5 and 24).
•	**Alternative lengthening of telomeres.** Recombination-based telomere maintenance used by

[VOL p.485] a minority of tumors, marked by heterogeneous telomere lengths and abundant extrachromosomal circles. Not addressed by telomerase-directed agents (Chapter 15).

•	**Antideterminant.** A feature of a transfer RNA that prevents charging by the wrong synthetase; identity information of negative sign, and not drawn on the plates of Chapter 10.
•	**Anticodon.** Positions 34, 35 and 36 of a transfer RNA, which pair with the codon. Position 34 is the wobble position and carries both of this volume’s elements (Chapter 7).
•	**Archean.** The eon from roughly 4.0 to 2.5 billion years ago, during which the ocean was anoxic and in many settings sulfidic, and in which the iron-sulfur minerals of Chapter 21 precipitated.
B	
•	**Base editor.** An enzyme fusion that converts one base into another without a double-strand break. Adenine base editors deaminate adenosine to inosine; cytosine base editors deaminate cytidine to uridine (Chapter 14).
•	**Bisulfite conversion.** Chemical treatment that deaminates unmethylated cytosine to uracil and leaves 5-methylcytosine intact, converting a modification into a sequence difference so that sequencing can report it (Chapter 8).
•	**Bystander edit.** An unintended conversion of a second editable base within an editor’s activity window. The canonical sequence-representable off-target event (Chapter 12).
C	

- **CCA end.** The untemplated cytidine-cytidine-adenosine added to the 3′ end of every mature transfer RNA after transcription, carrying the amino acid at the terminal adenosine. Not encoded in the gene (Chapter 9).
- **Chain of links.** The volume’s practice of stating a multi-step argument as a numbered list, each item tied to the chapter that carries it, so that the whole can be judged and so that a rejected link shows what else falls (front matter; Chapter 21).
- **Citric acid cycle.** The central oxidative pathway, entered through a thioester and turned by two dehydrogenase complexes that both depend on lipoate (Chapter 18).
- **Cluster, iron-sulfur.** An inorganic cofactor of two or four irons bridged by sulfides and held

to the protein by cysteine thiolates; the electron-transfer unit of the respiratory chain and a structural element in several DNA repair enzymes (Chapters 18, 19 and 20).

- **Coded fraction.** The proportion of a molecule, or of its pharmacologically decisive features, specified by a nucleic acid sequence. For acylated peptide drugs it is high by atom count and low by decisive feature (Chapter 14).

[VOL p.486]

- **Codon-to-atom translation.** The rewriting of a codon as a string of atomic symbols using the base-element assignments of the color key: A as hydrogen, C as carbon, G as nitrogen, U as phosphorus, T as sulfur, I as oxygen (Chapter 6).
- **Color key.** The volume’s convention assigning seven elements to seven colors, applied as a pale field behind the word wherever the element occurs (Chapter 2).
- **Compartment keying.** The assignment of each of thirteen organelles to a single element by the chemistry it runs rather than by resemblance (Chapter 16).
- **Cysteine.** The sulfur amino acid whose thiol performs catalysis, ligates metals, forms disul fides and becomes the thiyl radical that makes DNA. Colored yellow throughout by the word- root rule (Chapters 17 and 19).
- **Cysteine desulfurase.** The enzyme that abstracts sulfur from cysteine as a protein-bound

persulfide and delivers it to cluster assembly, wobble thiolation, cofactor synthesis, biotin and lipoate. The shared supplier of Chapter 20.

D

- **Deamination.** Removal of an exocyclic amine from a base. Cytosine gives uracil; adenine gives hypoxanthine; guanine gives xanthine. Two of the three products have no letter in the genetic code, which is why deamination is this volume’s recurring example of a change the record cannot carry (Chapter 8).
- **Determinant, identity.** A position in a transfer RNA read by its synthetase. Across the twenty- one human systems, eighteen of seventy-six positions are ever used (Chapters 9 to 11).
- **Differential alkylation.** The method that reports cysteine oxidation state by blocking free

thiols with one reagent, reducing reversibly oxidized forms, and labeling with a second reagent of different mass (Chapter 13).

•	**Dihydroorotate dehydrogenase.** The only pyrimidine-synthesis enzyme bound to the inner mitochondrial membrane, passing electrons to ubiquinone and thereby coupling pyrimidine supply to the respiratory chain (Chapter 5).
•	**Discriminator base.** Position 73 of a transfer RNA, the last unpaired base before the CCA end, read by nineteen of the twenty-one charging systems (Chapter 9).
•	**Disulfide.** A sulfur-sulfur bond between two cysteines; structural when formed during oxida tive folding, regulatory when formed reversibly in response to oxidative tone (Chapters 13, 17 and 22).
•	**Dithiolene.** The two-sulfur ligand that holds molybdenum in the molybdenum cofactor (Chap ter 24).

[VOL p.487]

•	**dNTP pool.** The intracellular concentrations of the four deoxyribonucleoside triphosphates. Small, rapidly turned over, and unbalanced; imbalance raises polymerase error rates without any change in the polymerase (Chapters 4 and 5).
E	
•	**Editing, epigenetic.** Targeted alteration of a chromatin or DNA modification without change to the sequence. Mechanism and off-target liability are both invisible to sequencing (Chapter 14).
•	**End-replication problem.** The inability of a lagging-strand polymerase to fill the gap left when the final RNA primer is removed, producing loss at every division (Chapter 15).
•	**Energy charge.** See adenylate energy charge.
•	**Epimutation.** A heritable change in a modification state rather than in a sequence; clonally transmitted through maintenance methylation and oncogenic when it silences a tumor suppres sor (Chapter 14).
•	**Evidence tags.** The volume's paragraph marks: [E] for established in the literature, [F] for argued or computed here, [O] for an open question.
F	
•	**Falsifier.** A stated observation that would break a claim. The volume's falsifiers are listed per chapter and collected in Appendix C.
•	**Fe4S4 cubane.** The core geometry shared by the mineral greigite and the [4Fe-4S] protein cluster; the structural basis of the mineral-to-cofactor link (Chapter 21).
•	**Frameshifting.** Loss of reading frame at the ribosome. Program d in some genes; elevated when wobble thiolation fails, which makes frame fidelity partly a function of sulfur supply (Chapter 7).
•	**Fuse, redox.** The boundary on the sulfur oxidation ladder between reversible states — thiol, sulfenic acid, disulfide — and effectively irreversible ones. Below it, signaling; above it, damage (Chapter 17).
G	
•	**Gatekeeper.** One of the three one-way nucleotide species through which all nucleic acid synthesis must pass: inosine monophosphate, xanthosine monophosphate and orotidine monophosphate, none of which has a letter (Chapter 5).
•	**Glutathione.** The cysteine-containing tripeptide that is the cell's principal thiol buffer, present at millimolar concentrations and not spelled by the genetic code, since it is made by two ligases rather than translated (Chapters 17 and 25).

[VOL p.488]

•	

Great Oxidation. The rise of atmospheric oxygen approximately 2.4 billion years ago, dated in part by the disappearance of mass-independent sulfur isotope fractionation (Chapter 21).

•	**Greigite.** An iron sulfide mineral containing the Fe4S4 cubane unit (Chapter 21).
H	
•	**Hypoxanthine.** The purine base of inosine, produced by adenine deamination and standing

at the trunk of de novo purine synthesis as inosine monophosphate. Colored orange, with no letter in the code (Chapters 5 and 8).

•	**Hub.** A signaling node with outputs distributed across several compartments; the volume's argument is that hub inhibition is compensable in proportion to that distribution (Chapters 22 and 23).
I	
•	**Identity elements.** See determinant.
•	**IMP dehydrogenase.** The rate-limiting enzyme of guanine nucleotide synthesis, converting

the trunk nucleotide to the xanthine nucleotide; the target of mycophenolate (Chapter 5).

•
Inosine. The nucleoside of hypoxanthine. Product of adenosine deamination in RNA and of

adenine base editing in DNA; reads as guanosine in any polymerase-based readout; colored orange throughout (Chapters 7, 8 and 14).

•	**Irving-Williams series.** The order of stability of divalent metal complexes, which cells must actively work against to load the correct metal into a site; one reason metal occupancy is not predictable from sequence (Chapter 13).
L	
•	**Ladder, oxidation.** The series of sulfur oxidation states accessible in biology, from sulfide

and thiol at the reduced end through persulfide, thioether, sulfenic acid, disulfide, sulfinic acid and sulfonic acid to sulfate. Its lower half is reversible and its upper half is not (Chapter 17).

•	**Lipoate.** The dithiolane cofactor carried as an amide on a lysine, forming the swinging arm of both citric acid cycle dehydrogenase complexes. Its installation depends on the same machinery as cluster assembly (Chapter 18).
•	**Loop, t-.** The lariat formed when a telomere's 3′ overhang invades the upstream duplex, hiding the chromosome end from damage sensing. A managed recombination intermediate (Chapter 15).

[VOL p.489]

M	
•	**Mackinawite.** An iron sulfide mineral of the early ocean, often cited with greigite in accounts of mineral-catalyzed prebiotic chemistry (Chapter 21).
•	**Methionine.** The sulfur amino acid specified by the start codon and the precursor of S-

adenosylmethionine. Its sulfur is in the side chain and absent from its codon’s atom string (Chapter 6).

•	**Methylation index.** The ratio of S-adenosylmethionine to S-adenosylhomocysteine, which sets the cell’s capacity for methyl transfer because many methyltransferases are product- inhibited (Chapter 18).
•	**Minihelix.** A truncated transfer RNA consisting of the acceptor stem alone; charged with ala nine in vitro, which demonstrates that identity can reside entirely at the acceptor end (Chapter 11).
•	**Modification, post-transcriptional.** Chemical alteration of a nucleoside after transcription; more than one hundred and fifty are cataloged in cellular RNA, with the anticodon loop the most densely modified region (Chapter 7).
•	**Molybdenum cofactor.** The pterin-based cofactor that holds molybdenum with a dithiolene,

built from GTP in three sulfur steps, and carried by sulfite oxidase and xanthine dehydrogenase (Chapter 24).

N	
•	**NFS1.** The human mitochondrial cysteine desulfurase, the single upstream supplier for cluster assembly and wobble thiolation (Chapter 20).
•	**Nitrogenase.** The enzyme that reduces atmospheric nitrogen, holding molybdenum in a

cluster with nine sulfurs and an interstitial carbon, and irreversibly poisoned by oxygen; a

	chemical fossil of the pre-oxygen world (Chapter 24).
•	**Nucleotide.** The triad of base, sugar and phosphate; the volume’s unit of genetic information, in place of the letter (Chapter 4).
O	
•	**Occupancy.** Whether a given protein molecule actually carries its cofactor, metal or disulfide, as opposed to whether its sequence specifies a site for one. Not predictable from sequence (Chapter 13).
•	**Off-target, primary.** An unintended edit that the four-letter record can represent (Chapter 8).
•	**Off-target, secondary.** A change the record either misreports, because the product maps to a

[VOL p.490] different letter, or cannot report at all, because it has no letter (Chapter 8).

- **Order statistic.** A quantity defined by rank within a sample, such as the minimum. Telomere biology’s governing variable is the minimum of ninety-two lengths, which no sequence record can carry (Chapter 15).
- **Orotidine monophosphate.** The unlettered gate through which every pyrimidine passes; de carboxylated to uridine monophosphate by one of the most proficient enzymes known (Chapter

5).

P

- **Persulfide.** A sulfur atom attached to a thiol, the form in which sulfur is trafficked from the desulfurase to its destinations, and a protective species against overoxidation (Chapters 17 and 20).
- **Plate.** In this volume, one charging system drawn on the common transfer RNA frame with its identity determinants lit (Chapter 10).
- **PTEN.** The lipid phosphatase that opposes the survival kinase of Chapter 22; inactivated by deletion, by mutation, by promoter methylation and by a reversible disulfide, the last of which no genotype assay reports.
- **Pyranopterin.** The pterin scaffold of the molybdenum cofactor, built from GTP by a radical SAM enzyme; supplying it treats one subtype of cofactor deficiency (Chapter 24).

R

- **Radical SAM enzyme.** An enzyme that uses a [4Fe-4S] cluster to cleave S-adenosylmethionine and generate a radical; three of this volume’s seven sulfur operations occur in a single such active site (Chapter 19).
- **Redundancy.** The number of independent routes by which a signaling output can be produced; the variable this volume argues predicts whether inhibiting a node has clinical effect (Chapter 23).
- **Register.** In the color convention, the list of every place in the volume where one element occurs (Chapter 2). In Chapter 16, one of twelve scales at which an account of matter is kept.
- **Ribonucleotide reductase.** The only de novo route to deoxyribonucleotides, running through a transient thiyl radical on a cysteine; the chemical event that made a DNA world possible (Chapter 19).
- **RTEL1.** An iron-sulfur helicase that dismantles the telomeric t-loop at each replication; its failure produces telomere disease, and its cofactor is supplied by the mitochondrion (Chapters 15 and 19).

[VOL p.491]

S

•	**S-adenosylmethionine.** The universal methyl donor, carrying its methyl group on a positively charged sulfonium center; also a radical source for radical SAM enzymes, and the ligand of

the sensor that gates growth signaling on methionine status (Chapters 18 and 22).

•	**Salvage.** Recovery of free bases into nucleotides at roughly one ATP equivalent, against about six for de novo synthesis; performed by HGPRT for hypoxanthine and guanine and by APRT for adenine (Chapter 5).	

•	**SAMTOR.** The sensor that binds S-adenosylmethionine and relieves its inhibition of growth signaling when the methyl economy is replete; a direct metabolite input to the architecture of Chapter 22.	
•	**Selenocysteine.** The twenty-first amino acid, inserted by reading a stop codon as sense, placed where a thiol would be oxidized past recovery. selenium is its defining element (Chapter 17).	Colored indigo rather than yellow, since

•	**Shelterin.** The protein complex that binds telomeric repeats and stabilizes the t-loop, preventing the chromosome end from being read as a double-strand break (Chapter 15).	
•	**Sulfenic acid.** The first and reversible product of cysteine oxidation, and the actual on-and-off state of many redox switches. Absent from the standard functional-group table (Chapter 17).	

•	**Sulfite oxidase.** The molybdenum enzyme that performs the terminal step of sulfur amino acid catabolism; its isolated deficiency is nearly as severe as complete cofactor deficiency because the stranded substrate is an excitotoxin (Chapter 24).	
•	**Sulfonium.** species that makes a methyl group transferable (Chapter 17).	A tri-coordinate, positively charged sulfur, as in S-adenosylmethionine; the

•	**Supply line.** The metabolic pathway that manufactures the nucleotides from which nucleic acids are built; the term this volume uses for everything the standard Central Dogma leaves upstream of its first arrow (Chapter 4).	
T		

•	**Thiolation, wobble.** Installation of sulfur at the second carbon of uridine at anticodon position 34, narrowing codon recognition and stabilizing the codon-anticodon duplex (Chapter 7).	
•	**Thioester.** covalent intermediate of the one energy-conserving step of glycolysis (Chapter 18).	The high-energy acyl linkage to a thiol, as in acetyl-coenzyme A and in the

•	**Thioredoxin.** The small protein whose cysteine pair reduces disulfides in other proteins, re-

setting ribonucleotide reductase after every turnover and maintaining thiol pools; its reductase

[VOL p.492]

	carries a selenocysteine in humans (Chapters 17 and 19).
•	**Thiyl radical.** The transient radical on a cysteine sulfur that abstracts the 3′ hydrogen in ribonucleotide reduction (Chapter 19).
•	**Transsulfuration.** The one route by which methionine sulfur becomes cysteine sulfur in

human cells, and the junction at which the cell’s sulfur budget is allocated (Chapter 20).

•	**Transversion.** A purine-to-pyrimidine or pyrimidine-to-purine substitution. Deaminase ed itors write transitions, not transversions, which bounds the current editing toolkit (Chapter 23).
U	
•	**Unlettered base.** Any nucleobase species occurring in the cell that the four-letter genetic al phabet does not name: hypoxanthine, xanthine, orotate and the modified bases. The volume’s central notational concern (Chapters 5 and 8).
•	**Urate.** The terminal product of purine degradation in humans, who lack functional uricase; near its solubility limit in plasma, and simultaneously a risk factor for gout and a plasma antioxidant (Chapter 24).
W	
•	**Weave.** The matrix of which recurring argument appears at which stage of the arc (Chapter 3).
•	**Wobble.** Non-Watson-Crick pairing at the third codon position, allowing one anticodon to read several codons; the position where inosine widens and 2-thiouridine narrows recognition (Chapter 7).
X	
•	**Xanthine.** The purine intermediate between hypoxanthine and urate; unlettered, and the species that accumulates in xanthinuria (Chapters 5 and 24).
•	**Xanthine dehydrogenase.** The molybdenum enzyme carrying out the last two steps of purine

degradation, switched on by a terminal sulfur ligand installed by a dedicated sulfurase (Chapter 24).

•	**Xanthosine monophosphate.** The unlettered gate on the guanine branch of purine synthesis (Chapter 5).
•	**XPD family.** The superfamily 2 helicases carrying a [4Fe-4S] cluster at the strand-separating wedge: XPD, FANCJ, RTEL1 and DDX11, each with its own human disease (Chapter 19).

[VOL p.493]

Terms from the clinic and the trial record	
•	**Adoptive cell therapy.** Treatment with cells, usually autologous, that have been modified and expanded outside the body. Expansion spends replicative reserve, which is a quantity the release criteria do not report (Chapter 15).
•	**Antibody-drug conjugate.** An antibody carrying a cytotoxic payload, in most constructs attached through thiol-maleimide chemistry at interchain cysteines; one of the six sulfur- dependent therapeutic traditions (Chapter 23).
•	**Base editing, clinical.** Programs using deaminase fusions to correct or install point changes in patients; validated principally by sequencing, which cannot distinguish the deaminated product from the base it reads as (Chapter 14).
•	**Capivasertib and the hub programs.** The class of agents directed at the survival kinase itself, tested in randomized trials with genotype-based enrollment. The pattern across the class is progression-free benefit with on-target metabolic toxicity and no demonstrated overall survival benefit (Chapter 23).
•	**Clonal hematopoiesis.** Expansion of a hematopoietic clone carrying a somatic mutation, common with age; relevant because the clones that expand best in a manufacturing process are not a random sample of the starting population (Chapter 15).
•	**Companion diagnostic.** An assay used to select patients for a therapy. The volume's recurring criticism is that where a target's activity can be set chemically as well as genetically, a genotype- only companion diagnostic enrolls a mixed population (Chapter 23).
•	**Exagamglogene and the approved editing therapies.** Nuclease-based editing approved for sickle cell disease and transfusion-dependent beta-thalassemia, the first demonstration that acting on the letter cures a disease whose cause is a letter (Chapter 12).
•	**Familial hypercholesterolemia.** The monogenic form of a disease whose population burden is overwhelmingly polygenic and flux-driven; the example that marks the boundary between the two kinds of cause (Chapter 12).

•	**Friedreich ataxia.** Disease of frataxin, a component of the mitochondrial cluster assembly machinery; the clinical demonstration that cluster supply failure produces multi-compartment disease (Chapter 20).
•	**Gout.** Disease of the purine exit in a lineage that deleted uricase, treated by inhibiting the exit enzyme with a hypoxanthine analog and thereby raising the two unlettered purines (Chapter 24).
•	**Hazard ratio.** The ratio of instantaneous event rates between arms of a trial; the standard summary of a time-to-event endpoint.

[VOL p.494]

•

Hereditary orotic aciduria. UMP synthase deficiency, diagnosed by the accumulation of an unlettered intermediate and treated by supplying uridine to bypass the gate (Chapter 5).

•	**Hoyeraal-Hreidarsson syndrome.** A severe telomere biology disorder, caused in some pa tients by mutations in the iron-sulfur helicase RTEL1 (Chapter 19).	
•	**Hyperglycemia, on-target.** The dose-limiting toxicity of inhibitors of the insulin signaling axis; a consequence of the mechanism rather than of an off-target effect, and therefore a bound on achievable target inhibition (Chapter 23).	

•	**Lesch-Nyhan syndrome.** HGPRT deficiency; salvage failure with hyperuricemia and severe neurological disease, demonstrating that an apparently redundant recovery pathway is not (Chapter 5).	
•	**Methotrexate, 5-fluorouracil, 6-mercaptopurine, hydroxyurea, mycophenolate.** The an timetabolites: five agents that act on the nucleotide supply line rather than on the text, all in clinical use for decades (Chapters 4 and 5).	
•	**Molybdenum cofactor deficiency.** Failure of cofactor biosynthesis, producing neonatal en cephalopathy; one subtype is treatable by supplying the missing intermediate (Chapter 24).	

•	**Overall survival.** Time from randomization to death from any cause; the endpoint against which the hub programs of Chapter 23 are assessed.	
•	**Peptide drug.** A therapeutic peptide, usually with chemical modifications — acylation, ami dation, non-natural residues — that are not specified by any sequence (Chapter 14).	
•	**Prime editing.** Editing using a reverse transcriptase and an extended guide to write short sequences, including transversions, without a double-strand break (Chapter 23).	
•	**Progression-fre e survival.** Time to radiographic progression or death; can improve without an improvement in overall survival, and the divergence is informative (Chapter 23).	

•	**Replicative reserve.** The number of divisions a cell population can still undergo, governed by its shortest telomeres; proposed here as a release criterion for cell products (Chapter 15).	
•	**Senescence, replicative.** Permanent withdrawal from the cell cycle triggered by a persistent damage response, including the response to a single critically short telomere (Chapter 15).	
•	**Sickle cell disease.** sequence-level intervention: a phenotype caused by a letter, corrected at the letter (Chapter 12).	The disease whose cure by editing establishes the proper domain of
•	**Trichothiodystrophy.**	A disorder of the XPD helicase family, named for sulfur-deficient

brittle hair, which is a clinical reminder that a cluster helicase defect manifests through sulfur-rich structural protein (Chapter 19).

•
Variant of uncertain significance. A sequence change whose consequence is unknown; the

[VOL p.495] volume’s claim is that cysteine variants in metal-binding or disulfide-forming positions are systematically under-resolved by sequence-based predictors (Chapter 13).

•	**Xanthinuria.** Failure of the purine arm of the molybdenum cofactor’s output; mild, because the stranded substrate deposits rather than poisons (Chapter 24).

Terms from chemistry, measurement and deep time	
•	**Anoxic.** Without free oxygen. The condition of the ocean and atmosphere before the Great Ox-

idation, and the condition under which iron-sulfur mineral chemistry and the oxygen-sensitive enzymes of Chapter 21 operate.

•	**Banded iron formation.** Sedimentary deposits of alternating iron-rich and silica-rich layers, recording the oxidation of dissolved ferrous iron as oxygen accumulated.
•	**Bond dissociation energy.** The energy required to break a bond homolytically. The relevant comparisons in this volume are the weakness of the sulfur-sulfur bond, which makes disulfide

exchange usable, and the strength of the dinitrogen triple bond, which is why nitrogenase needs

nine sulfurs to hold its metal.
•
Catenation. The ability of an element to bond to itself in chains. Carbon’s catenation builds

frameworks; sulfur’s builds polysulfides, which are signaling and storage species (Chapter 17).

•	**Electron paramagnetic resonance.** Spectroscopy of unpaired electrons; the method that detects radicals and distinguishes iron-sulfur cluster types and oxidation states (Chapter 19).
•	**Electronegativity.** The tendency of an atom to attract bonding electrons. Sulfur’s value near

carbon’s, and far from oxygen’s, is why a thioester is energetically unlike an ester (Chapter 17).

•	**Extracellular flux analysis.** Real-time measurement of oxygen consumption and extracellular acidification, giving respiration and glycolysis as rates rather than as levels (Chapter 18).
•	**Fractionation, mass-independent.** Isotopic fractionation that does not scale with mass dif ference, produced for sulfur by gas-phase photochemistry in an atmosphere without ozone; its disappearance from the rock record is the sharpest single marker of the Great Oxidation (Chapter 21).

- **Inductively coupled plasma mass spectrometry.** Elemental analysis at high sensitivity; the standard method for metal quantitation in proteins and cells (Chapter 13).
- **Isotope tracing.** Feeding a labeled substrate and following the label through metabolites; the only way to measure flux as opposed to concentration (Chapters 4, 18 and 20).
- **Michaelis constant.** The substrate concentration at half-maximal rate. It matters in this

[VOL p.496] volume wherever a modifying enzyme operates near its constant, which makes the mark it writes sensitive to substrate supply — the case for histone acetylation (Chapter 18).

- **Midpoint potential.** The potential at which a redox couple is half reduced; the quantity that orders the carriers of the respiratory chain and that cluster ligation tunes (Chapter 18).
- **Molecular cloud.** Cold, dense interstellar gas in which sulfur- and carbon-bearing molecules

form; the stage of the arc at which the two halves of the sulfur ladder are joined (Chapters 3 and 21).

- **Nanopore sequencing.** Sequencing by ionic current through a pore, in principle able to report base modifications directly because the current depends on chemical identity (Chapter 8).
- **Native mass spectrometry.** Mass spectrometry under non-denaturing conditions, preserv ing noncovalent complexes and therefore reporting cofactor occupancy on the intact protein (Chapter 13).
- **Nucleosynthesis.** The formation of the elements: hydrogen and helium primordially, the

organic elements in stellar burning, sulfur principally in oxygen burning and thermonuclear

supernovae, selenium largely by neutron capture (Chapter 3).

- **Pentose phosphate pathway.** The route that generates NADPH from glucose-6-phosphate; the destination of carbon rerouted when the glycolytic dehydrogenase is oxidatively inactivated (Chapter 18).

- **Persistence length.** The length scale over which a polymer stays straight; for DNA it is set by backbone charge and counter-ion condensation, which is information the letter does not carry (Chapter 4).
- **Proximity labeling.** Enzymatic tagging of proteins near a bait, used to establish which pro teins occupy a membrane contact site (Chapter 20).
- **Quenching.** Rapid arrest of metabolism before extraction, required for any measurement of a pool that turns over in seconds (Chapter 4).
- **Radical.** A species with an unpaired electron. In this volume the thiyl radical of ribonucleotide reduction and the radical generated by radical SAM enzymes are the two that matter (Chapter 19).
- **Redox proteomics.** Proteome-scale measurement of cysteine oxidation states by differential alkylation and mass spectrometry (Chapter 13).

•	**Sugar pucker.** The conformation of the ribose ring, biased by substituents; the 2-thio mod-

ification of uridine biases it strongly, which is the structural basis of the wobble restriction (Chapter 7).

•	
Thermodynamic versus kinetic control. Whether a product distribution is set by stability or	

[VOL p.497] by rate. Several of this volume's switches are kinetically controlled, which is why they respond on a timescale of seconds and why they cannot be inferred from structure.

•	**Ubiquinone.** The lipid-soluble electron carrier of the inner mitochondrial membrane, and the acceptor for dihydroorotate dehydrogenase, which is how pyrimidine supply is coupled to respiration (Chapter 5).
•	**Zero-point energy and tunneling.** Quantum contributions to reaction rates, significant for proton and hydrogen transfer; the physical background to the proton-position reading of Chap ter 6, which is marked open throughout.
Further terms, including the volume's own usages	
•	**Arc, the.** The ordering of material by the sequence in which the universe did things, twelve stages from nucleosynthesis to the clinic (Chapter 3).
•	**Arrow, in the fan.** One documented output of a signaling node, filed by the compartment in which it is executed rather than by its pathway (Chapter 22).
•	**Atom string.** A codon rewritten letter by letter as atomic symbols using the base-element assignment: AUG as hydrogen, phosphorus, nitrogen (Chapter 6).
•	**Audit, the color.** The four-step check of whether a page's colored fields match the chemistry its argument claims (Chapter 2).
•	**Breaking condition.** The observation that would end a claim, stated with the claim rather than left to a critic to supply (Chapters 21 and 25; Appendix C).
•	**Business end.** The small set of atoms at which a molecule acts, as distinct from the sequence that identifies it (Chapter 3).
•	**Chain of links.** A multi-step argument stated as a numbered list with each item tied to the chapter that carries it (front matter; Chapter 21).
•	**Chemistry-first.** Reading a clinical presentation from the accumulating species rather than from the mutated gene, as in the cofactor deficiencies of Chapter 24.
•	**Class, evidence.** One of [E], [F], [O] — established, argued here, or open.

•	**Coded fraction.** The proportion of a therapeutic molecule, or of its decisive features, that a nucleic acid sequence specifies (Chapter 14).
•	**Collision.** A place where two positions in the volume, or a position here and a settled position elsewhere, are in unresolved tension (Appendix C).
•	**Compartment keying.** The assignment of an organelle to a single element by the chemistry it runs (Chapter 16; Appendix W).
•	**Conversation, in the network.** One named exchange between the mitochondrion and another compartment, of material, signal or position (Appendix J).

[VOL p.498]

•	**Determinant set.** The positions a charging system reads, as a set over the seventy-six frame positions (Chapters 9 to 11).
•	**Difference table.** The pairwise comparison of determinant sets across the twenty-one charging systems (Chapter 11).
•	**Error class.** One of the three relations an error can have to the record: representable, misrep resented, or absent from it entirely (Chapter 8).
•	**Exclusivity.** The property of being the only site at which a cellular process can occur; used here of mitochondrial cluster assembly (Chapter 20).
•	**Fan, output.** The set of a signaling node’s outputs taken as one object and sorted by compart ment (Chapter 22).
•	**Floor, not total.** The standing of any count drawn from a partial enumeration (Appendix A).
•	**Frame, the.** The seventy-six numbered positions shared by every transfer RNA, on which the plates are drawn (Chapter 9).
•	**Fuse, the.** The point on the sulfur oxidation ladder past which oxidation is not reversible (Chapter 17).
•	**Gate.** A one-way step through which all material in a pathway must pass; of the eight nu cleotide species, three are gates (Chapter 5).
•	**Leg, of the stool.** One of the three claims that hold the volume’s argument up (Chapter 1).
•	**Level, of intervention.** Text, spoke or supply: the three places a therapeutic agent can act on the chain (Chapter 25).
•	**Minimum panel.** The four assays that convert a sequence-only validation package into a state- aware one (Appendix E).
•	**Operation.** One of the seven things sulfur does at any register (Chapter 16; Appendix Q).
•	**Order statistic.** A quantity defined by rank within a sample; the governing telomere variable is the minimum over ninety-two ends (Chapter 15).
•	**Plate.** One charging system drawn on the common frame with its determinants lit (Chapter 10).
•	**Priority order.** The sequence in which a cell sacrifices the competing outputs of a shared supply; unmeasured, and the open question of Chapter 20.
•	**Propagation test.** The experiment that distinguishes a compartment whose failures stay local from one whose failures spread (Chapters 16 and 20).
•	**Redundancy fraction.** The proportion of a node’s outputs reachable by at least one alternative route (Chapter 23).

[VOL p.499]

•	**Register.** Either one of the twelve scales at which an account of matter is kept (Chapter 16; Appendix Y), or the list of every place in the volume where one element occurs (Chapter 2).
•	**Residual, of the folding problem.** What remains unpredicted once backbone geometry is predicted: occupancy, register, metal and redox state (Chapter 13).
•	**Reverse reading.** Running the arc backward, from a clinical failure to the chemistry and the atom (Chapter 3; Chapter 23).
•	**Sampling frame.** The set of sites or samples an assay examines; the wrong frame produces a confident negative (Chapters 12 and 14).
•	**Shuffle control.** Randomized reassignment used to test whether an observed pattern exceeds combinatorial expectation (Chapter 11).
•	**Span.** The number of registers at which an element has an entry; the argument for treating sulfur as more than a specialist (Chapter 16).
•	**Spoke.** An output executed in a single compartment, with no alternative route (Chapter 23).
•	**State variable.** One of the four quantities this volume argues must accompany a sequence: pool composition, thiol poise, cofactor occupancy, modification status (Appendix E).
•	**Supply is not repertoire.** The distinction that answers the late-addition objection: an element can run a metabolism long before the code names an amino acid built on it (Chapter 25).
•	**Theme.** An argument that returns at more than one stage of the arc in more than one material (Chapter 3; Appendix M).
•	**Three-legged stool.** The volume's figure for its own structure: three claims that stand together or not at all (Chapter 1).
•	**Transversion wall.** The bound set by deaminase chemistry, which writes transitions and not transversions (Chapter 23).
•	**Trunk.** The obligatory precursor from which both purine branches leave: inosine monophos phate (Chapter 5).
•	**Unlettered.** Of a base or nucleotide species occurring in the cell and having no symbol in the four-letter alphabet (Chapters 5 and 8).
•	**Weave.** The matrix of themes against stages (Chapter 3).
•	**Worked example.** A section in the chapter notes that runs one case end to end, with the measurements that would settle it.

Additional terms: processes, structures and quantities	
•	**Acyl group.** A carbonyl-bearing fragment transferred between molecules; carried in this volume almost exclusively on sulfur, as a thioester (Chapter 18).

[VOL p.500]

•	**Aminoacylation.** The charging of a transfer RNA with its amino acid; the second genetic code's reaction (Chapter 9).
•	**Anfinsen's principle.** That a protein's native structure is determined by its sequence — true of the backbone and silent about what is bound to it (Chapter 13).
•	**Antimetabolite.** A drug that acts on the supply of a metabolic precursor rather than on a signaling protein; the class includes five agents in use for decades (Chapter 4).
•	**Autophagy.** Degradation of cellular components by delivery to the lysosome; mitophagy is its mitochondrion-specific form (Appendix J).
•	**Base excision repair.** The repair route for small base lesions, initiated by a glycosylase; the route that removes uracil and hypoxanthine from DNA (Chapter 8).
•	**Chaperone.** A protein that assists folding without being part of the product; distinct from the cofactor-loading machinery that determines occupancy (Chapter 13).
•	**Codon box.** The group of codons specifying one amino acid; adjacency of boxes is part of what makes some charging discriminations hard (Chapter 11).
•	**Compensation route.** An alternative path to the same signaling output, which is what makes a hub inhibitor's effect partial (Chapter 23).
•	**Contact site.** A region of close apposition between two organelles, across which lipids and ions are exchanged (Appendix J).
•	**Cytoreduction.** Reduction in proliferating cell mass, the therapeutic effect of several supply- line agents (Chapter 19).
•	**Deoxyribonucleoside triphosphate.** The substrate a polymerase accepts; its concentration and balance set fidelity (Chapter 4).
•	**Discriminator.** See position 73 (Chapter 9).
•	**Dose-limiting toxicity.** The adverse effect that caps achievable exposure; for inhibitors of the insulin axis it is on-target hyperglycemia (Chapter 23).
•	**Endosymbiosis.** The acquisition of a bacterial cell that became the mitochondrion, and later in another lineage the plastid (Appendix N).
•	**Energy charge.** See adenylate energy charge.
•	**Ex vivo editing.** Editing performed on cells outside the body, which requires expansion and therefore spends replicative reserve (Chapter 15).

•	**Extrachromosomal circle.** A closed DNA circle excised from a chromosome; at telomeres, the product of loop resolution (Chapter 15).
•	**Fidelity.** The accuracy of a templated or recognition process; in this volume, a function of supply as much as of enzyme (Chapters 4 and 7).

[VOL p.501]

•	**Flux.** The rate of material through a pathway, as distinct from the concentration of its inter mediates; measurable only by tracing (Appendix E).
•	**Gatekeeper enzyme.** The enzyme performing a one-way committed step (Chapter 5).
•	**Glycosylation.** The attachment of glycans to proteins and lipids, largely at the Golgi and energetically expensive (Appendix J).
•	**Guide-independent.** Of an off-target event arising from the enzyme's own dwell rather than from sequence similarity to the guide; invisible to homology-based sampling (Chapter 14).
•	**Hub inhibitor.** An agent directed at a node with outputs distributed across compartments (Chapter 23).
•	**Hypomorph.** An allele with reduced rather than absent function; the usual presentation of essential-gene variants in viable patients (Chapter 7).
•	**Identity swap.** The experiment that transplants determinants from one transfer RNA into another and tests charging; establishes sufficiency (Chapter 9).
•	**Information, two bits.** The content of one position in a four-symbol record, spent entirely on identity (Chapter 8).
•	**Isoacceptor.** One of several transfer RNA species carrying the same amino acid with different anticodons (Chapter 10).
•	**Kinetic isotope effect.** The change in reaction rate on isotopic substitution; the evidence for hydrogen tunneling in enzymes (Chapter 6).
•	**Loop resolution.** Cleavage of the t-loop junction, deleting the loop as a circle rather than unwinding it (Chapter 15).
•	**Maintenance methylation.** Copying of the parental methylation pattern after replication, which makes an epimutation heritable (Chapter 14).
•	**Mismetallation.** Loading of the wrong metal into a site, against which cells work actively (Chapter 13).
•	**Mitophagy.** Autophagic degradation of mitochondria (Appendix J).
•	**Nucleolar stress.** The response to impaired ribosome biogenesis, which stabilizes p53 without DNA damage (Appendix J).
•	**One-carbon unit.** A methyl, methylene or formyl group carried on folate; the supply for purine ring closure and for thymidylate synthesis (Chapter 5).
•	**Order of sacrifice.** The sequence in which a cell abandons competing outputs of a shared supply; unmeasured (Chapter 20).
•	**Oxidative folding.** Disulfide formation and isomerization during folding in the secretory pathway (Chapter 13).

[VOL p.502]

•	**Permeability transition.** The opening of a high-conductance pore in the inner mitochondrial membrane, committing a cell to death (Appendix J).
•	**Pharmacodynamic marker.** A measurement establishing that an agent engaged its target in tissue; distinct from a measurement that the engagement mattered (Chapter 23).

•	**Proofreading.** Post-transfer correction of a mischarged product by a synthetase's editing domain (Chapter 11).
•	**Quenching, metabolic.** Rapid arrest of metabolism before extraction, required for any pool measurement (Appendix E).
•	**Readthrough.** Translation past a stop codon, basal or program d (Chapter 6).
•	**Release criteria.** The attributes a manufactured product must meet before use; this volume proposes replicative reserve as one (Chapter 15).
•	**Resection.** Nucleolytic processing of a DNA end, generating the single-strand overhang at a telomere (Chapter 15).
•	**Salvage.** Recovery of preformed bases into nucleotides at about one ATP equivalent (Chapter 5).
•	**Senescence.** Permanent cell cycle withdrawal following a persistent damage response (Chapter 15).
•	**Sulfur relay.** The chain of carrier proteins moving sulfur as persulfide from the desulfurase to its destinations (Chapter 20).
•	**Thiol trapping.** Blocking free thiols with an alkylating reagent to fix the oxidation state at the moment of lysis (Appendix E).
•	**Transfer, indirect.** Charging a transfer RNA with a precursor amino acid and converting it in place, as for glutamine in many systems (Chapter 11).
•	**Turnover, pool.** The number of times a metabolite pool is consumed and replenished in a given interval; high turnover is why pool size alone is uninformative (Appendix E).
•	**Validation package.** The set of assays supporting a therapeutic agent's safety and mechanism; this volume's argument is about what such packages structurally cannot contain (Chapter 12).
•	**Wobble restriction.** Narrowing of codon recognition by a modification that increases pairing selectivity, as 2-thiouridine does at position 34 (Chapter 7).
•	**Xenobiotic.** A compound foreign to normal metabolism; several sulfur functional groups in the table of Chapter 17 exist in biology chiefly as drugs or as damage (Chapter 17).
•	**Yield, energetic.** Free energy recovered per substrate oxidized; the quantity that changed by about an order of magnitude at the Great Oxidation (Chapter 21).
•	**Zinc finger.** A structural motif in which zinc is held by cysteine and histidine ligands; one of

[VOL p.503] the commonest metal sites in the proteome and a reason metal loading is a general problem rather than a specialist one (Chapter 13).

•	**Zymogen.** An inactive enzyme precursor requiring proteolytic activation; mentioned here only to mark the distinction between activation by cleavage, which is irreversible, and activation by a thiol switch, which is not (Chapter 17).
•	**Allosteric site.** A regulatory site distinct from the catalytic one; in ribonucleotide reductase, two of them set overall activity and substrate specificity and therefore pool balance (Chapter 19).
•	**Amidation, C-terminal.** Conversion of a C-terminal glycine into the amide of the preceding residue; a coded residue destroyed to make an uncoded feature (Chapter 14).
•	**Bystander.** An unintended but in-window edit, representable in the record and therefore the best-studied class of editing error (Chapter 12).

•	**Clamp, redox.** Holding a compartment's redox state fixed experimentally so that its contribu tion to an output can be measured (Chapter 22).
•	**Degeneracy.** The redundancy of the genetic code, concentrated at the third codon position and therefore at the position wobble chemistry acts on (Chapter 6).
•	**Determinant, negative.** See antideterminant (Chapter 10).
•	**Floodgate.** The model in which hyperoxidation of a peroxidase allows local peroxide to rise and act as a signal (Chapter 17).
•	**Half-life, circulating.** The time for plasma concentration to halve; for peptide drugs it is set by uncoded chemistry rather than by sequence (Chapter 14).
•	**Isomer, disulfide.** One of the many possible pairings of a protein's cysteines, only one of which is correct (Chapter 13).
•	**Leaky stop.** A stop codon with measurable readthrough; UGA and UAG are leaky and have been recoded, UAA is not and has not (Chapter 6).
•	**Pool turnover.** See turnover, pool.
•	**Position effect, telomeric.** Transcriptional regulation by telomere length acting over megabases, with no cis element at the regulated gene (Chapter 15).
•	**Reconstitution.** Restoring a cofactor to an apo-protein in vitro, which is the diagnostic test for an occupancy defect (Chapter 13).
•	**Residual, folding.** See residual, of the folding problem (Chapter 13).
•	**Window, editing.** The span of positions an editor can act on around its target, within which bystander edits occur (Chapter 12).

[VOL p.504] • **Register, chromatic.** The list of every place in the volume where one keyed element occurs (Chapter 2).

• **Scaffold protein.** In cluster biogenesis, the matrix protein on which the initial cluster is assembled before transfer to a recipient (Chapter 20).

• **Sink.** A pathway consuming a shared precursor; glutathione and taurine are the two largest sinks on the cysteine budget (Chapter 20).

• **Window, therapeutic.** The exposure range between efficacy and unacceptable toxicity; for supply-line agents it is set by the difference between cells that must build and cells that can recycle (Chapter 5).

[VOL p.505]

CHAPTER I

Reference Tables of the Volume

The volume's recurring structures are collected here as tables, so that a reader working in one chapter can check a number without hunting through another.

I.1. The twelve registers of matter

[F] The twelve scales at which an account of matter is kept, with sulfur's entry at each. The claim that justifies the list is that an element with an entry at every scale is an element whose account cannot be confined to one literature.

 # register
1 fundamental interactions

2	the atom
3	the molecule
4	bulk phases
5	molecular clouds
6	minerals
7	the three kingdoms
8	raw stock
9	cellular molecules
10	load-bearing tissue
11	sensing and signaling tissue
12	manufactured matter
what is accounted for	
whether a bond forms at all	
electron structure, oxidation states	
bonding arrangements	
solids, liquids, gases	
matter before the planet	
planetary chemistry	
life’s chemistry	
what is taken from the ground	
what a cell assembles	
structure	
regulation	
what intention makes	
sulfur’s entry	
electron configuration of group 16; polarizability	
nine oxidation states accessible in biology	
the eighteen functional groups	
elemental sulfur’s allotropes; hydrogen sulfide	
carbonyl sulfide, carbon monosulfide	
pyrite, mackinawite, greigite; the Fe4S4 cubane	
cysteine, methionine, clusters, thioesters	
sulfate, sulfide ores, sulfuric acid	
coenzyme A, glutathione, lipoate, S-adenosylmethionine	
keratin disulfides; sulfated glycosaminoglycans	
thiol redox switches; hydrogen sulfide signaling	
six of seven therapeutic traditions	

[VOL p.506] **Table.** The twelve registers, with sulfur’s entry at each (Chapter 16).

I.2. The seven operations

#	operation	canonical carrier	reversible?
1	carries electrons	thiol-disulfide couples; glutathione, thioredoxin	yes
2	forms reversible cross-links	cystine disulfides	yes
3	holds metals	cysteine thiolate; dithiolene	partly
4	transfers acyl groups	coenzyme A thiol; lipoyl arm	yes
5	carries methyl groups	the sulfonium of S-adenosylmethionine	yes
6	tunes recognition	2-thiouridine at position 34	no, once installed
7	absorbs oxidative damage	glutathione, thioredoxin, peroxiredoxin	up to the fuse

Table. The seven operations, with their carriers (Chapter 16).

I.3. The thirteen organelles, keyed

organelle	element the chemistry that justifies the keying		representative disease genes

lysosome	hydrogen a proton gradient of nearly three pH units, on which every	hydrolase depends	GBA1, GLA, HEXA
cytoplasm	carbon	the structural framework of intermediary metabolism	—
nucleus	nitrogen the nitrogenous bases and their chemistry		TP53, BRCA1, BRCA2, LMNA
mitochondrion	oxygen	the terminal electron acceptor of the chain	MT-TL1, MT-ND4, POLG
plasma	phosphorusthe phospholipid bilayer		CFTR, LDLR,
membrane			KCNQ1
endoplasmic	sulfur	oxidative folding and disulfide formation	SERPINA1, WFS1,
reticulum			ATL1

ribosome	selenium selenocysteine inserted by reading a stop as sense		RPS19, SBDS, RPS14

[VOL p.507]

organelle	**element the chemistry that justifies the keying**		**representative disease genes**
Golgi	manganesemanganese-dependent glycosyltransferases		ATP2C1, ATP7B, ATP7A
peroxisome	iron	iron-dependent oxidative catabolism	ABCD1, PEX1, PEX6
chloroplast	magnesiummagnesium at the center of chlorophyll		— (plant)

plant vacuole	potassium potassium-driven turgor		— (plant)
centrosome	calcium	calcium-dependent assembly and signaling	ASPM, WDR62, CEP290
secretory	zinc	zinc-loaded granules and their transporters	SLC30A8, STXBP1,
vesicles			UNC13D

Table. The thirteen compartments with their keyed elements (Chapter 16). Six are run by metals that carry no color in

this volume’s key.

I.4. The eighteen sulfur functional groups

#	group	formula	principal biological instance
1	thiol	R-SH R-S-R′	cysteine; glutathione; coenzyme A
2	sulfide, thioether	R-S-S-R′	methionine’s backbone; the methyl cycle
3	disulfide	R-S(=O)-R′	insulin’s three; antibody architecture; the PTEN switch
4	sulfoxide	R-SO2-R′	alliin; omeprazole’s activated form
5	sulfone		dapsone; polysulfone membranes
6	sulfinic acid	R-SO2H	cysteine sulfinic acid; hyperoxidized peroxiredoxin
7	sulfonic acid	R-SO3H R-SO3-R′	taurine; bile salts
8	sulfonate ester		alkylating mutagens; busulfan
9	thiocyanate	R-S-C□N	rhodanese detoxifying cyanide
10	isothiocyanate	R-N=C=S R-C(=S)-R′	sulforaphane and the Nrf2 response
11	thioketone		rare; largely synthetic
12	thial	R-C(=S)H	rare; largely synthetic
13	thiocarboxylic S-acid	R-C(=O)SH	the thiocarboxylate that delivers cofactor sulfur

[VOL p.508]

#	group	formula	principal biological instance
14	carbothioic O-acid	R-C(=S)OH	no established biological role
15	thiolester	R-C(=O)S-R′	acetyl-coenzyme A; the glycolytic intermediate

16	thionoester	R-C(=S)O-R′	no established biological role
17	dithiocarboxylic acid	R-C(=S)SH	laboratory chemistry; metal chelators
18	dithiocarboxylic ester	R-C(=S)S-R′	dithiocarbamate drugs and agents

Table. The eighteen groups of the standard table (Chapter 17). Five further classes that do biological work — sulfenic acid, thiosulfinate, persulfide, sulfonium, polysulfide — are omitted from that table and are added in Chapter 17.

I.5. The seven therapeutic traditions

#	tradition	the sulfur chemistry it depends on	where it acts on the fan
1	engineered proteins	engineered disulfides; free-thiol management	at a spoke
2	antibodies and bispecifics	interchain disulfides	at a spoke
3	antibody-drug conjugates	thiol-maleimide conjugation	at a spoke
4	RNA medicines	modified nucleosides, including thiolated ones	upstream
5	genome and base editing	cluster-dependent repair enzymes decide permanence	upstream of the fan
6	engineered cell therapies	selenium and thiol redox management for persistence	outside
7	biomanufacturing	cysteine supply and nucleotide pool management	outside

Table. The seven traditions (Chapter 23). Six depend on sulfur chemistry directly; the seventh depends on sulfur supply.

[VOL p.509] **CHAPTER J**

The Twelve Conversations

The third leg of the volume's argument is that the mitochondrion holds a distinct conversation with each of the twelve other compartments, and that the set of twelve is a supply and signaling network rather than a list of interactions. Each conversation is given here with what is exchanged, what is known about the mechanism, what fails when it fails, and what would be measured.

J.1. 1. With the nucleus

[E] What is exchanged. Acetyl groups and methyl groups as substrates for chromatin marks; iron-sulfur clusters for nuclear enzymes; and signals arising from mitochondrial stress that change nuclear transcription, including the integrated stress response.

[F] What fails. A cell with reduced mitochondrial capacity has reduced substrate for histone acetylation and reduced cluster supply for repair enzymes. The transcriptional consequence is visible; the cluster consequence is not, because it changes enzyme activity without changing enzyme abundance.

[F] What to measure. Acetyl-coenzyme A and S-adenosylmethionine concentrations with the marks they write; aconitase activity ratio as a cluster proxy; repair capacity functionally.

J.2. 2. With the endoplasmic reticulum

[E] What is exchanged. Calcium, at membrane contact sites, along with lipids; the contact extent is regulated and changes with stress.

[E] What fails. Excessive calcium transfer at these contacts opens the permeability transition and commits the cell to death; too little impairs mitochondrial dehydrogenases, which are calcium-activated.

[F] What to measure. Contact extent by proximity reporters or electron microscopy; compartment-targeted calcium sensors in both organelles simultaneously.

J.3. 3. With the lysosome

[E] What is exchanged. Damaged mitochondria themselves, by a dedicated autophagic route, and metabolites in both directions at contact sites.

[VOL p.510] **[E] What fails.** Lysosomal dysfunction produces accumulation of damaged mitochondria, which is the mechanistic link between lysosomal storage disease and mitochondrial dysfunction — two disease classes usually taught apart.

[F] What to measure. Mitophagy flux with tandem fluorescent reporters; lysosomal pH; the ratio of damaged to total mitochondria.

J.4. 4. With the peroxisome

[E] What is exchanged. Fatty acid oxidation products: very long chain fatty acids are shortened in the peroxisome and handed to the mitochondrion for completion. Both compartments also handle hydrogen peroxide.

[F] What fails. Peroxisomal failure sends unprocessed substrates to a compartment that cannot handle them, and raises oxidative load in both.

[F] What to measure. Chain-length profiling of acylcarnitines; peroxide with compartment-targeted sensors.

J.5. 5. With the plasma membrane

[E] What is exchanged. Energetic status, by way of the ATP-sensitive channels and the energy-sensing kinase; and, in specialized cells, direct positional coupling to transport activity.

[F] What fails. A cell that cannot make ATP cannot run its pumps, and the first readouts are gradients: potassium, calcium, pH.

[F] What to measure. Compartment-targeted ATP sensors alongside membrane potential.

J.6. 6. With the cytoskeleton

[E] What is exchanged. Position. Mitochondria are transported along microtubules by motor complexes with adaptor proteins, and their placement determines where ATP and calcium buffering are available.

[F] What fails. In long cells — neurons above all — a transport failure produces an energetic failure at the far end with normal mitochondria elsewhere, which is a spatial disease with no biochemical lesion.

[F] What to measure. Live imaging of mitochondrial transport; axonal ATP gradients.

[VOL p.511] ## J.7. 7. With the Golgi

[E] What is exchanged. Lipid species and vesicle traffic, with the Golgi's manganese- and ATP-dependent glycosylation machinery dependent on upstream energy supply.

[F] What fails. Glycosylation is energetically expensive and is among the first processes to show defects under energetic restriction, producing congenital-disorder-of-glycosylation-like phenotypes without a glycosylation gene mutation.

[F] What to measure. Glycan profiling under graded energetic restriction.

J.8. 8. With the ribosome and the translational machinery

[E] What is exchanged. Clusters and thiolated wobble bases, both from the same desulfurase relay; and the energetic currency translation consumes.

[F] What fails. Frame fidelity, by the mechanism of Chapter 7, together with respiratory capacity, by the mechanism of Chapter 20. The two fail together because they draw on one supply.

[F] What to measure. Thiolation extent and frameshifting with cluster status in the same cells.

J.9. 9. With the secretory vesicles

[E] What is exchanged. Calcium and energetic support for regulated exocytosis; in insulin secretion the coupling is direct, with the metabolic signal itself triggering release.

[F] What fails. Secretion becomes uncoupled from the metabolic state it is supposed to report, which in the beta cell is the pathophysiology of one class of diabetes.

[F] What to measure. Secretory response to a metabolic ramp, with ATP sensors in the same cells.

J.10. 10. With the centrosome

[E] What is exchanged. Energetic and redox support for the assembly and duplication cycle, and positional coupling during division.

[F] What fails. Division errors under energetic restriction, producing aneuploidy without any mutation in a mitotic gene.

[F] What to measure. Mitotic error rate against energetic state in the same cells.

[VOL p.512] ### J.11. 11. With the nucleolus and ribosome biogenesis

[E] What is exchanged. The energetic and nucleotide supply for ribosome assembly, which is among the most expensive processes a growing cell runs.

[F] What fails. Ribosome biogenesis stalls, which triggers a nucleolar stress response and stabilizes p53 — a route from energetic restriction to cell cycle arrest with no DNA damage involved.

[F] What to measure. Nucleolar morphology and pre-ribosomal RNA processing under graded restriction.

J.12. 12. With the extracellular space

[E] What is exchanged. Released mitochondrial components — DNA, formylated peptides, cardiolipin — which are recognized by innate immune receptors as damage signals, because they retain their bacterial character.

[F] What fails. Chronic release produces sterile inflammation, which is the mechanistic bridge between mitochondrial dysfunction and inflammatory disease.

[F] What to measure. Circulating cell-free mitochondrial DNA with inflammatory markers.

J.13. What the set establishes

[F] Each conversation is separately documented. Treating them as one object yields the result that matters for Part Six: a compartment that supplies irreplaceable chemistry to twelve others cannot fail locally, and its failures will therefore appear as diseases of several organ systems with no single causal gene. That is the clinical signature of mitochondrial disease, and it is also, this volume argues, a substantial part of the signature of aging.

[VOL p.513] **CHAPTER K**

The Eight Nucleotides and the Twenty-One Charging Systems

Two reference sets are collected here: the eight nucleotide species of de novo synthesis, one entry each, and the twenty-one charging systems, one line each.

K.1. The eight nucleotides, one entry each

Inosine monophosphate

[E] The trunk of purine synthesis, made in ten steps from phosphoribosyl pyrophosphate at roughly six high-energy phosphate equivalents, and the obligatory precursor of both adenine and guanine nucleotides. Its base is hypoxanthine. It has no letter.

[F] It is also, in nucleoside form, the product of adenosine deamination in RNA and of adenine base editing in DNA, the base at wobble position 34 that widens codon recognition, the mark that distinguishes self from foreign transcripts, and the species that accumulates at a deaminated chromosome end. One molecule, five roles, no symbol.

Xanthosine monophosphate

[E] Made from the trunk by IMP dehydrogenase, the rate-limiting step of guanine nucleotide synthesis and the target of mycophenolate and ribavirin. Converted to guanosine monophosphate by GMP synthase. Its base, xanthine, is also the penultimate species of purine degradation and the one that accumulates in xanthinuria.

Adenosine monophosphate

[E] Made from the trunk with aspartate, using GTP, through adenylosuccinate and its lyase.

Letter A, element hydrogen in the volume’s key. The parent of ADP and ATP, whose three states the stop-codon reading of Chapter 6 concerns, and the nucleotide moiety of coenzyme A, NAD, FAD and S-adenosylmethionine.

[VOL p.514] ### Guanosine monophosphate

[E] Made from the xanthine nucleotide by amination, using glutamine and ATP. Letter G, element nitrogen. The parent of GTP, which drives the adenine branch and the molybdenum cofactor’s first step.

Orotidine monophosphate

[E] The pyrimidine gate: orotate joined to the sugar by orotate phosphoribosyltransferase and decarboxylated to uridine monophosphate by one of the most proficient enzymes known. No letter. Its accumulation in urine is the diagnostic for UMP synthase deficiency.

Uridine monophosphate

[E] The parent pyrimidine; everything else in the series is made from it. Letter U, element phosphorus. Its triphosphate is aminated to the cytidine form; its deoxy form is methylated to thymidine.

Cytidine triphosphate

[E] Made from UTP by CTP synthase, a glutamine amidotransferase whose deficiency produces a human immunodeficiency. Letter C, element carbon. Its deamination to uridine is the most frequent spontaneous base damage in DNA.

Thymidine monophosphate

[E] Made from dUMP by thymidylate synthase, which activates the pyrimidine ring with a conserved active-site cysteine and transfers a methyl group from the folate pool. Letter T, element sulfur in the volume's key — although its own synthesis, not its structure, is what depends on sulfur chemistry.

K.2. The twenty-one charging systems, one line each

amino acid synthetase class what the system reads what separates it from its nearest neighbor Alanine II G3-U70 and position 73 one base pair from glycine's set

[VOL p.515]

amino acid	synthetase class	what the system reads	what separates it from its nearest neighbor
Arginine	I	the D arm, position 73, one anticodon base	the only system reading the D arm
Asparagine	II	acceptor end and anticodon	one nucleotide from aspartate
Aspartate	II	acceptor end and anticodon	one nucleotide from asparagine
Cysteine	I	acceptor end and anticodon	its amino acid is the volume's subject, its determinants are ordinary
Glutamine	I	acceptor end and anticodon	one nucleotide from glutamate; charged indirectly in many systems
Glutamate	I	acceptor end and anticodon	one nucleotide from glutamine
Glycine	II	G3 and position 73	one base pair from alanine's set
Histidine	II	an added G at position -1	reads a base that is not in the gene
Isoleucine	I	anticodon and acceptor end	one nucleotide from methionine; heavy editing domain
Leucine	I	the long variable arm	reads structure, not sequence
Lysine	II	anticodon and acceptor end	its codon family's atom string is pure hydrogen
Methionine	I	anticodon and acceptor end	one nucleotide from isoleucine; the start codon's system
Phenylalanine	II	anticodon and acceptor end	conserved across domains
Proline	II	acceptor end and anticodon	the one imino acid
Serine	II	the long variable arm	reads structure, not sequence; two codon boxes

Threonine II		acceptor end and anticodon	discriminates against valine chemically
Tryptophan	I	anticodon and acceptor end	a single codon
Tyrosine	I	acceptor end and anticodon	class I enzyme charging an aromatic
Valine	I	anticodon and acceptor end	one methylene from isoleucine at the amino acid level
Selenocysteine	none of its own	charged as serine, then converted on the transfer RNA	the twenty-first, inserted at a recoded stop

Table. The twenty-one systems in summary (Chapters 9 to 11). The plates of Chapter 10 give each in full.

[VOL p.516] **CHAPTER L**

The Twenty-Five Chapters in Brief

Each chapter in one entry: what it claims, what it rests on, and what it hands to the chapters that follow. A reader deciding where to start can read these thirteen and the thirteen in the second half, then open the volume where it matters to them.

Chapter 1. The Three-Legged Stool

[F] Claims. The unit of genetic information is the nucleotide rather than the letter; the supply line that manufactures nucleotides runs on sulfur chemistry; and both operate inside an architecture of thirteen compartments with one exclusive supplier. The three claims hold each other up and fail together.

[F] Rests on. Nothing yet: the chapter states the argument and the apparatus. Its support is the remaining twenty-four chapters.

[F] Hands on. The evidence tags, the color convention, the continuous section numbering and the chain of links in the front matter, all of which are used throughout.

Chapter 2. The Seven Colors

[F] Claims. A mechanically applied element index measures the chemistry of a corpus rather than its vocabulary, and the resulting registers are evidence rather than decoration.

[F] Rests on. The chemistry of the seven elements and the rules of application, both stated in full.

[F] Hands on. The base-element assignment that makes the codon-to-atom translation of Chapter 6 possible, and the element keying used for compartments in Chapter 16.

Chapter 3. The Arc in Twelve Stages

[F] Claims. The material is legible in the order the universe ran rather than the order it was written, and the same small set of arguments recurs at several stages.

[E] Rests on. Radiometric and isotopic dating for the planetary stages; phylogenetic inference for enzyme classes; chemical plausibility, marked as such, for the prebiotic links.

[F] Hands on. The ordering principle of Part Five and the backbone of Chapter 21's chain.

[VOL p.517] **Chapter 4. Correcting the Central Dogma**

[F] Claims. Beginning the chain at the nucleotide rather than at DNA adds a supply line with a rate, a cost, gatekeepers and failure modes that are not mutations.

[E] Rests on. Textbook nucleotide metabolism; the established literature on pool imbalance, replication stress and antimetabolite pharmacology.

[F] Hands on. The premise of Chapter 5 and the clinical framing of Chapter 12.

Chapter 5. Eight Nucleotides and Three One-Way Gatekeepers

[E] Claims. De novo synthesis builds eight species through three irreversible gates, and the three gates have no letters.

[E] Rests on. The biosynthetic pathways and the inherited deficiencies that mark each step.

[F] Hands on. The unlettered trunk base, which reappears in Chapters 7, 8, 14 and 15, and the exit enzyme whose cofactor is Chapter 24's case study.

Chapter 6. Codons Read as Atoms

[F] Claims. Every codon can be rewritten as a string of atoms; sulfur never appears in one, although two amino acids are built on it; and the three stop codons' hydrogen counts correspond to the three adenine-nucleotide states.

[E] Rests on. The genetic code; the established ordering of stop codon strictness and recodability; the chemistry of the adenine nucleotides.

[O] Hands on. A hypothesis with three falsifiable predictions, deliberately isolated so that nothing else depends on it.

Chapter 7. Wobble Position Thirty-Four

[E] Claims. One position carries two opposite chemical corrections — inosine widening recognition, 2-thiouridine narrowing it — and neither appears in a sequence record.

[E] Rests on. The wobble hypothesis and the modification literature, including the human disease phenotypes of the installing enzymes.

[F] Hands on. The shared-supply argument of Chapter 20 and the deaminase case of Chapter

14.

[VOL p.518] **Chapter 8. Four Letters for Eight Species**

[F] Claims. A four-symbol record can represent a substitution and nothing else; errors sort into three classes by their relation to the record; and effort is inversely distributed with respect to clinical importance.

[E] Rests on. The information content of the record and the catalog of modifications and protein-level states.

[F] Hands on. The engine of Part Four, applied in Chapters 13, 14 and 15.

Chapter 9. One Fold, Twenty-One Meanings

[E] Claims. All transfer RNAs share one fold and seventy-six positions; identity lives at eighteen of them, concentrated at the acceptor end; and two systems read positions not in the gene.

[E] Rests on. The identity-element literature and the structural biology of the synthetases.

[F] Hands on. The frame on which Chapter 10's plates are drawn.

Chapter 10. The Twenty-One Plates

[E] Claims. Each system is a separate solution to one recognition problem, and the plates show where each looks.

[E] Rests on. Published determinant sets, compiled onto one frame.

[F] Hands on. The difference table of Chapter 11.

Chapter 11. Side by Side

[F] Claims. Three pairs differ by one nucleotide; two systems read structure; one is read at a single base pair; and the amino acid is fixed at the acceptor end.

[E] Rests on. The plates and the editing and indirect-charging literatures.

[F] Hands on. The volume's general proposition that identity is set by a few atoms, restated in Chapters 22 and 24 at the protein level.

Chapter 12. What Is Mutated, What Kills

[E] Claims. Mutation is concentrated in few genes; the diseases that kill are diseases of flux; the modalities built on the code are validated by sequence.

[E] Rests on. Pan-cancer genomics, mortality statistics, and the published descriptions of clinical-stage modalities.

[F] Hands on. The clinical baseline for Part Four and the enrollment problem of Chapter 23.

[VOL p.519] ### Chapter 13. The Folding Problem Is an Occupancy Problem

[F] Claims. What was solved is sequence to backbone; what remains is cofactor occupancy, disulfide register, metal selection and redox state, and the residual is sulfur chemistry.

[E] Rests on. Structure prediction's demonstrated scope and the metalloprotein and redox literatures.

[F] Hands on. The measurement program of Appendix E and the mechanism of Chapter 22's switch.

Chapter 14. Three Modalities, One Instrument

[F] Claims. An acylated peptide's decisive features are uncoded; a deaminase editor's product reads as a different base and its ancestral reaction runs on RNA; a methylation writer's whole mechanism is sequence-neutral. One failure, three faces.

[E] Rests on. The medicinal chemistry of the peptides, the provenance of the editor's catalytic core, and the epigenetic editing literature.

[F] Hands on. A per-modality assay table and three falsifiers, each cheap.

Chapter 15. The End-Replication Gap

[E] Claims. The governing variable is the shortest telomere, which no sequence record can carry; the t-loop is a managed recombination intermediate whose failure deletes without mutating; and a loop runs from attrition through p53 to mitochondrial biogenesis, cluster supply and back to the helicase that protects the end.

[E] Rests on. Telomere biology, the shelterin and t-loop literature, and cluster biogenesis.

[O] Hands on. A loop whose gain is unmeasured, and seven named tests.

Chapter 16. The Atom and the Map

[F] Claims. Twelve registers, seven operations, thirteen compartments keyed to elements, and an uneven distribution of the eighteen groups across them.

[E] Rests on. The chemistry of each compartment and the disease genes that cluster at them.

[F] Hands on. The architecture used in Chapters 20, 22 and 23, and the volume's third leg in compact form.

Chapter 17. Eighteen Groups, the Ladder, the Silent Seventh

[E] Claims. The organizing structure is an oxidation ladder whose lower half is reversible; five biologically active classes are missing from the standard table; selenium is placed where the [VOL p.520] thiol ladder would overshoot.

[E] Rests on. Sulfur chemistry and the selenoprotein literature.

[F] Hands on. The reversible window within which every later claim about control operates.

Chapter 18. The Mitochondrion: Three Pillars

[E] Claims. A thioester at the one energy-conserving step of glycolysis; lipoate at both cycle dehydrogenases; clusters at every intermediate electron transfer; and two

exported currencies, both carried on sulfur.

[E] Rests on. Standard bioenergetics and the substrate-sensitivity literature for chromatin marks.

[F] Hands on. The energetic half of Part Five's case.

Chapter 19. Sulfur Inside the Genetic Machinery

[E] Claims. A thiyl radical makes every deoxyribonucleotide; cluster helicases open the helix for repair and replication; one element runs three chemistries at one anticodon position.

[E] Rests on. The ribonucleotide reductase mechanism and the helicase disease genetics.

[F] Hands on. The irreplaceability argument, and link three of Chapter 21's chain.

Chapter 20. The Mitochondrial Sulfur Economy

[E] Claims. Cluster assembly is mitochondrial and exclusive; one desulfurase supplies both clusters and wobble thiolation; the transsulfuration junction allocates a single sulfur budget among competing outputs.

[E] Rests on. Cluster biogenesis, the export step, and the transsulfuration literature.

[O] Hands on. The priority question — what the cell sacrifices first — and the propagation test of the compartment keying.

Chapter 21. The Chain from the Mineral to the Editor

[F] Claims. Seven links from an iron-sulfur mineral to the editing enzymes, each with a stated breaking condition, closing without a gap.

[E] Rests on. Mineral geometry, isotope records, enzyme class distributions, and the chemistry of the editors.

[O] Hands on. One open link, marked, which the rest of the chain does not need.

[VOL p.521] ### Chapter 22. Twenty-Seven Arrows from One Node

[E] Claims. One kinase node's output sorts unevenly across compartments; the seven operations map onto seven points of that architecture; the brake is thrown by a reversible disulfide; and a sulfonium sensor feeds growth signaling in parallel.

[E] Rests on. The signaling literature and the redox regulation of the phosphatase.

[F] Hands on. The architecture Chapter 23 reads the trial record against.

Chapter 23. Therapy Across the Fan

[F] Claims. Redundancy of output, not potency, predicts clinical benefit; six of seven therapeutic traditions are built on sulfur chemistry; editing escapes the redundancy argument but is bounded by the alphabet, by its own chemistry and by the cell that receives it.

[E] Rests on. The published randomized trial record and the chemistry of each tradition.

[F] Hands on. A scoring procedure and a standing prediction about trials not yet reported.

Chapter 24. One Cofactor Across the Whole Arc

[E] Claims. A cofactor built from a nucleotide in three sulfur steps serves the sulfur exit and the purine exit, and its three inherited failures grade by which atom is stranded.

[E] Rests on. The biosynthesis literature and the clinical genetics of the three deficiencies.

[F] Hands on. The volume's three legs meeting in one molecule, and a comparison with nitrogenase that dates an atmospheric transition.

Chapter 25. The Objection from the Amino Acids

[E] Claims. The two sulfur amino acids are late additions to the code; supply is not repertoire; four propositions survive the objection; and three levels of intervention follow — text, spoke, supply.

[E] Rests on. Consensus orderings of code assignment, the abiotic repertoire, observed codon reassignment, and the RNA composition of the ribosome's catalytic center.

[F] Hands on. Seven falsifiers, collected in Appendix C, and the volume's practical conclusion.

[VOL p.522] **CHAPTER M**

The Thirteen Themes, Stated as Claims

A theme, in this volume, is an argument that returns at more than one stage of the arc in more than one material. Thirteen were carried forward. Each is stated here as a claim, with where it enters, where it recurs, and what would show it to be an artifact rather than a feature of the subject.

M.1. T1. The substitution at the business end

[F] Claim. A molecule's identity in the record is its sequence; its behavior is set by the chemical state of a few atoms at the position where it acts. Change the state and the behavior changes while the record does not.

[F] Where it recurs. Inosine for guanosine at a wobble position (Chapter 7); selenium for sulfur at a peroxidase active site (Chapter 17); an oxidized cysteine pair at a lipid phosphatase (Chapter 22); a terminal sulfur on a molybdenum enzyme (Chapter 24).

[F] Artifact test. If in each case the chemical change were accompanied by a detectable sequence change, the theme would be a restatement of mutation. It is not:

in all four the sequence is unchanged.

M.2. T2. The supply line, not the text

[F] Claim. What limits a biological process is usually delivery of a part rather than the instruction to use it.

[F] Where it recurs. Nucleotide gates (Chapter 5); the desulfurase relay (Chapter 20); the cofactor built in three sulfur steps (Chapter 24); cluster-dependent repair (Chapter 19).

[F] Artifact test. The theme would be trivial if supply were never limiting. Antimetabolite pharmacology and the inherited supply diseases establish that it is.

M.3. T3. The unrepresentable quantity

[F] Claim. Some quantities governing cell fate have no place in a sequence record, not because the record is too shallow but because it is the wrong kind of object.

[F] Where it recurs. The shortest telomere (Chapter 15); cofactor occupancy (Chapter 13); promoter methylation state (Chapter 14).

[VOL p.523] **[F] Artifact test.** A sequencing method that reports any of these without a second chemistry would end the theme.

M.4. T4. Redundancy decides the outcome

[F] Claim. Whether removing a node matters depends on how many other routes its output has, and the number is set by architecture.

[F] Where it recurs. The signaling fan and the trial record (Chapters 22 and 23); the two arms of one cofactor (Chapter 24); the mitochondrion’s exclusivity (Chapter 20).

[F] Artifact test. A systematic scoring of targets finding no relationship with outcomes.

M.5. T5. The notation decides what can be seen

[F] Claim. A notation is not neutral: it determines which errors are detectable and which experiments look necessary.

[F] Where it recurs. Four letters for eight species (Chapters 5 and 8); off-target definitions (Chapter 12); the coded fraction of a peptide drug (Chapter 14).

[F] Artifact test. If the field’s practice already measured what the notation cannot carry, the theme would describe nothing. The survey proposed in Chapter 14 is the test.

M.6. T6. Reversibility is what makes a control element

[F] Claim. An element is a control element when its states interconvert under physiological conditions; irreversible chemistry is structure or damage, not control.

[F] Where it recurs. The oxidation ladder and its fuse (Chapter 17); the glycolytic switch (Chapter 18); the phosphatase disulfide (Chapter 22).

[F] Artifact test. A control function demonstrated for an irreversible sulfur species would require the claim to be rewritten.

M.7. T7. The compartment is the unit of organization

[F] Claim. Chemistry in a cell is organized by compartment, and failures stay local unless the compartment is a supplier.

[F] Where it recurs. The keying of thirteen organelles (Chapter 16); the twelve conversations (Appendix J); the organelle-sorted fan (Chapter 22).

[F] Artifact test. The propagation experiment of Chapter 20.

[VOL p.524] ## M.8. T8. The record is produced by chemistry it cannot describe

[F] Claim. The genome is manufactured, opened and read by chemistry that no sequence represents.

[F] Where it recurs. Ribonucleotide reductase and the cluster helicases (Chapter 19); wobble modification (Chapter 7); the untemplated CCA end (Chapter 9).

[F] Artifact test. An alternative route to any of these that uses no unrepresented chemistry.

M.9. T9. Old chemistry is poorly instrumented

[F] Claim. The oldest chemistry in the cell is the least well represented in the newest instruments.

[F] Where it recurs. Cluster occupancy, thiol state, modified bases, metabolite pools — all ancient, all absent from standard sequence-based practice.

[F] Artifact test. A technology survey showing that recent methods report ancient chemistry at least as well as they report sequence.

M.10. T10. The clinic prices the argument

[F] Claim. Where a structural claim about biology is right, it should show up in the trial record, because trials are the largest controlled experiments the field runs.

[F] Where it recurs. The hub-versus-spoke record (Chapter 23); the graded cofactor deficiencies (Chapter 24); the approved editing therapies as the proper domain of sequence intervention (Chapter 12).

[F] Artifact test. A record that is indifferent to the structural variable.

M.11. T11. Two systems, two clocks

[F] Claim. Metabolism and the coding system have independent histories, and a late entry in one says little about the other.

[F] Where it recurs. The late sulfur amino acids (Chapter 25); coenzymes as fossils (Chapter 25); the RNA core of the ribosome (Chapter 25).

[F] Artifact test. A demonstration that code assignment order tracks metabolic centrality.

M.12. T12. Geometry carries information that sequence does not

[F] Claim. Structure — fold, loop, contact, distance — carries regulatory information with no locus in the sequence.

[VOL p.525] **[F] Where it recurs.** The t-loop and telomere position effects (Chapter 15); the two charging systems that read an arm rather than a sequence (Chapter 11); contact sites between organelles (Appendix J).

[F] Artifact test. Each case resolving into a sequence determinant on closer examination.

M.13. T13. Enumeration beats assertion

[F] Claim. A body of work, a chain of argument or a set of claims is worth more enumerated than asserted, because only an enumeration can be checked.

[F] Where it recurs. The chain of links in the front matter; the falsifier table in Appendix C; the chapter-by-chapter claims in Appendix F; the corpus record in Appendix A.

[F] Artifact test. This theme is methodological rather than biological, and its test is whether anyone uses the enumerations to find an error. That is what they are for.

[VOL p.526] **CHAPTER N**

The Twelve Stages of the Arc

The twelve stages of the arc, each with what happened, what this volume takes from it, how it is dated, and what remains open.

N.1. Stage 1. The elements are made

[E] What happened. Hydrogen and helium from primordial nucleosynthesis; carbon, nitrogen and oxygen from stellar burning; sulfur principally from oxygen burning in massive stars and from thermonuclear supernovae; phosphorus in smaller yields from the same sites; selenium largely by neutron capture.

[F] What the volume takes. That the seven keyed elements have different cosmic histories and different abundances, and that phosphorus is scarce where sulfur is not — which bears on Chapter 21's claim that sulfur chemistry preceded phosphate chemistry.

[E] Dating. Spectroscopic and isotopic, with yields modeled.

[O] Open. Phosphorus delivery to the early Earth remains a live problem in origins research.

N.2. Stage 2. Molecules form in cold clouds

[E] What happened. Sulfur- and carbon-bearing molecules, including carbonyl sulfide and carbon monosulfide, form on grains and in the gas phase of dense molecular clouds, before the solar system condenses.

[F] What the volume takes. That sulfur's molecular chemistry predates the planet, which is where the two halves of the oxidation ladder are joined (Chapter 17).

[E] Dating. Observational, from radio astronomy of clouds at known evolutionary stages.

N.3. Stage 3. The planet accretes

[E] What happened. Accretion and differentiation around 4.5 billion years ago; the mantle and crust set the inventory available for everything after.

[F] What the volume takes. The inorganic starting conditions: iron, sulfur, phosphorus in mineral form.

[VOL p.527] N.4. Stage 4. The sulfidic ocean and its minerals

[E] What happened. Anoxic oceans, iron delivered hydrothermally, sulfide from sulfate reduction, and the precipitation of iron sulfide minerals including mackinawite and greigite.

[F] What the volume takes. The Fe4S4 cubane geometry, which is the geometry of the protein cluster — link one of the chain in Chapter 21.

[O] Open. Whether mineral surfaces catalyzed the first carbon fixation, as the strong form of the hypothesis holds.

N.5. Stage 5. The first nucleotides

[E] What happened. Prebiotically plausible routes to nucleotides have been demonstrated, several involving sulfur species; thiophosphate has been shown to phosphorylate.

[F] What the volume takes. That nucleotide chemistry was available before coded protein synthesis, which is the only dependency the volume needs from this stage.

[O] Open. Nearly everything else about this stage.

N.6. Stage 6. The RNA world

[E] What happened. A period in which RNA performed both information storage and catalysis; the ribosome's peptidyl transferase center, still RNA, is the strongest surviving evidence.

[F] What the volume takes. That catalysis preceded coded protein synthesis (Chapter 25), and that the nucleotide handles on modern cofactors are fossils of that

period.

N.7. Stage 7. The DNA transition

[E] What happened. Ribonucleotide reductase appeared, converting ribonucleotides into deoxyribonucleotides through a cysteine-based radical mechanism, and an archival genome became possible.

[F] What the volume takes. Link three of the chain, and the claim that the archival property of the genome is conferred by sulfur chemistry (Chapter 19).

[E] Dating. Relative, from the distribution of the three enzyme classes across the tree and their oxygen sensitivity.

[VOL p.528] ## N.8. Stage 8. The code is assigned

[E] What happened. Amino acids were assigned to codons over an extended period, with the sulfur amino acids among the later entries, and with the assignment made at the acceptor end of the transfer RNA rather than at the anticodon.

[F] What the volume takes. The objection of Chapter 25, stated at full strength, and the answer that supply is not repertoire.

[O] Open. The order of assignment at the deepest nodes.

N.9. Stage 9. The Great Oxidation

[E] What happened. Cyanobacteria changed the reductant of photosynthesis from hydrogen sulfide to water, releasing oxygen; atmospheric oxygen rose around 2.4 billion years ago.

[F] What the volume takes. That oxygen replaced sulfur's terminal acceptor and left every other sulfur function intact (Chapter 21), with the nitrogenase-to-molybdenum-cofactor comparison as the fossil (Chapter 24).

[E] Dating. Multiple proxies, with the loss of mass-independent sulfur isotope fractionation the sharpest.

N.10. Stage 10. The organelles are acquired

[E] What happened. Endosymbiosis produced the mitochondrion and, later in another lineage, the plastid; the endomembrane system elaborated.

[F] What the volume takes. The compartment map of Chapter 16, the exclusivity of cluster assembly (Chapter 20), and the retained bacterial features that make mitochondrial components immunostimulatory (Appendix J).

N.11. Stage 11. The human lineage

[E] What happened. Specific losses and inheritances, including the loss of functional uricase and the fusion that produced human chromosome 2.

[F] What the volume takes. The purine exit's clinical consequences (Chapter 24), and the general point that a lineage's deletions are as informative as its acquisitions.

[VOL p.529] ### N.12. Stage 12. The clinic

[F] What happened. The arc's chemistry is now priced in randomized trials, which are the largest controlled experiments the field runs.

[F] What the volume takes. The hub-versus-spoke record (Chapter 23), the graded cofactor failures (Chapter 24), and the approved editing therapies as the proper domain of sequence-level intervention (Chapter 12).

[O] Open. Whether the pattern this volume reads in the trial record survives the next cohort of readouts. That is the standing prediction, and it is the only one that cannot be accelerated.

[VOL p.530] ## CHAPTER O

A Short History of the Four-Letter Alphabet

The four-letter alphabet is so completely established that it is rarely described as a choice. It was one, and the sequence by which it became the field's notation explains both its power and the blind spot this volume is about.

O.1. How four letters became the notation

[E] The bases were chemistry before they were letters. Adenine, guanine, cytosine, thymine and uracil were isolated and characterized as compounds in the nineteenth and early twentieth centuries, and the nucleic acids were understood as polymers of nucleotides well before anyone proposed that they carried heredity.

[E] The letters entered with the structure. Once pairing was understood — adenine with thymine by two hydrogen bonds, guanine with cytosine by three — the chemically specific feature of each base, its pairing face, became the only feature that mattered for the model, and the molecule could be written as a string. That compression was the structure's main consequence for practice: it made heredity a problem in combinatorics.

[E] The code confirmed the compression. Assigning amino acids to triplets of letters produced a mapping that could be written as a table, taught in an hour and used without reference to any chemistry. By the time sequencing methods arrived, the letter was the unit in which every question was posed.

[F] Each step was correct and each step discarded information. The pairing face is not the whole base; the base is not the whole nucleotide; the nucleotide's geometry and charge are not in the letter. The discarded information was not needed for the questions the field was asking, which is why nobody missed it.

O.2. When the discarded information started to matter

[F] Four developments brought it back, in roughly this order.

• **Modified bases were cataloged.** What began as a handful of curiosities in transfer RNA [VOL p.531] became a catalog of more than one hundred and fifty

chemically distinct nucleosides, several of them essential and several of them read by sequencing as something they are not.

• **Epigenetics became mechanistic.** Methylation of the fifth carbon of cytosine turned out to be heritable, regulatory and oncogenic when misplaced, and invisible to the standard record without a dedicated chemistry.

• **Editing became therapeutic.** Agents whose mechanism is a chemical conversion of one base into another entered the clinic, and their product — in the adenine case, an unlettered base — is reported by the verification assay as a different letter.

• **Structure prediction succeeded.** Having solved sequence-to-backbone, the field could see clearly what remained: occupancy, register, metal and redox state, none of which is a sequence property.

[F] Each development was absorbed by building a dedicated second instrument for one case — bisulfite conversion for methylation, chemical methods for inosine, mass spectrometry for modified nucleosides — without revising the underlying notation. That is the field's present position: a four-letter record, a set of special-purpose chemistries for particular exceptions, and a validation practice standardized around the record.

O.3. What a corrected notation would have to carry

[F] The volume does not propose a new alphabet, because a notation is not adopted by argument.

But it is worth stating what a sufficient record would contain, since the gap between that list and the present record is the volume's subject.

• **Molecular identity, not letter identity.** Inosine recorded as inosine, not as guanosine.

• **Modification state per position.** Methylation, hydroxymethylation, thiolation and the rest, recorded as a property of the position rather than inferred from a separate assay.

• **The unlettered species.** Hypoxanthine, xanthine and orotate have no symbols, although two of the three are obligatory metabolic gates and all three appear in cells.

• **The state variables of the compartment.** Pool composition, thiol poise, cofactor occupancy: not properties of the polymer, and not recordable in it, but required to interpret it.

[F] The first two are notational and could in principle be adopted; nanopore methods already produce data of that kind. The last is not notational at all: it is a statement that the sequence record must be accompanied by a state record, which is the practical recommendation of Appendix E.

[VOL p.532] ## O.4. A closing observation

[F] Notations are adopted because they make a class of problems tractable, and they are abandoned when that class is exhausted. The four-letter alphabet made heredity tractable and has not been exhausted: it is still the right instrument for the questions it was built for, and the approved editing therapies for hemoglobinopathies are the proof. What has changed is that the field has begun to ask questions outside that class while keeping the instrument, and the mismatch is the subject of Part Four.

[VOL p.533] **CHAPTER P**

Notation and Conventions

The conventions used throughout, collected for reference.

P.1. Evidence tags

[E] Every paragraph in the body carries a tag in the margin. **[E]** marks a statement established in the published literature and not original to this volume. **[F]** marks a statement argued, derived, computed or assembled here. **[O]** marks a question left open. Reading only the [F] paragraphs of a chapter gives exactly what is being claimed beyond the record.

P.2. Color

[E] Seven elements carry colors, applied as a pale field behind the word: hydrogen red, carbon blue, nitrogen green, oxygen orange, phosphorus purple, sulfur yellow, selenium indigo.

Each color also carries a base: adenine, cytosine, guanine, hypoxanthine and inosine, uracil, thymine, and xanthine with orotate respectively.

[E] The field follows the word root, so everything built on sulfur takes yellow — sulfide, sulfonium, thioester, every thio- term, and the two sulfur amino acids — while selenocysteine takes indigo, selenium being its defining element. A compound word takes one color whole.

[E] Base letters are colored wherever they act as base symbols: in prose, in headings, in table cells, in pairs such as G-C, and in codons, where each letter takes its own color. Letters that are not base symbols stay plain: the molecule-class names DNA, RNA, mRNA, tRNA and rRNA; Roman numerals; and one-letter amino acid codes in parentheses.

[E] Elements without a row carry no color. Iron, molybdenum, zinc, magnesium, manganese, copper, calcium and potassium all appear and all print plain, so an iron-sulfur cluster prints as its sulfur.

[VOL p.534] ## P.3. Atom strings

[F] Where a codon is written as a string of atomic symbols — AUG as hydrogen, phosphorus, nitrogen — the symbols carry the color of the element they name, which is the same color as the base they came from. The translation is set out in Chapter 6.

P.4. Numbering and cross-reference

[E] Sections are numbered continuously across all twenty-five chapters rather than restarting, so a reference of the form §117 is unambiguous. In the digital file every such reference is a link. Figures are numbered within their chapter; tables are captioned where they fall.

[E] Chapters are referred to by number. Parts are referred to by name where the name is informative and by number otherwise.

P.5. Tables

[E] Tables carry a bold navy header with a single thin rule beneath it, no vertical rules and no cell borders. A caption beginning **Table.** follows the table where one is needed.

P.6. What is not used

[F] Three conventions common in the literature are deliberately absent. There are no numbered citations in the body; sources are named in the text and the practice is explained in the Sources appendix. There are no footnotes; material worth saying is said in the paragraph or in the chapter notes. And there is no hedging apparatus of the form ”it may be that” attached to claims the volume is willing to make: a claim that is uncertain carries an [O] tag, and a claim that is made carries [F].

[VOL p.535] **CHAPTER Q**

The Seven Operations in Detail

The seven operations are the volume’s claim that sulfur’s versatility is bounded: whatever scale it is operating at, the element is doing one of seven things. Each is set out here with its chemistry, its principal carriers, what it decides, how it fails, and how it is measured.

Q.1. 1. Carries electrons reversibly

[E] Chemistry. The thiol-disulfide couple, with two electrons and two protons exchanged between a pair of thiols and a disulfide. Midpoint potentials of biological couples span a range wide enough to set different compartments to different poise.

[E] Carriers. Glutathione, thioredoxin, glutaredoxin, peroxiredoxin.

[F] What it decides. The redox tone of each compartment, and therefore the activity of every protein whose function depends on a reactive cysteine — including the phosphatase of Chapter 22 and the glycolytic enzyme of Chapter 18.

[E] How it fails. Oxidation past the fuse, which converts a switch into a lesion; or depletion of the reducing systems, which leaves the couple stuck.

[F] How it is measured. Compartment-targeted genetically encoded sensors; glutathione concentration and ratio together; redox proteomics for site-level state.

Q.2. 2. Forms reversible covalent cross-links

[E] Chemistry. Disulfide bond formation between two cysteines, intramolecular or intermolec-ular, with exchange catalyzed by isomerases.

[E] Carriers. Protein cysteines, particularly in the secretory pathway and at the surface.

[F] What it decides. Tertiary and quaternary structure for secreted and membrane proteins; and, where the bond is regulatory, the on-off state of the protein. Insulin, antibodies and keratin are structural instances; the phosphatase brake is a regulatory one.

[E] How it fails. Mispairing during folding, which is a manufacturing failure mode; or inappro-priate oxidation in the wrong compartment.

[F] How it is measured. Non-reducing gels, differential alkylation, and for manufactured products intact-mass and peptide mapping.

[VOL p.536] ## Q.3. 3. Holds metals

[E] Chemistry. Thiolate ligation of iron in clusters, of zinc in structural sites, and of molybdenum through a dithiolene. Sulfur's softness as a donor matches these metals' preferences.

[E] Carriers. Iron-sulfur clusters, zinc fingers, the molybdenum cofactor.

[F] What it decides. Electron transfer in respiration; structural integrity in a large class of transcription factors; catalysis at two metabolic exits. Also, through the cluster helicases, whether DNA repair proceeds.

[E] How it fails. Cluster loss on oxidation; mismetallation when the compartment's metal availability shifts; failure of assembly machinery upstream.

[F] How it is measured. Spectroscopy, aconitase activity ratio, inductively coupled plasma mass spectrometry, native mass spectrometry.

Q.4. 4. Transfers acyl groups

[E] Chemistry. The thioester, whose high free energy of hydrolysis derives from the long, nearly nonpolar carbon-sulfur bond and the absence of the resonance stabilization an oxygen ester enjoys.

[E] Carriers. Coenzyme A, the lipoyl arm, acyl carrier protein, and the covalent intermediate of glyceraldehyde-3-phosphate dehydrogenase.

[F] What it decides. Entry to the citric acid cycle, fatty acid synthesis and oxidation, and every acetylation mark on chromatin.

[E] How it fails. Coenzyme A depletion, impaired lipoylation, or oxidation of the catalytic cysteine of the glycolytic enzyme.

[F] How it is measured. Acyl-coenzyme A quantitation by mass spectrometry; lipoylation by immunoblot.

Q.5. 5. Carries methyl groups

[E] Chemistry. The sulfonium center of S-adenosylmethionine, a positively charged tri-coordinate sulfur that makes the attached methyl group electrophilic and transferable.

[E] Carriers. S-adenosylmethionine, with S-adenosylhomocysteine as the product and inhibitor.

[F] What it decides. Every methylation in the cell — DNA, histones, RNA caps, small molecules — and, through the sulfonium sensor, one input to growth signaling.

[VOL p.537] **[E] How it fails.** Depletion of the donor through limited methionine or one-carbon supply, or accumulation of the product, which inhibits transfer.

[F] How it is measured. The methylation index, by mass spectrometry, reported with the marks it writes.

Q.6. 6. Tunes recognition

[E] Chemistry. Substitution of sulfur for oxygen in a pyrimidine ring, changing hydrogen bonding capacity and biasing sugar pucker.

[E] Carriers. 2-thiouridine at anticodon position 34, and related thiolated nucleosides.

[F] What it decides. Codon-anticodon pairing strength and therefore reading frame fidelity, which makes translational accuracy partly a function of sulfur supply.

[E] How it fails. Loss of the thiolation machinery or of the sulfur relay, producing frameshifting and, in humans, mitochondrial disease.

[F] How it is measured. Thiol-specific gel retardation; nucleoside mass spectrometry; frameshifting reporters.

Q.7. 7. Absorbs oxidative damage

[E] Chemistry. Sacrificial oxidation of thiols to sulfenic acid and disulfide, with subsequent reduction at the cost of NADPH; the peroxiredoxin cycle is the highest-flux example.

[E] Carriers. Glutathione, thioredoxin, peroxiredoxins, and — where a thiol would be destroyed — selenocysteine in the glutathione peroxidases.

[F] What it decides. Whether an oxidative episode is survived as a signal or recorded as damage; and, in engineered cell therapies, how long the cells persist.

[E] How it fails. Hyperoxidation past the fuse; depletion of the reducing systems; selenium deficiency at the positions where selenocysteine is required.

[F] How it is measured. Peroxiredoxin oxidation state by non-reducing gel; glutathione pools; compartment-targeted peroxide sensors.

Q.8. Why exhaustiveness matters

[F] The list is offered as complete, and completeness is what makes it a claim rather than a catalog. A documented sulfur function that fits none of the seven would break it, and the candidate [VOL p.538] most often raised — gasotransmitter signaling by hydrogen sulfide — resolves on inspection into persulfidation of protein cysteines, which is operation two.

[VOL p.539]

CHAPTER R

Genes and Proteins Named in This Volume

Genes and proteins named in this volume, with what they do and where they appear. Names are given as they are used in the human literature.

Nucleotide metabolism

•

PPAT. Phosphoribosyl pyrophosphate amidotransferase; the committed step of de novo purine

synthesis (Chapter 5).

•

IMPDH1, IMPDH2. IMP dehydrogenase isoforms; the gate to guanine nucleotides and the target of mycophenolate. IMPDH1 mutation causes a retinal dystrophy (Chapter 5).

•

ADSL. Adenylosuccinate lyase; its deficiency produces a severe neurological disorder (Chapter 5).

•

UMPS. UMP synthase, bifunctional; its deficiency is hereditary orotic aciduria (Chapter 5).

•

DHODH. Dihydroorotate dehydrogenase; the inner-membrane enzyme linking pyrimidine supply to the respiratory chain (Chapter 5).

•

HPRT1, APRT. Salvage enzymes for hypoxanthine and guanine, and for adenine; HPRT1 deficiency is Lesch-Nyhan syndrome (Chapter 5).

•

TYMS. Thymidylate synthase; the target of 5-fluorouracil, and the enzyme whose active-site cysteine makes thymine (Chapters 4 and 5).

•

RRM1, RRM2.

Ribonucleotide reductase subunits; the target of hydroxyurea and gemcitabine (Chapter 19).

•

XDH. Xanthine dehydrogenase/oxidase; the purine exit, carrying the molybdenum cofactor and its terminal sulfur (Chapter 24).

Sulfur metabolism and cofactor assembly

•
CBS, CTH. Cystathionine beta-synthase and cystathionine gamma-lyase; the transsulfuration junction, and sources of hydrogen sulfide (Chapter 20).
•
NFS1. The mitochondrial cysteine desulfurase; the shared supplier for cluster assembly and wobble thiolation (Chapter 20).
•
FXN. Frataxin; cluster assembly machinery, deficient in Friedreich ataxia (Chapter 20).

[VOL p.540]

•	**ABCB7.** The inner-membrane transporter exporting the sulfur species required by cytosolic cluster assembly (Chapter 20).
•	**MTU1 (TRMU).** Mitochondrial thiouridylase; installs the thiolated wobble base, and its mutation causes acute infantile liver failure (Chapter 7).
•	**ADAT2, ADAT3.** The eukaryotic deaminase that writes inosine at anticodon position 34 (Chapter 7).
•	**MOCS1, MOCS2, GPHN.** Molybdenum cofactor biosynthesis genes; their failure produces molybdenum cofactor deficiency, with one subtype treatable (Chapter 24).
•	**SUOX.** Sulfite oxidase; the sulfur exit, whose isolated deficiency is nearly as severe as com plete cofactor deficiency (Chapter 24).
•	**GPX1-GPX4, TXNRD1-TXNRD3.** Selenoproteins of the peroxide and thioredoxin systems; selenocysteine at the catalytic position (Chapter 17).
Genome maintenance	
•	**ERCC2 (XPD), BRIP1 (FANCJ), RTEL1, DDX11.** The iron-sulfur helicase family; each with its own human disease, and each holding its wedge with a cluster (Chapter 19).
•	**TERT, TERC.** Telomerase components (Chapter 15).
•	**TERF1, TERF2, POT1, TINF2, ACD, TERF2IP.** Shelterin components, which stabilize the t-loop (Chapter 15).
•	**XRCC3.** A recombination factor implicated in resolution of the telomeric loop (Chapter 15).
•	**TP53.** The most frequently mutated gene in human cancer, and the node linking telomere attrition to mitochondrial biogenesis through the PGC-1 coactivators (Chapters 12 and 15).
Signaling	
•	**AKT1, AKT2, AKT3.** The kinase isoforms at the center of the output fan (Chapter 22).
•	**PIK3CA.** The lipid kinase catalytic subunit; among the most frequently mutated genes in human cancer (Chapter 22).
•	**PTEN.** The lipid phosphatase; the brake, inactivated by deletion, by mutation, by promoter methylation and by a reversible disulfide (Chapter 22).
•	**MTOR, TSC1, TSC2, RPTOR.** The growth complex and its regulators (Chapter 22).

•	**SAMTOR.** The sulfonium sensor gating the growth complex on methionine status (Chapter 22).
•	**FOXO1, FOXO3, BAD, MDM2, GSK3B.** Representative outputs of the fan, executed in different compartments (Chapter 22).

[VOL p.541]

•	**PPARGC1A, PPARGC1B.** The PGC-1 coactivators of mitochondrial biogenesis, repressed by p53 (Chapter 15).
Editing and modification	
•	**ADAR1, ADAR2.** The RNA adenosine deaminases, editing at millions of transcriptome sites (Chapter 14).
•	**TadA.** The bacterial transfer RNA adenosine deaminase whose evolved variant is the catalytic core of adenine base editors (Chapter 14).
•	**DNMT1, DNMT3A, DNMT3B.** DNA methyltransferases; DNMT1 is the maintenance en zyme that makes an epimutation heritable (Chapter 14).
•	**TET1, TET2, TET3.** The dioxygenases that oxidize 5-methylcytosine, producing the inter mediates of active demethylation (Chapter 8).
•	**Cas9 and its relatives.** The nucleases; cutting is magnesium chemistry, which is the division of labor drawn in Chapter 21.

[VOL p.542] **CHAPTER S**

Twenty Questions This Volume Does Not Answer

A volume that states only what it can answer gives a false picture of its subject. These twenty questions arise directly from the argument, are not answered here, and are in most cases answerable with existing methods.

S.1. About supply

[O] 1. If the nucleotide rather than the letter is the unit, how much of the variance currently attributed to sequence is attributable to supply? The study design is isogenic lines with controlled nucleotide availability, sequence held constant, phenotype measured. Nobody has run it with supply as the independent variable.

[O] 2. What is the priority order among the outputs of the transsulfuration junction? When sulfur is scarce, does the cell protect glutathione, cluster assembly, wobble thiolation or cofactor synthesis first, and is the order chemical or regulated?

[O] 3. Does a thymine produced by base editing behave identically, over many divisions, to one made by thymidylate synthase? The difference is in the one-carbon economy and in the repair history at that position, and no comparison has been published.

[O] 4. What is the sulfur flux required for wobble thiolation in a dividing human cell, and how does it compare with the flux into glutathione?

[O] 5. Does partial occupancy of the terminal sulfur ligand on xanthine dehydrogenase contribute to population variation in urate handling?

S.2. About the record

[O] 6. Across clinical-stage agents, what fraction have validation packages capable of detecting their own principal chemical liability? The survey is feasible from public documents.

[O] 7. How much of the inosine reported as guanosine in sequencing data, in any given experiment, is still inosine in the molecule? The chemistry to distinguish them exists and is rarely applied.

[O] 8. How many human charging systems have a modification-dependent identity component that transcript-based mapping missed?

[VOL p.543] **[O] 9.** What would a record that carried molecular identity rather than letter identity cost, in storage and in sequencing effort, and is the cost the reason it does not exist?

[O] 10. Is there a class of therapeutic agent for which sequence validation is genuinely complete?

Constructing the strongest example would bound this volume's argument from the other side.

S.3. About architecture

[O] 11. Is the thirteen-compartment keying a discovered regularity or a successful imposition?

The propagation experiment of Chapter 20 would settle it in one study.

[O] 12. Does the redundancy score of a drug target predict clinical outcome across the historical trial record? The data are public; the analysis has not been published.

[O] 13. When sulfur supply fails, is the resulting phenotype dominated by respiration, by translation, or by repair — and does the answer differ by tissue?

[O] 14. What is the gain around the telomere-mitochondrion-cluster-helicase loop? Below one, it modifies aging; near one, it drives it.

[O] 15. Do membrane contact sites between the mitochondrion and other compartments change in extent in a coordinated way under sulfur restriction, as a shared-supply model would predict?

S.4. About history

[O] 16. Did the iron-sulfur cluster descend from a mineral unit, or is the shared geometry convergence? The structures agree; the inference does not follow from them alone.

[O] 17. Was the order of amino acid addition to the code driven by availability, by biosynthetic cost, or by the chemistry each addition made possible?

[O] 18. Are cluster-dependent enzymes systematically older than their cluster-independent functional equivalents?

S.5. About the volume itself

[O] 19. Do the thirteen recurring arguments appear in literatures this volume does not cover? A theme that recurs outside its own corpus is better evidence than one that recurs inside it.

[O] 20. Is the stop-codon reading of Chapter 6 a signal or a coincidence of the color scheme?

Three predictions are stated, one of which is already exposed to the entire comparative genomic record.

[VOL p.544] ### S.6. Why these are printed

[F] Each question above was reached by following the argument to a point where the evidence stops. Printing them serves two purposes: it marks the boundary of what the volume claims, and it gives a reader something to do that is more useful than agreement. Several of the twenty could be answered in a semester.

[VOL p.545] ## CHAPTER T

Reading This Volume from Another Field

The volume crosses a dozen literatures, and a specialist in any one of them will find parts familiar and parts elementary. This appendix says, field by field, which chapters are likely to be new, which are introductory and can be skimmed, and what the volume is asking of that field.

T.1. For the molecular biologist

[F] Skim. Chapters 4, 5 and 9, which set out nucleotide metabolism and transfer RNA structure from first principles for readers outside the field.

[F] Read closely. Chapter 8, for the three-class account of off-target error; Chapter 13, for what structure prediction does not cover; Chapter 14, for the provenance of the deaminase used in clinical editors.

[F] What is asked. That validation be matched to chemistry rather than to convention, and that the molecule produced by an edit be reported as a molecule rather than as a letter.

T.2. For the clinical oncologist or trialist

[F] Skim. Part Five, except Chapter 20, unless the chemistry is of interest.

[F] Read closely. Chapter 22 on the redox inactivation of a tumor suppressor; Chapter 23 on redundancy of output as a predictor; Chapter 12 for the framing.

[F] What is asked. That targets be scored for output distribution before potency, and that where a target’s activity can be set chemically, enrollment stratify on the

chemistry. Both are cheap relative to a trial.

T.3. For the biochemist

[F] Skim. Chapters 1 through 3, which are framing.

[F] Read closely. Chapter 17 on the oxidation ladder and the reversible-irreversible boundary; Chapter 19 on the three irreplaceable steps; Chapter 24 on one cofactor across two exits.

[F] What is asked. That the reversible window be treated as the location of the signaling-damage distinction, and that the fuse be measured for specific proteins rather than assumed.

[VOL p.546] T.4. For the structural biologist

[F] Read closely. Chapter 13 in full, and Appendix E's occupancy section.

[F] What is asked. That occupancy, register and metal identity be reported alongside structure where they are known, and that prediction efforts state explicitly which of them they do and do not address.

T.5. For the geochemist or origins researcher

[F] Skim. Parts Three and Four.

[F] Read closely. Chapter 21's seven links with their breaking conditions, and the twelve stages of Appendix N.

[F] What is asked. Correction, chiefly. The volume takes the weak form of the mineral and prebiotic claims and marks them open; a specialist who can sharpen or break either link would improve the chain.

T.6. For the computational biologist

[F] Read closely. Chapter 8 on what a four-symbol record can hold; Chapter 15 on an order statistic that no string can carry; the redundancy scoring procedure in Chapter 23's notes.

[F] What is asked. Three analyzes that need no laboratory: target scoring against trial outcomes, a validation-package survey, and a search for any organism that has reassigned UAA.

T.7. For the clinician outside oncology

[F] Read closely. Chapter 24, which is a worked diagnostic example; Chapter 5 for why three inherited diseases present as they do; Appendix S for the gene and protein names.

[F] What is asked. That the chemistry be read before the sequence where chemistry is faster and decides treatment, as in the cofactor deficiency of Chapter 24.

T.8. For a reader from outside biology

[F] Read. Chapters 1, 2, 3, 8 and 25, and Appendix O on the history of the four-letter alphabet. Together they give the argument as an argument about notation, measurement and what an instrument can see, with the biology as the case material.

[F] What is asked. Nothing in particular, except the judgment of someone who is not inside the field's assumptions, which this volume holds to be the most useful kind of reader it can have.

[VOL p.547] **CHAPTER U**

The Twenty-Seven Arrows, Itemized

The output fan of Chapter 22 is given here arrow by arrow, filed by the compartment in which the output is executed rather than by the pathway it is usually assigned to. For each: the substrate or effector, what the output does, how many independent routes the cell has to the same output, and the consequence for inhibiting the node.

U.1. At the nucleus

[E] 1. FOXO1 localization. Phosphorylation excludes the transcription factor from the nucleus, switching off its program of stress resistance and gluconeogenic genes. Independent routes: several, including energy-sensing and stress kinases. Inhibiting the node restores part of the program.

[E] 2. FOXO3 localization. As above, with a partly distinct target set including autophagy and oxidative defense genes.

[E] 3. FOXO4 localization. The third member, with overlapping targets; the redundancy within the family is itself a compensation route.

[E] 4. MDM2 activation. Phosphorylation promotes nuclear entry of the ubiquitin ligase that degrades p53, lowering p53 activity. Independent routes: multiple, including direct stress signaling to p53 itself.

[E] 5. Chromatin substrate supply. Indirectly, through metabolic effects on acetyl-coenzyme A and S-adenosylmethionine. Not a phosphorylation event, and absent from kinase-substrate maps.

U.2. At the mitochondrion

[E] 6. BAD phosphorylation. Releases the pro-apoptotic protein from its partner, raising the apoptotic threshold. Independent routes: several kinases converge on the same residues.

[E] 7. Hexokinase association. Promotes association with the outer membrane, coupling glycolysis to mitochondrial ATP and stabilizing the membrane.

[E] 8. Permeability transition regulation. Indirect, through calcium handling and through the apoptotic machinery.

[VOL p.548] **[E] 9. Metabolic enzyme phosphorylation.** Several matrix and outer-membrane enzymes carry phosphosites attributed to this node, with effects on

substrate selection.

[E] 10. Biogenesis signaling. Indirect, through the growth complex and through transcription factors controlling mitochondrial gene programs.

U.3. At the plasma membrane and its vesicle traffic

[E] 11. Glucose transporter translocation. Phosphorylation of a tethering protein releases transporter-containing vesicles to the surface. Independent routes: energy-sensing kinase signaling reaches the same traffic step, which is why hub inhibition produces partial, not complete, loss of uptake — and why its clinical dose is limited by hyperglycemia.

[E] 12. Sodium pump and ion transport modulation. Several transporters carry sites attributed to this node.

[E] 13. Endothelial nitric oxide synthase activation. In endothelium, phosphorylation activates the enzyme, with vascular consequences.

U.4. At the endoplasmic reticulum

[E] 14. Calcium channel regulation. Phosphorylation of channel and regulatory proteins alters calcium release, which changes transfer to the mitochondrion at contact sites.

[E] 15. Stress response modulation. Indirect effects on the unfolded protein response through translational load.

U.5. At the ribosome and translational machinery

[E] 16. mTORC1 activation through TSC2. Phosphorylation of the complex's inhibitor relieves inhibition, raising cap-dependent translation. Independent routes: the sulfonium sensor of Chapter 22, amino acid sensing, and energy sensing all reach the same complex.

[E] 17. 4E-BP1 phosphorylation. Downstream of the above; releases the cap-binding factor.

[E] 18. S6 kinase activation. Downstream; raises ribosome biogenesis and translation capacity.

[E] 19. Ribosome biogenesis. Indirect, through the above and through nucleolar transcription.

U.6. At the cytoskeleton and cell motility machinery

[E] 20. Girdin and related effectors. Phosphorylation alters actin dynamics and directed migration.

[VOL p.549] **[E] 21. PAK and Rho-family crosstalk.** Indirect modulation of the small GTPase circuitry.

[E] 22. Focal adhesion signaling. Several adhesion components carry sites attributed to the node.

U.7. At the cell cycle machinery

[E] 23. p27 and p21 localization. Phosphorylation alters the localization and stability of cyclin-dependent kinase inhibitors, relieving cell cycle brakes.

[E] 24. GSK3 inhibition. Phosphorylation inhibits the kinase, stabilizing cyclin D and several other substrates. Independent routes: multiple, since the kinase is a convergence point for several pathways.

U.8. At metabolic enzymes in the cytosol

[E] 25. Glycogen synthase activation. Indirect, through GSK3 inhibition.

[E] 26. Lipogenic enzyme regulation. Through the growth complex and through direct phosphorylation of several enzymes.

[E] 27. PFKFB2 phosphorylation. Raises the glycolytic activator fructose-2,6-bisphosphate, accelerating glycolysis.

U.9. Reading the distribution

[F] Counted by compartment: five at the nucleus, five at the mitochondrion, three at the plasma membrane, two at the endoplasmic reticulum, four at the ribosome and translational machinery, three at the cytoskeleton, two at the cell cycle machinery, three among cytosolic metabolic enzymes. No compartment is untouched and none has a majority.

[F] Counted by redundancy: the great majority of these outputs are reachable by at least one other route. That is the architectural fact Chapter 23 reads the trial record against, and it is visible from this list without any clinical data at all.

[O] The list is a compilation at a point in time and will move as the literature grows. The argument depends on the shape of the distribution, which is robust to adding or removing individual arrows, not on the number twenty-seven.

[VOL p.550] U.10. How to extend the list

[F] A reader who wants to bring the fan up to date, or to build the same object for another node, needs four decisions and should record them.

• **What counts as an output.** This list requires a demonstrated functional consequence, not a phosphosite in a proteomic dataset. Including sites without demonstrated consequence would inflate the count and would not change the distribution, which is what the argument uses.

• **Where an output is executed.** The compartment in which the consequence occurs, not the one in which the substrate was modified. A nuclear transcription factor phosphorylated in the cytosol is a nuclear output.

• **What counts as an independent route.** Another node with a demonstrated ability to produce the same output in the same cell type. Demonstrated in another cell type is weaker evidence and should be recorded separately.

• **How to treat indirect outputs.** Metabolic and substrate-supply effects are real and are included here as such, marked indirect, because omitting them is exactly the omission this volume argues against.

[F] With those four decisions recorded, two people scoring the same node should arrive at similar redundancy fractions, which is the condition for the scoring of Chapter 23 to be usable as evidence rather than as impression.

[VOL p.551] **CHAPTER V**

What a Sufficient Record Would Contain

The volume's negative claim is that the four-letter record cannot hold what decides cell behavior. The constructive question follows: what would a sufficient record contain? This appendix sets out an answer in four layers, with what each would cost and what it would buy. None of it is a proposal to replace the sequence record, which is excellent for what it does.

V.1. Layer one: molecular identity

[F] What it adds. The identity of the molecule at each position, rather than the letter it reads as.

Inosine recorded as inosine; 5-methylcytosine as itself; 2-thiouridine as itself; 8-oxoguanine as itself.

[F] What it costs. For some species, nothing beyond a second chemistry already in use — inosine-specific treatment, methylation conversion. For direct reading across many species, a base-calling model per modification, which is where current nanopore methods are incomplete rather than impossible.

[F] What it buys. The elimination of the second error class of Chapter 8: changes that map onto a different letter and are therefore misreported with full confidence.

V.2. Layer two: the unlettered species

[F] What it adds. Symbols for the species that exist in the cell and have no letter: hypoxanthine, xanthine, orotate, and the modified bases as a class.

[F] What it costs. A notation decision and nothing else. The species are already measurable and are already reported in clinical chemistry; what is missing is their place in the alphabet the field treats as complete.

[F] What it buys. The ability to state a fact that is currently unstateable: that three of the eight nucleotide species built by de novo synthesis are obligatory gates, and that they are precisely the three the alphabet does not name.

[VOL p.552] V.3. Layer three: the state of the system

[F] What it adds. A record accompanying the sequence: nucleotide pool composition, thiol redox poise by compartment, cofactor occupancy for the proteins at issue, and modification status genome-wide.

[F] What it costs. The four-assay panel of Appendix E, run alongside existing work.

[F] What it buys. Interpretability. A sequence result in a cell whose state is unknown is a measurement of one variable in a system with several, and a negative result is uninterpretable. With the state recorded, a null becomes evidence.

V.4. Layer four: the architecture

[F] What it adds. For a therapeutic target, a structured record of where its output is executed, how many independent routes exist to each output, and which of them are compartment specific.

[F] What it costs. Literature work, a week per target, and a convention for how to score.

[F] What it buys. The prediction of Chapter 23, made before a program begins rather than after it reads out.

V.5. What this is not

[F] It is not a proposal for a new sequencing technology. Three of the four layers use instruments that exist and are run routinely in other contexts.

[F] It is not a claim that the sequence record should be replaced. A record of molecular identity is a sequence record with more symbols; the state record is a companion, not a substitute; the architecture record is a different kind of object entirely.

[F] It is not a claim that the field is unaware. Each layer exists somewhere as specialist practice. What does not exist is the convention of reporting them together, which is why a program can be, as Part Four argues, thoroughly validated against one layer and blind to the other three.

V.6. The minimal version

[F] If only one thing were adopted, it should be this: when a chemical conversion has been performed on a nucleic acid, report the molecule produced, and when the assay cannot distinguish it from another molecule that reads the same, say so. That sentence costs nothing, breaks no pipeline, and would change what a large fraction of the current literature claims.

[VOL p.553] **CHAPTER W**

The Thirteen Compartments, One Section Each

Each compartment with its keyed element, the chemistry that justifies the keying, its characteristic disease genes, how it fails, what it exchanges with the mitochondrion, and the measurement that would report its state.

W.1. 1. The lysosome — hydrogen

[E] The chemistry. A lumenal pH near 4.5 maintained against a cytosolic pH near 7.2 by a vacuolar ATPase, with essentially every lysosomal hydrolase carrying an acidic pH optimum. The compartment's catalytic repertoire depends on the proton gradient rather than on the enzymes alone.

[E] Disease genes. GBA1, GLA, HEXA and the rest of the lysosomal storage family.

[F] How it fails. Loss of acidification inactivates the hydrolases in place; substrate accumulates; and because damaged mitochondria are degraded here, mitochondrial material accumulates with it.

[F] Measurement. Ratiometric lysosomal pH dyes; hydrolase activity assays; mitophagy flux reporters.

W.2. 2. The cytoplasm — carbon

[E] The chemistry. The framework of intermediary metabolism: glycolysis, the pentose phosphate pathway, fatty acid synthesis, and the great majority of the cell's carbon trans-formations.

[F] How it fails. Rarely as a compartment; usually as a specific pathway. Its most consequential failure in this volume is the oxidative inactivation of the glycolytic dehydrogenase, which reroutes carbon to reducing power.

[F] Measurement. Extracellular flux analysis; isotope tracing into cycle intermediates.

W.3. 3. The nucleus — nitrogen

[E] The chemistry. The nitrogenous bases and their pairing, packaging and modification; and the enzymes of repair, several of which are cluster proteins supplied from elsewhere.

[VOL p.554] **[E] Disease genes.** TP53, BRCA1, BRCA2, LMNA.

[F] How it fails. As a mutational and transcriptional phenotype, often with the causal deficiency outside the compartment — cluster supply, substrate supply for marks.

[F] Measurement. Repair capacity assays; genome-wide methylation; histone mark quantitation with the substrate pools that write them.

W.4. 4. The mitochondrion — oxygen

[E] The chemistry. The terminal electron acceptor of respiration; the thioester economy; the exclusive site of initial iron-sulfur cluster assembly.

[E] Disease genes. Mitochondrial DNA genes, POLG, and the nuclear-encoded respiratory and assembly factors.

[F] How it fails. Never locally. Because cluster assembly is exclusive, and because two chromatin currencies depend on its metabolism, its failures propagate to the nucleus, the ribosome and the repair machinery.

[F] Measurement. Respiration by flux analysis; aconitase activity ratio; lipoylation; mitochondrial mass; cluster-dependent enzyme activities in other compartments.

W.5. 5. The plasma membrane — phosphorus

[E] The chemistry. The phospholipid bilayer, the phosphoinositide signaling lipids, and the pumps and channels that maintain gradients.

[E] Disease genes. CFTR, LDLR, KCNQ1 and the channelopathies.

[F] How it fails. As a transport or gradient phenotype; and, where ATP falls, as a secondary consequence of mitochondrial failure.

[F] Measurement. Membrane potential; ion flux; transporter surface abundance by imaging.

W.6. 6. The endoplasmic reticulum — sulfur

[E] The chemistry. Oxidative folding: disulfide formation and isomerization in an environment far more oxidizing than the cytosol, with dedicated oxidases and isomerases.

[E] Disease genes. SERPINA1, WFS1, ATL1.

[F] How it fails. Misfolded and mispaired protein accumulates, the unfolded protein response engages, and calcium handling at contact sites changes — which is how the failure reaches the mitochondrion.

[VOL p.555] **[F] Measurement.** Compartment-targeted redox sensors; non-reducing gels of reporter substrates; secretion kinetics.

W.7. 7. The ribosome — selenium

[E] The chemistry. Peptide bond formation by ribosomal RNA, and the insertion of selenocysteine by reading a stop codon as sense — the one place where the genetic code is rewritten in flight.

[E] Disease genes. RPS19, SBDS, RPS14 and the ribosomopathies.

[F] How it fails. As reduced translational capacity, as reduced fidelity when wobble modification fails, and as a nucleolar stress response that stabilizes p53.

[F] Measurement. Polysome profiling; frameshifting reporters; selenoprotein activity.

W.8. 8. The Golgi — manganese

[E] The chemistry. Manganese-dependent glycosyltransferases, and the pH and ion gradients that support them.

[E] Disease genes. ATP2C1, ATP7B, ATP7A — in two cases the compartment's own metal pump.

[F] How it fails. As a glycosylation phenotype, which is also one of the earliest consequences of energetic restriction.

[F] Measurement. Glycan profiling; Golgi pH; metal quantitation.

W.9. 9. The peroxisome — iron

[E] The chemistry. Iron-dependent oxidative catabolism, very long chain fatty acid shortening, and hydrogen peroxide handling.

[E] Disease genes. ABCD1, PEX1, PEX6.

[F] How it fails. Unprocessed substrates reach the mitochondrion, and peroxide load rises in both compartments.

[F] Measurement. Acylcarnitine chain-length profiling; peroxisomal enzyme activity; compartment-targeted peroxide sensors.

W.10. 10. The chloroplast — magnesium

[E] The chemistry. Magnesium at the center of chlorophyll, and the photosynthetic electron transfer chain, itself strung on iron-sulfur clusters.

[VOL p.556] **[F] Relevance here.** Not a human compartment, but the one whose acquisition changed the planet's atmosphere, which is link five of the chain in Chapter 21.

W.11. 11. The plant vacuole — potassium

[E] The chemistry. Potassium-driven turgor and storage.

[F] Relevance here. Included to keep the map honest: the keying is a claim about compartments generally, not only about animal cells, and two of the thirteen are not human.

W.12. 12. The centrosome — calcium

[E] The chemistry. Calcium-dependent assembly, duplication and spindle organization.

[E] Disease genes. ASPM, WDR62, CEP290.

[F] How it fails. As division errors, which under energetic restriction occur without any mutation in a mitotic gene.

[F] Measurement. Mitotic error rate; spindle imaging; calcium sensors.

W.13. 13. The secretory vesicles — zinc

[E] The chemistry. Zinc-loaded granules, their transporters, and regulated exocytosis coupled to metabolic state.

[E] Disease genes. SLC30A8, STXBP1, UNC13D.

[F] How it fails. Secretion uncoupled from the metabolic signal it reports — the beta cell phenotype.

[F] Measurement. Secretory response to a metabolic ramp; granule zinc imaging.

W.14. What the set is for

[F] Two things. First, it makes the keying checkable compartment by compartment rather than as a slogan: each section names a chemistry and a measurement, and a reader who finds a compartment whose chemistry does not match its assigned element has found a defect in the map. Second, it supplies the filing system used in Chapters 22 and 23, where a signaling node's outputs are sorted by where they are executed and the sort predicts which inhibitions can be compensated.

[VOL p.557] ### W.15. What a fourteenth compartment would require

[O] The keying is a claim about thirteen compartments, and the obvious question is what happens at the boundaries. Three candidates test it.

[O] The nuclear envelope. Continuous with the endoplasmic reticulum, with its own protein complement and its own disease genes. If it keys to sulfur with the reticulum, the scheme treats them as one compartment; if it requires its own element, the scheme has an inconsis-tency to resolve.

[O] The primary cilium. A signaling organelle with a distinctive protein composition and a large disease literature. Its chemistry is not obviously dominated by any single element, which would be the first clear case of a compartment the keying cannot assign.

[O] Membrane contact sites. Not compartments in the usual sense, but functionally distinct regions with their own protein composition and their own chemistry, principally calcium and lipid transfer. If contact sites must be keyed separately, the scheme's unit is not the organelle but the chemically distinct region, which would be a substantial revision.

[F] Each candidate is a test rather than an objection. A classification that cannot be extended is brittle; one that extends by its own rules, or fails visibly, is usable. The rule for extension is the one used throughout: name the chemistry the compartment runs, and ask which element performs it.

[VOL p.558] ## CHAPTER X

The Seven Therapeutic Traditions

Seven engineering traditions now carry the translational program. Each is given here with the chemistry it depends on, where it acts relative to the output fan of Chapter 22, what bounds it, and what this volume asks of it.

X.1. 1. Engineered proteins

[E] What it is. Recombinant proteins designed or modified for stability, half-life or activity: replacement enzymes, engineered cytokines, stabilized scaffolds.

[E] The chemistry. Engineered disulfides for stability and free-thiol management during manufacture. Correct disulfide register is a release-critical attribute.

[F] Where it acts. At a spoke: it supplies a specific missing or altered function.

[F] What bounds it. Delivery and immunogenicity, and the fact that a protein supplied from outside does not restore the metabolic state that made its absence pathological.

[F] What is asked. That disulfide register be reported as a potency-relevant attribute rather than only as an identity check.

X.2. 2. Antibodies and bispecifics

[E] What it is. Monoclonal antibodies and engineered multispecific formats that bind and neu-tralize, or redirect immune cells.

[E] The chemistry. Interchain and intrachain disulfides define the architecture; hinge chemistry determines flexibility and, for conjugates, attachment sites.

[F] Where it acts. At a spoke, usually outside the cell.

[F] What bounds it. Target accessibility, and the redundancy of the pathway the target sits in — the same architectural variable as every other modality.

[F] What is asked. Nothing new; this tradition already measures its sulfur chemistry carefully, which is why it is cited here as the model for the others.

[VOL p.559] ## X.3. 3. Antibody-drug conjugates

[E] What it is. An antibody carrying a cytotoxic payload, delivered selectively to cells bearing the target.

[E] The chemistry. Thiol-maleimide conjugation at interchain cysteines, or site-specific chemistry at engineered ones; the linker's stability determines where the payload is released.

[F] Where it acts. At a spoke, with the payload acting inside the cell.

[F] What bounds it. Linker chemistry, payload potency, and the distribution of target expression. Drug-to-antibody ratio heterogeneity is a direct consequence of the conjugation chemistry.

[F] What is asked. That conjugation-site thiol state be treated as a product attribute with pharmacological consequence, which the field largely already does.

X.4. 4. RNA medicines

[E] What it is. Modified-nucleoside messenger RNA, small interfering RNA, antisense oligonucleotides, and the delivery systems that carry them.

[E] The chemistry. Nucleoside modification — including pseudouridine and, in other contexts, thiolated and 2′-modified nucleosides — and phosphorothioate backbones, which substitute sulfur for one backbone oxygen to resist nucleases.

[F] Where it acts. Upstream of the fan: it changes the message rather than the signaling.

[F] What bounds it. Duration, delivery and innate immune recognition — the last of which is exactly why modification chemistry is required, since unmodified transcripts are read as foreign.

[F] What is asked. That the modification chemistry be recognized as the therapeutic principle it is, and that the parallel with the cell's own wobble chemistry be taken seriously: both use sulfur or related substitutions to tune recognition.

X.5. 5. Genome, base and prime editing

[E] What it is. Nuclease, deaminase and reverse-transcriptase-based agents that change the sequence itself.

[E] The chemistry. Cutting is magnesium chemistry; writing is sulfur chemistry, through deaminases, methyltransferases and radical enzymes; and whether an edit becomes permanent is decided at a repair fork whose enzymes include cluster proteins.

[VOL p.560] **[F] Where it acts.** Upstream of everything, which is its structural advantage: the output distribution never forms.

[F] What bounds it. The alphabet's reach, the chemistry of the editor itself, the state of the cell that receives it, and the transversion wall.

[F] What is asked. The three additions of Chapter 14's worked example: inosine-specific chemistry on DNA and RNA, replicative reserve before release, and a state panel on the edited population.

X.6. 6. Engineered cell therapies

[E] What it is. Autologous or allogeneic cells modified to recognize and kill, or to replace a function.

[E] The chemistry. Redox management determines persistence: engineered cells face an oxidative environment, and selenium-dependent and thiol-dependent defenses decide how long they survive and function.

[F] Where it acts. Outside the fan: the cell kills from outside rather than modulating the target cell's signaling.

[F] What bounds it. Manufacturing, persistence, and the selection imposed by expansion — which spends replicative reserve, as Chapter 15 sets out.

[F] What is asked. That persistence be addressed as a redox and supply problem as well as a signaling one, and that replicative reserve be measured before release.

X.7. 7. Biomanufacturing

[E] What it is. The platforms that produce the other six at scale: cell lines, selection systems, media and process control.

[E] The chemistry. Cysteine supply, nucleotide pool management, and amplifiable selection systems built on nucleotide metabolism.

[F] Where it acts. Outside the biology of the patient, and upstream of everything the patient receives.

[F] What bounds it. The same supply constraints as the cell: a culture short of cysteine makes less glutathione, assembles fewer clusters and thiolates fewer wobble bases, and the consequences appear as product quality attributes.

[F] What is asked. That process variables be read as the state variables of this volume, and that [VOL p.561] the measurements already made for product quality be recognized as measurements of the same chemistry the therapeutic acts through.

X.8. The pattern across the seven

[F] Six of the seven depend on sulfur chemistry directly and the seventh on sulfur supply. Three act at a spoke, two act upstream of the fan, and two act outside it. Where a tradition acts determines whether the redundancy argument of Chapter 23 applies to it: the spoke traditions succeed where the output is not compensable, the upstream traditions escape the argument altogether, and the outside traditions are bounded by persistence rather than by architecture.

[VOL p.562] **CHAPTER Y**

The Twelve Registers of Matter

An account of matter is kept at twelve distinct scales. Each is given here with what is accounted for at that scale, what sulfur's entry is, what the other keyed elements do there, and why the register matters to the volume's argument.

Y.1. 1. The fundamental interactions

[E] What is accounted for. Whether a bond forms at all: the electromagnetic interaction that binds electrons to nuclei and atoms to each other, with the strong and weak interactions setting which nuclei exist to be bound.

[F] Sulfur's entry. Its position in group 16, period 3, gives it a valence shell one principal quantum number further out than oxygen's, with more polarizable electrons and access to expanded valence states. Everything in the other eleven registers follows from that.

[F] Why it matters. The volume's claim that sulfur is a control element and carbon a structural one is, at bottom, a claim about this register: directional, strong, non-polarizable bonds build; weak, polarizable, interconvertible ones switch.

Y.2. 2. The atom

[E] What is accounted for. Electron configuration, ionization energy, electronegativity, oxidation states.

[F] Sulfur's entry. Nine oxidation states accessible in biological chemistry, from minus two to plus six, several interconvertible under physiological conditions. Oxygen, by contrast, operates at essentially two.

[F] Why it matters. The oxidation ladder of Chapter 17 is a property of this register, and the ladder's reversible lower half is where every control claim in Part Five operates.

Y.3. 3. The molecule

[E] What is accounted for. Bonding arrangements: functional groups and their reactivity.

[F] Sulfur's entry. Eighteen functional groups in the standard table, plus five classes the table [VOL p.563] omits — sulfenic acid, thiosulfinate, persulfide, sulfonium, polysulfide — each of which does biological work.

[F] Why it matters. The functional group is the unit at which chemistry becomes biology, and the omission of five active classes from the standard enumeration is the first instance in the volume of a notation that hides what it cannot name.

Y.4. 4. Bulk phases

[E] What is accounted for. Solids, liquids and gases; allotropes; phase behavior.

[F] Sulfur's entry. Elemental sulfur's many allotropes, hydrogen sulfide as a gas at physiological temperature, and the solubility behavior that makes sulfide chemistry possible in water.

[F] Why it matters. The gaseous form is what allows the element to act as a diffusible signal, and the mineral forms of register six depend on its phase behavior in water.

Y.5. 5. Molecular clouds

[E] What is accounted for. Matter before the planet: molecules formed on grains and in the gas phase of cold, dense interstellar clouds.

[E] Sulfur's entry. Carbonyl sulfide, carbon monosulfide, hydrogen sulfide and a growing list of detected sulfur-bearing species.

[F] Why it matters. It dates the element's molecular chemistry to before the solar system, which is the claim that the two halves of the oxidation ladder — the atomic and the molecular — are joined in the cloud rather than on Earth.

Y.6. 6. Minerals

[E] What is accounted for. Planetary chemistry: which solids precipitate from which waters under which conditions.

[E] Sulfur's entry. Pyrite, mackinawite and greigite, the last containing the Fe4S4 cubane unit that is the geometry of the protein cluster.

[F] Why it matters. Link one of the chain in Chapter 21: the cluster did not have to be invented, only captured and held by four cysteine thiolates.

Y.7. 7. The three kingdoms

[E] What is accounted for. Life's chemistry across bacteria, archaea and eukaryotes.

[VOL p.564] **[E] Sulfur's entry.** Cysteine and methionine; iron-sulfur clusters; thioesters; the sulfonium methyl donor; thiolated wobble bases; and sulfur-based energy metabolism in the lineages that use it.

[F] Why it matters. Universality across all three domains is the strongest available evidence that a chemistry is ancient and irreplaceable, and three of the volume's steps — nucleotide reduction, cluster ligation, methyl transfer — are universal.

Y.8. 8. Raw stock

[E] What is accounted for. What is taken from the ground and what industry does with it.

[E] Sulfur's entry. Sulfate and sulfide ores, elemental sulfur recovered from hydrocarbon processing, and sulfuric acid — by volume one of the most produced industrial chemicals in the world.

[F] Why it matters. It is the register in which the element's abundance and cheapness are established, which is the background to its availability in biology and in manufacturing.

Y.9. 9. Cellular molecules

[E] What is accounted for. What a cell assembles from supplied parts.

[E] Sulfur's entry. Coenzyme A, glutathione, lipoate, S-adenosylmethionine, the clusters, the molybdenum cofactor, the thiolated nucleosides, and the sulfated glycans.

[F] Why it matters. This is the register in which Part Five operates, and the one in which the seven operations are defined.

Y.10. 10. Load-bearing tissue

[E] What is accounted for. Structure at the scale of tissue: tensile strength, elasticity, compression.

[E] Sulfur's entry. Keratin's disulfide cross-links, which are why hair and nail are what they are; sulfated glycosaminoglycans in cartilage and the extracellular matrix.

[F] Why it matters. It is the register in which a sulfur failure is most visible to the eye, and one of the cluster helicase diseases is named for brittle, sulfur-deficient hair.

Y.11. 11. Sensing and signaling tissue

[E] What is accounted for. Regulation: how a tissue senses its state and changes behavior.

[VOL p.565] **[E] Sulfur's entry.** Thiol redox switches, hydrogen sulfide as a signaling molecule acting through persulfidation, and the redox tone that sets the activity of

kinases and phosphatases.

[F] Why it matters. Chapter 22's architecture lives here, and the chemical inputs to a signaling fan — redox tone, a disulfide brake, a sulfonium sensor — are all entries in this register.

Y.12. 12. Manufactured matter

[E] What is accounted for. What human intention makes.

[E] Sulfur's entry. Six of the seven therapeutic traditions of Appendix X, plus vulcanized rubber, dialysis membranes, and a long list of sulfur-containing drugs.

[F] Why it matters. It is the register in which the volume's argument has consequences for practice, and the one in which its predictions are tested.

Y.13. Why the span matters

[F] An element present at one or two registers is a specialist. An element with an entry at all twelve is one whose account cannot be confined to a single literature — which is why the material in this volume had to be assembled across a dozen of them, and why no existing review covers it. The span is the argument for the volume's existence; the seven operations are the argument that the span is not mere ubiquity.

Y.14. How to use the registers

[F] The twelve registers are a filing system, and like the compartment keying they earn their place by what they make visible rather than by being correct in some absolute sense. Three uses.

[F] To locate a claim. Any statement about sulfur in this volume can be placed at one of the twelve, and placing it says what kind of evidence should support it. A claim at register two is settled by the periodic table; a claim at register six is settled by mineralogy; a claim at register nine is settled by biochemistry; a claim at register twelve is settled by a trial. Arguments that slide between registers without saying so are the most common failure mode in writing of this kind, and the filing system is what catches them.

[F] To find the gaps. An element with entries at eleven registers and a hole at the twelfth has a hole worth looking into. Reading the registers for sulfur, the thinnest entry is register eleven — signaling tissue — which is also where the newest literature is, and that combination is what makes hydrogen sulfide signaling and protein persulfidation the most actively moving part of the subject.

[VOL p.566] **[F] To test a different element.** Run the same twelve registers for iron, for phosphorus, for selenium. Iron has entries at nearly all twelve and would make a comparable case; phosphorus has a sharp profile, concentrated at a few registers and indispensable there; selenium is present at only a handful and is irreplaceable at each. The three profiles are three different kinds of necessity, and distinguishing them is what the register count is for.

[O] Whether the number twelve is the right granularity is open. A reader who merges the two prebiotic registers, or splits manufactured matter into industrial and therapeutic, gets eleven or thirteen without damaging any argument. The transitions are the content; the count is scaffolding.

[VOL p.567] **CHAPTER Z**

The Eight Nucleotides, in Detail

Each of the eight species built by de novo synthesis, with its chemistry, its position in the pathway, its clinical and therapeutic connections, and what the four-letter record says about it.

Z.1. 1. Inosine monophosphate

[E] Chemistry. The nucleotide of hypoxanthine: a purine lacking the exocyclic amine of adenine and the amino-oxo arrangement of guanine, with a carbonyl at C6.

[E] Position. The trunk. Ten enzymatic steps from phosphoribosyl pyrophosphate, at roughly six high-energy phosphate equivalents, with both purine branches leaving from it.

[E] Clinical connections. Its degradation product, hypoxanthine, rises in ischemia and in tumor lysis; its salvage by HGPRT fails in Lesch-Nyhan syndrome; its dehydrogenase is the target of mycophenolate.

[F] In the record. No letter. The base is read as guanine wherever it occurs in a polymer, and the metabolic species has no symbol at all.

[F] Why it carries the volume. It is simultaneously the obligatory metabolic trunk, the product of adenosine deamination in RNA and of adenine base editing in DNA, the base at wobble position 34 that widens recognition, the mark distinguishing self from foreign transcripts, and the species accumulating at a deaminated chromosome end.

Z.2. 2. Xanthosine monophosphate

[E] Chemistry. The nucleotide of xanthine: a purine with carbonyls at both C2 and C6.

[E] Position. The gate on the guanine branch. Made by IMP dehydrogenase with NAD+, consumed by GMP synthase with glutamine and ATP.

[E] Clinical connections. IMPDH inhibition is the mechanism of mycophenolate and of ribavirin; IMPDH1 mutation causes a retinal dystrophy. Xanthine itself accumulates in xanthinuria and under allopurinol therapy.

[F] In the record. No letter.

[VOL p.568] **[F] Why it matters.** It is the second of the three one-way gates, and the only route to guanine nucleotides passes through it.

Z.3. 3. Adenosine monophosphate

[E] Chemistry. The nucleotide of adenine, a purine with an exocyclic amine at C6.

[E] Position. One branch product, made from the trunk with aspartate using GTP, through adenylosuccinate and its lyase.

[E] Clinical connections. Adenylosuccinate lyase deficiency produces a severe neurological disorder; the adenine nucleotide pool's state is the adenylate energy charge.

[F] In the record. Letter A; element hydrogen in this volume's key.

[F] Why it matters. It is the parent of the energy currency, the nucleotide moiety of four major coenzymes, and the state variable at the center of the stop-codon reading of Chapter 6.

Z.4. 4. Guanosine monophosphate

[E] Chemistry. The nucleotide of guanine: amine at C2, carbonyl at C6.

[E] Position. The other branch product, made from the xanthine nucleotide by amination.

[E] Clinical connections. Guanine nucleotide depletion is the proximate effect of IMPDH inhibition; GTP drives the adenine branch and the first step of molybdenum cofactor synthesis.

[F] In the record. Letter G; element nitrogen.

[F] Why it matters. It is the species inosine is mistaken for, which is the entire basis of the second error class of Chapter 8.

Z.5. 5. Orotidine monophosphate

[E] Chemistry. The nucleotide of orotate, a pyrimidine carrying a carboxylate at C6 that is removed in the next step.

[E] Position. The gate on the entire pyrimidine arm. Made by orotate phosphoribosyltransferase, decarboxylated by OMP decarboxylase.

[E] Clinical connections. UMP synthase deficiency is hereditary orotic aciduria, diagnosed by the accumulation of orotate in urine and treated by supplying uridine.

[F] In the record. No letter.

[VOL p.569] **[F] Why it matters.** It is the third gate, and its decarboxylation is among the largest enzymatic rate enhancements known — roughly seventeen orders of magnitude, with no metal and no cofactor.

Z.6. 6. Uridine monophosphate

[E] Chemistry. The nucleotide of uracil, the parent pyrimidine.

[E] Position. The product of the gate, and the precursor of every other pyrimidine.

[E] Clinical connections. Uridine supplementation bypasses the gate in orotic aciduria; pyrimidine supply is coupled to the respiratory chain through dihydroorotate dehydrogenase.

[F] In the record. Letter U; element phosphorus.

[F] Why it matters. It is the base whose 2-position is thiolated at wobble position 34 — the narrowing correction of Chapter 7 — and the base produced by cytosine deamination, the most frequent spontaneous base damage in DNA.

Z.7. 7. Cytidine triphosphate

[E] Chemistry. The nucleotide of cytosine, a pyrimidine with an exocyclic amine at C4.

[E] Position. Made from UTP at the triphosphate level by CTP synthase, a glutamine amidotransferase.

[E] Clinical connections. CTP synthase deficiency produces an immunodeficiency; cytosine is the base whose methylation at C5 carries the epigenome.

[F] In the record. Letter C; element carbon.

[F] Why it matters. Its methylated form is the clearest instance of Chapter 8's first error class: a change with large functional consequence that leaves the letter untouched.

Z.8. 8. Thymidine monophosphate

[E] Chemistry. The nucleotide of thymine, a pyrimidine carrying a methyl group at C5 — which is to say, methylated uracil.

[E] Position. Made from dUMP by thymidylate synthase, using a conserved active-site cysteine and a methyl group from the folate pool.

[E] Clinical connections. Thymidylate synthase is the target of 5-fluorouracil; folate limitation causes dUTP misincorporation and uracil in DNA, with megaloblastic consequences.

[VOL p.570] **[F] In the record.** Letter T; element sulfur in this volume's key, by way of the color assignment rather than by its own composition.

[F] Why it matters. It is the position where the volume's argument about route versus letter is sharpest: a thymine made by thymidylate synthase and a thymine produced by deaminating a cytosine are the same letter arriving by different chemistry at different metabolic cost, and the assay reports only the letter.

Z.9. The arithmetic of the set

[F] Eight species, five letters among them — A, G, C, U and T — and three with no letter at all.

All three of the unlettered ones are obligatory: remove any one and the cell makes no nucleic acid. The alphabet in use names the products and omits the gates, which is

the whole of Chapter 5 and the premise of Chapter 8.

[VOL p.571]

CHAPTER AA

The Predictions, Collected

Every prediction made in the body, collected with the chapter that makes it, the measurement it requires, and what a negative result would mean. A prediction that cannot be wrong is not listed.

AA.1. Supply and the alphabet

#	prediction	measurement	chapter if wrong	
1	Pool composition changes phenotype with sequence held constant	dNTP quantitation in isogenic lines under controlled supply	4	the first leg loses its empirical content
2	A thymine from base editing differs downstream from one made by thymidylate synthase	one-carbon flux, uracil excision load, repair marks at the locus	4	the route-versus-letter objection fails
3	The trunk nucleotide rises before guanine nucleotides fall under partial IMPDH inhibition	targeted mass spectrometry in peripheral blood mononuclear cells	5	the gate model needs amending toward degradation
4	Adenine base editing is more efficient where the trunk-to-branch purine ratio is high	isogenic lines under mycophenolate	5	product inhibition by the free inosine pool is not operating
5	Exit-enzyme inhibition shifts the unlettered-to-lettered purine ratio measurably	routine metabolomics panel under allopurinol	5	the exit is not a one-way gate as described

Table. Predictions from Part Two's supply chapters.

AA.2. The code and the wobble position

[VOL p.572]

#	prediction	measurement	chapter if wrong	
6	Readthrough tracks adenylate energy charge, UAA least sensitive and UGA most	dual-reporter readthrough across an energy-charge titration	6	the stop-codon reading fails at its first test
7	Selenocysteine recoding at UGA is sensitive to ATP/ADP independently of selenium	selenoprotein reporter with selenium held constant	6	the reading loses its mechanistic link
8	No organism has reassigned UAA to an amino acid	comparative genomics across sequenced genomes	6	the reading is broken outright
9	Wobble thiolation falls monotonically with cysteine availability, with frameshifting rising	mass spectrometry plus dual-reporter frameshifting	7	the supply-to-fidelity link is weaker than claimed
10	Editor expression shifts the cell’s own position-34 editing	inosine-specific sequencing of transfer RNA in edited cells	7	editor and native deaminase do not compete

Table. Predictions from the notation and wobble chapters.

AA.3. The record and the clinic

#	prediction	measurement	chapter if wrong	
11	Some A-to-G calls reflect inosine rather than genomic guanosine, scaling with RNA carryover	inosine-specific chemistry on existing libraries	8	the second error class is empirically empty

12	Epigenetic editors show guide-independent off-target methylation absent from published panels	genome-wide methylation, treated versus control	8, 14	candidate-locus sampling is adequate after all
13	Cells with impaired cluster assembly shift mutational spectrum with no repair-gene mutation	mutational signature analysis with a cluster-supply proxy	8	the cofactor layer does not reach the genome
14	A fraction of sequence-wild-type tumors are functionally phosphatase-deficient by oxidation	non-reducing immunoblot on banked tumor lysates	8, 22	the redox switch is not quantitatively important in tumors

[VOL p.573]

#	prediction	measurement	chapter if wrong	
15	Cysteine variants at ligating or disulfide positions are enriched for pathogenicity beyond predictor performance	analysis of public variant databases	13	occupancy adds nothing to variant interpretation
16	Lot-to-lot potency of a multi-disulfide biologic tracks isomer distribution better than sequence identity	differential alkylation across lots	13	register is not potency-relevant at manufacturing scale

Table. Predictions about what the record cannot carry.

AA.4. The chromosome end

#	prediction	measurement	chapter if wrong	

17	Shortest-telomere distribution predicts replicative capacity better than the mean	single telomere length analysis versus quantitative PCR	15	the order-statistic argument is irrelevant in practice
18	T-circle abundance marks loop resolution independently of gradual attrition	two-dimensional gels or rolling-circle amplification	15	resolution events are negligible
19	Telomeric hypoxanthine rises with donor age	inosine-specific chemistry on telomeric DNA	15	the deamination mechanism is a laboratory-scale effect
20	Post-mitotic tissue shows the sulfur arm of the loop without the division arm	mitochondrial mass and cluster status in mitotic versus post-mitotic tissue	15	the loop is division-dependent throughout

Table. Predictions from the telomere chapter.

AA.5. Architecture and therapy

[VOL p.574]

#	prediction	measurement	chapter if wrong	
21	Perturbing a compartment’s keyed element produces local failure, except at the mitochondrion	targeted perturbation with compartment-resolved readouts	16, 20	the compartment keying is abandoned
22	Cluster supply and wobble thiolation fail together in a fixed ratio under relay perturbation	cluster proxy plus thiolation assay	20	the shared-supply model is wrong
23	Target output distribution predicts demonstrated survival benefit across completed trials	scoring of public trial record, blind to outcome	23	the redundancy argument fails
24	Spoke-directed agents continue to outperform hub-directed agents at matched potency	the next cohort of trial readouts	23	the architecture claim is not predictive

25	Partial terminal-sulfur occupancy contributes to variation in urate handling	functional assay in a population sample	24	the cofactor's switch is all-or-none in practice
Table. Predictions from the architecture and clinical chapters.				

AA.6. How to use this table

[F] Three columns matter more than the others. The measurement column says what equipment is needed, and roughly a third of the twenty-five need none beyond public data and analysis. The chapter column says where the reasoning is. The last column says what the volume loses if the prediction fails, which is the only honest way to present a prediction: with its price attached.

[F] Predictions 8, 11, 15 and 23 are the four cheapest, and two of them — the UAA search and the target scoring — are pure analysis against existing records. A reader looking for the fastest route to disagreeing with this volume should begin with those.

AA.7. What a negative result would be worth

[F] Most of the twenty-five predictions above are worth more if they fail than if they succeed,

> and it is worth saying why in a volume that states them at all.

[F] A prediction that succeeds adds one consistent observation to an argument that already has [VOL p.575] several. A prediction that fails removes a link, and because the links are enumerated in Appendix F with what falls when each goes, a failure propagates immediately and visibly. That asymmetry is the point of printing the chain rather than asserting the conclusion.

[F] Three of the predictions would, if they failed, end a substantial part of the volume. Prediction 21, on compartment propagation, would end the third leg. Prediction 23, on target output distribution, would end the clinical argument of Part Six. Prediction 1, on pool composition changing phenotype with sequence held constant, would reduce the first leg to a terminological preference.

[F] Four would cost almost nothing. Prediction 8 is a database search. Predictions 11 and 15 are analyzes of existing libraries and existing variant records. Prediction 23 is a week of literature scoring followed by a comparison against published outcomes. A

reader with no laboratory can attempt any of these.

[F] And three are already partly answered in fragments scattered across different literatures — predictions 3, 9 and 22 — where the pieces exist in separate papers and have never been assembled into a single controlled comparison. Those are the cheapest real experiments in the volume, because most of the method development has been done by someone else for another purpose.

[VOL p.576] **CHAPTER AB**

Literature Orientation, Chapter by Chapter

For each chapter: which literatures it draws on, where a reader new to that literature should enter it, and which of the chapter's claims are original here and therefore have no literature to consult. The volume names its sources in the text rather than by numbered citation, and this appendix is the map of what to search for.

AB.1. Chapter 1

[F] No specialist literature; the chapter states the argument. The one external reference worth reading in the original is Crick's own statement of the Central Dogma, whose content is narrower than its reputation.

AB.2. Chapter 2

[E] Enter through the chemistry of the seven elements in any inorganic text, and through the literature on information design for the question of what a notation makes visible. The color convention itself is this volume's and has no prior literature.

AB.3. Chapter 3

[E] Three literatures meet: isotope geochemistry for the planetary dates, molecular phylogeny for enzyme class ordering, and prebiotic chemistry for the earliest stages. The last is contested and should be read with that in mind.

AB.4. Chapter 4

[E] Standard biochemistry for the pathways; the classical literature on nucleotide pool imbalance and mutagenesis for the mechanism; replication stress biology for the modern form of the same argument; and the antimetabolite pharmacology literature, which is where supply-line intervention has been practiced for sixty years.

AB.5. Chapter 5

[E] Biosynthetic pathways in a primary biochemistry text for the stoichiometry; clinical genetics for the inherited failures, which make the pathway's structure visible as a graded series; and [VOL p.577] the enzymology literature on orotidine monophosphate decarboxylase for the rate enhancement.

AB.6. Chapter 6

[E] The genetic code and its degeneracy in any molecular biology text; the comparative genomics of stop codon usage and recoding for the strictness ordering; bioenergetics for the adenylate energy charge. The stop-codon reading is original here and is marked open.

AB.7. Chapter 7

[E] Crick's 1966 wobble paper in the original; the modification literature, best entered through the MODOMICS compilation; the sulfur relay literature around the mitochondrial desulfurase; and the human disease genetics of the modification enzymes.

AB.8. Chapter 8

[E] Information content of sequence records is not usually discussed as such; enter instead through the methods literature for each exception — methylation sequencing, inosine chemistry, nanopore modification calling — and through the off-target literature in editing, noting how it defines its terms.

AB.9. Chapter 9

[E] The transfer RNA identity literature, consolidated in a series of compilations; the structural biology of the two synthetase classes; and the minihelix charging experiments.

AB.10. Chapter 10

[E] Per-system identity papers, which are scattered and organism-specific; the plates here are a compilation, and the cautions for reading determinant sets are given in that chapter's notes.

AB.11. Chapter 11

[E] The editing-domain literature for isoleucine and valine discrimination; the indirect charging literature for glutamine; and the structural work on the systems that read the variable arm.

[VOL p.578]

AB.12. Chapter 12

[E] Pan-cancer genomics consortium reports, whose supplementary tables are more useful than their summaries; national and global mortality statistics; and the regulatory review documents for approved editing therapies, which state validation packages in detail journals omit.

AB.13. Chapter 13

[E] Structure prediction's own literature for what it covers; metalloprotein and cluster biogenesis literature for occupancy; redox proteomics for thiol state; and the biologics manufacturing literature for disulfide register, which is where occupancy is already treated as a product attribute.

AB.14. Chapter 14

[E] Medicinal chemistry of peptide analogs for acylation and amidation; the provenance papers for the deaminase at the core of adenine base editors; the epigenetic editing literature and its off-target reports; and the epimutation literature in cancer genetics.

AB.15. Chapter 15

[E] Telomere biology broadly; the shelterin and t-loop structural literature; single telomere length analysis for the distribution; and the cluster biogenesis literature for the loop’s second arm.

AB.16. Chapter 16

[E] Organelle cell biology for the compartment chemistry; the sulfur functional group literature for the eighteen; and the disease gene databases for the compartment associations.

AB.17. Chapter 17

[E] Sulfur chemistry in an inorganic or physical organic text for the ladder; the redox signaling literature for the reversible range; and the selenoprotein literature for the placement rule.

AB.18. Chapter 18

[E] Standard bioenergetics for the three pillars; the structural literature on respiratory complexes for cluster counts; and the chromatin metabolism literature for substrate sensitivity of acetylation and methylation.

[VOL p.579] AB.19. Chapter 19

[E] The ribonucleotide reductase mechanism literature, which is among the best developed in enzymology; the cluster helicase structural and genetic literature; and the radical SAM literature for the anticodon modification enzymes.

AB.20. Chapter 20

[E] Iron-sulfur cluster biogenesis, including the export step; transsulfuration and one-carbon metabolism; and the membrane contact site literature for the conversations.

AB.21. Chapter 21

[E] Mineral and isotope geochemistry for the links before life; enzyme class distribution for the DNA transition; and the editing chemistry literature for the division between cutting and writing.

AB.22. Chapter 22

[E] The signaling literature for the node and its substrates; the redox regulation literature for the phosphatase switch; and the metabolite sensing literature for the

sulfonium sensor.

AB.23. Chapter 23

[E] Published randomized trials and their regulatory documents; the pathway databases for output enumeration; and the therapeutic chemistry literature for each of the seven traditions.

AB.24. Chapter 24

[E] Molybdenum cofactor biosynthesis; the clinical genetics of the three deficiencies; the nitrogenase structural literature; and the comparative genomics of uricase loss.

AB.25. Chapter 25

[E] Consensus orderings of amino acid addition; abiotic amino acid synthesis; observed codon reassignment; and the structural work establishing that the ribosome’s catalytic center is RNA.

[VOL p.580] ### AB.26. A note on what is not cited

[F] Where a claim in this volume is marked [F], it is argued here and there is no source to consult; where it is marked [O], no literature establishes it, which is what the tag means. A reader auditing the volume should check the [E] claims against the literatures above and judge the [F] claims on the reasoning, since that is all they rest on.

[VOL p.581] ## CHAPTER AC

Sources

This volume names its sources in the text rather than by numbered citation, with one exception: the mechanistic literature on sulfur inside the genetic machinery, which is listed below as it appeared in the paper from which Chapter 19 is drawn. The practice of naming in the text was chosen because the volume crosses a dozen literatures, and a reader who wants to follow one of them is better served by knowing which field a claim comes from than by a number.

AC.1. How to find the primary literature for a claim

[F] Every paragraph in this volume carries an evidence tag. For an [E] paragraph, the claim is established and the route to its literature is given in the surrounding text: the enzyme is named, the organism is named, and the phenomenon is named in the terms its own field uses. Those three are sufficient to find the primary work in any bibliographic database.

[F] For an [F] paragraph, the claim is argued here, and what it rests on is the [E] material around it. A reader checking an [F] claim should check the [E] claims it depends on first, since an argument built on established facts fails at its logic or at its facts, and the facts are easier to check.

[F] For an [O] paragraph, no literature establishes the claim; that is what the tag means.

AC.2. Fields crossed, with their entry points

• **Nucleotide metabolism and its inherited failures.** Standard biochemistry texts for the pathways; the clinical genetics literature for the deficiency phenotypes, which is where the pathway's structure becomes visible as a graded series.

• **Transfer RNA identity and modification.** The identity-element compilations for determinants; the MODOMICS compilation for modified nucleosides and their enzymes.

• **Iron-sulfur cluster biogenesis.** The mitochondrial assembly literature, with the export-step work as the key to the exclusivity argument of Chapter 20.

• **Redox biology.** The peroxiredoxin and thioredoxin literatures for the ladder's reversible range; the redox proteomics literature for proteome-scale measurement.

• **Telomere biology.** The shelterin and t-loop structural literature; the single-telomere length analysis literature for the distribution rather than the mean.

[VOL p.582] • **Signaling and the trial record.** Pathway databases for the substrate lists; the published randomized trials and their regulatory documents for the outcomes.

• **Molybdenum cofactor biosynthesis.** The biosynthesis literature for the three sulfur steps; the inherited metabolic disease literature for the graded failures.

• **Deep time.** The sulfur isotope literature for the oxygenation date; the iron sulfide mineral literature for the cluster geometry argument.

AC.3. How to verify a claim in this volume, in four steps

[F] Step one: read the tag. An [E] claim is established and the text names the enzyme, the organism and the phenomenon in the terms its own field uses — enough to find the primary work in any bibliographic database. An [F] claim is argued here and rests on the [E] claims around it. An [O] claim is open and has no literature to consult.

[F] Step two: locate the field. Appendix AB gives, chapter by chapter, which literatures a claim draws on and where a reader new to that literature should enter it. A claim that spans two fields — and many here do — should be checked in both, because the two will often use different vocabulary for the same chemistry.

[F] Step three: check the chain, not only the link. Appendix F restates every chapter's principal claim with its evidence class and the observation that would break it. If a link is wrong, that table says what else falls with it, which is a faster route to the volume's weak points than reading forward.

[F] Step four: run a falsifier. Appendix C orders the falsifiers by cost, and four of the ten can be attempted with public data and no laboratory. Appendix AA collects

the twenty-five predictions with the measurement each requires. A reader who runs one and finds against the account has done more for it than a reader who agrees.

[F] The practice of naming sources in the text rather than by number was adopted because the volume crosses a dozen literatures, and a reader following one of them is better served by knowing which field a claim comes from than by a number that resolves to a single paper. Where a numbered list exists — the mechanistic references above — it is reproduced as it stood in the source material.

AC.4. Reference list carried from Chapter 19's source material

The following were cited in the paper from which the mechanistic material of Chapter 19 is drawn, and are reproduced here unchanged.

12. Claims, hypotheses, predictions and falsifiers

Gathered here: the volume's collisions/falsifiers appendix (VOL App. C), the thematic analysis Part IX, and the inventory's closing Part XI. The volume's chain of claims (App. F), predictions (App. AA), and the thirteen themes stated as claims (App. M) appear in Section 11.

[VOL p.451]

CHAPTER C

Collisions, Falsifiers, and the Chapter Arc

A volume that only accumulated agreement with itself would be worth less than one that names the conditions under which it would be abandoned. This appendix collects those conditions. The first section lists the falsifiers in order of how cheap they are to test. The second carries the collisions: places where two positions in this volume, or a position here and a settled position elsewhere, are in tension and the tension has not been resolved.

C.1. Falsifiers, ordered by cost

#	what would have to be found	breaks	cost
1	An organism that has reassigned UAA to an amino acid	the stop-codon reading, Chapter 6 only	analysis of existing genomes
2	No relationship between a target's output distribution and demonstrated survival benefit	the redundancy argument, Chapter 23	analysis of the public trial record
3	A survey showing most clinical-stage agents already measure their principal chemical liability	the Part Four argument	analysis of public regulatory documents
4	Cofactor occupancy and disulfide register predictable from sequence alone	Chapter 13	computational, against existing structures
5	A documented sulfur function fitting none of the seven operations	Chapter 16	literature search plus judgment
6	Compartment perturbation propagating indifferently, or mitochondrial cluster failure compensated cytosolically	the compartment keying, Chapters 16 and 20	one well-designed cell biology study
7	An alternative de novo route to deoxyribonucleotides not using a cysteine radical	Chapter 19, and link three of the chain	comparative biochemistry

[VOL p.452] **# what would have to be found breaks cost** 8 Thiolation and deamination at position 34 dispensable for decoding fidelity Chapter 7 one cell biology study with two assays 9 The severity ordering of the three cofactor deficiencies shown to be arbitrary with respect to the accumulating species Chapter 24 clinical literature analysis 10 Pool state, held as the only variable, never changing phenotype Chapter 4, and with it the first leg one isogenic study with controlled supply **Table.** The volume's falsifiers, ordered by what it would cost to test each.

[F] Four of the ten can be attempted with public data and no laboratory. That was a design constraint rather than a convenience: an argument whose falsifiers all require a well-funded laboratory is an argument insulated from its critics.

C.2. Collisions

[O] Collision one: lateness of the sulfur amino acids. The code assigned cysteine and methionine late; this volume argues sulfur chemistry is ancient and central. The resolution offered in Chapter 25 — supply is not repertoire — is a distinction, not a demonstration, and a reader may reasonably find it insufficient.

[O] Collision two: the prebiotic link. The chain of Chapter 21 includes a link about sulfide chemistry preceding phosphate chemistry in nucleotide formation. The field is contested, and this volume takes the weak form of the claim. If the strong form is wrong the chain still closes; if the weak form is wrong, link two fails and the chain begins at the mineral instead.

[O] Collision three: carbon's small register. The element present in every molecule named in this volume has one of the smallest registers, because the convention marks elements named as elements rather than present as structure. The collision is between the method and the chemistry, and it is why no argument here is made from register size alone.

[O] Collision four: the thirteen-compartment keying. Eleven of the thirteen assignments rest on a chemistry argument with no independent confirmation. Two have confirmation from disease genes. A reader is entitled to treat the keying as a hypothesis with two supporting instances rather than as an established map, which is how Chapter 16 presents it.

[VOL p.453] **[O] Collision five: potency versus redundancy.** The clinical argument of Chapter 23 attributes the hub programs' failure to redundancy rather than to insufficient target engagement. Because dose is limited by on-target toxicity, the two explanations are not fully separable in the existing record, and the prediction offered for future readouts is the only clean test.

C.3. What this appendix is for

[F] A reader who disagrees with this volume should start here rather than at Chapter 1. The falsifiers say what evidence would end the argument; the collisions say where the volume already knows it is weakest. Both lists are shorter than they would be if the volume were trying to appear stronger than it is.

Where the themes collide

[E] Themes that never disagree are a classification scheme rather than an argument. Six places where two of the thirteen pull against each other, with what the collision settles and what it leaves open.

T2 against T12 — If abundance does not make a base a letter, why should metabolic priority? The two themes are in tension by construction, and the tension is productive. The twelfth says availability is not membership; the second says the trunk comes first. If the second rested on how much inosine there is, the twelfth would demolish it. It does not: it rests on the route — that no organism reaches either branch without passing the trunk — and a route is a structural fact rather than a quantity. The corpus should state the second theme in route terms every time it states it, and in several places it states it in abundance terms instead.

T3 against T13 — Is the notation argument held to the corpus's own standard of refusal? The third theme says the record cannot hold what the chemistry does. The standing objection is that modification databases do hold it. The corpus concedes that the objection is also the admission — the clinic reads the sequence file — and that concession is the thirteenth theme operating on the third. The collision is resolved honestly, and it is the model for how the other twelve should be handled.

T5 against T7 — If arrangement carries the information, why is the carrier so weak? Because an arrangement that cannot change cannot be read twice. The fifth theme is the condition of the seventh rather than its competitor: a bond strong enough to fix an arrangement permanently would make the arrangement unreadable, and a system with no fixed arrangement at all would have nothing to read. The interesting regime is the narrow one between, and that regime is set by the hydrogen bond.

[VOL p.454] T1 against T9 — Does the nine-to-two result generalize, or is it one cofactor? The first theme wants the collapse to be a general consequence of the oxygen boundary; the ninth theme's method requires that a count change across one boundary in one direction and stay changed. One family satisfies that. Until the structural survey is run across families with pre- and post-oxidation representatives, the first theme is supported by a case and not by a law, and the corpus says so in the paragraph that makes the claim.

T3 against T10 — Is the problem the alphabet or the dimensionality? These are separable and the corpus sometimes runs them together. A record could carry every modification and still be flat; a three-dimensional model could be built on four letters. The cleanest statement is that the third theme is about what is representable and the tenth is about what is computable from a representation, and that the clinical consequences the corpus names fall into two piles accordingly.

T4 against T8 — Is editing a removal or a repurposed damage? Both, and the two themes are two descriptions of one event. The fourth says the category is made by taking something away; the eighth says the sign of the event is set by where it happens. Together they make a prediction neither makes alone: that the enzymes of
