Follow a sugar from the moment it enters a cell to the moment its last electron reaches oxygen, and sulfur is standing at every gate. It carries the two carbons out of sugar and into the cycle. It is the swinging arm on the two enzymes that do the carrying. It is bonded to the iron in the wires that move the electrons. And the fatty

acid that gets burned was built two carbons at a time on a sulfur tether in the first place. The energy system of a cell is a sulfur system with iron in it.

1029. Where This Part Stands ↩

Part One Hundred and Nine established that a fatty acid is assembled on a sulfur tether. This Part follows the fat and the sugar into the mitochondrion and watches what happens to them.

sugar → glycolysis → pyruvate\n the gate\nfat → beta-oxidation → acetyl-CoA → citric acid cycle → electrons → oxygen

Sulfur appears at the gate, in the cycle, and in the wire.

1030. The Gate ↩

Pyruvate dehydrogenase

Glycolysis ends with pyruvate. Pyruvate cannot enter the citric acid cycle as it is. One enzyme complex converts it, and that step is the point of no return — once a carbon goes through it, an animal cannot turn it back into sugar.

the complex	pyruvate dehydrogenase
what it does	pyruvate → acetyl-CoA + carbon dioxide
how many sulfur cofactors it needs	three

the cofactor	the sulfur
thiamine pyrophosphate — vitamin B1	a sulfur in the ring
lipoic acid	two sulfurs, on an eight-carbon chain
coenzyme A	the thiol that takes the acetyl

The single most important gate in energy metabolism requires three separate sulfur cofactors, and there is no version of it that works without them.

1031. The Swinging Arm ↩

Lipoic acid is attached to the enzyme by one end and swings. The two sulfurs at its far end pick up the two-carbon piece at one active site and carry it to the next.

what it is	an eight-carbon fatty acid with sulfurs at carbon six and carbon eight
what it does	carries the piece between active sites
the same arm appears in	alpha-ketoglutarate dehydrogenase, inside the citric acid cycle itself

Part One Hundred and Nine records how those two sulfurs get there: lipoyl synthase takes them from its own iron-sulfur cluster and destroys the cluster doing it.

A fatty acid with two sulfurs, built by dismantling an iron-sulfur cluster, swinging between active sites, at the two gates of the citric acid cycle.

1032. And the Same Arm Again, Inside the Cycle ↩

The citric acid cycle has eight steps. Two of them are the same kind of reaction, and both use lipoic acid.

the step	what it does
alpha-ketoglutarate dehydrogenase	the second carbon dioxide leaves here, and the same three sulfur cofactors are required
succinyl-CoA	the product is a thioester, and the energy in that bond is what makes GTP at the next step

The only step of the citric acid cycle that makes a nucleotide directly does it by breaking a sulfur-carbon bond.

1033. And One More Step of the Cycle Is an Iron-sulfur Protein ↩

Aconitase, the second enzyme of the cycle, holds a [4Fe-4S] cluster — and one iron of that cluster is not held by a cysteine at all. It sticks out and grabs the substrate.

what most iron-sulfur clusters do	move electrons
what this one does	holds the molecule while the shape is changed
what happens when iron is short	the cluster falls apart and the same protein becomes a regulator that controls iron uptake

One protein. Two jobs. Which job it does depends on whether the cluster is assembled, and the gene sequence is identical in both cases.

1034. The Wire ↩

Once the cycle has stripped the electrons off, they have to be carried to oxygen. They are carried along iron-sulfur clusters.

the complex	what carries the electrons
Complex I	a chain of iron-sulfur clusters, in a line, about ninety-five angstroms long
Complex II — succinate dehydrogenase	three iron-sulfur clusters, and this enzyme is in the citric acid cycle and the respiratory chain at once
Complex III	the Rieske protein, a [2Fe-2S] cluster, and Complex III does not work without it

The published account is direct: iron-sulfur clusters carry the electrons through Complexes I, II and III to cytochrome c, and from there to oxygen.

Every calorie an animal has ever burned went down a row of iron and sulfur atoms.

1035. And the Clusters Have to Be Built and Delivered ↩

A cell cannot simply find these clusters. It builds them and carries them to the right protein.

the step	
the sulfur comes from a cysteine	an enzyme called a cysteine desulfurase pulls it off
the cluster is assembled on a scaffold protein	
a chaperone pair delivers it	one cochaperone-scaffold complex serves Complexes I, II and III

Failures in this delivery system cause human disease. One is a deficiency of the desulfurase itself, which produces a combined failure of Complex II and Complex III in infants.

1036. Now the Fat ↩

Part One Hundred and Nine followed the fatty acid being built. Here it is being taken apart.

	building	taking apart
where	the cytosol	inside the mitochondrion
the carrier	the phosphopantetheine arm	coenzyme A
the bond	a thioester	a thioester
the unit	two carbons on	two carbons off

Both directions run on a sulfur ester, and neither direction lets the chain go free.

1037. And the Door Into the Furnace ↩

A long fatty acid cannot cross the inner membrane while it is attached to coenzyme A. The cell swaps the carrier.

fatty acyl-CoA → fatty acyl-carnitine → across the membrane → fatty acyl-CoA again

the swap out	CPT1, on the outer face
the swap back	CPT2, on the inner face

the swap out	CPT1, on the outer face
what CPT1 is inhibited by	malonyl-CoA — the same molecule that extends a growing fatty acid

The signal that says "we are building fat" is the same molecule that closes the door to burning it. One thioester turns the traffic in both directions, and it does it by sitting on a gate.

1038. The Carbon Account, in One Line ↩

step	what happens to the two carbons
fat is built	acetyl on the ACP thiol, two at a time
fat is stored	as an ester on glycerol — no sulfur
fat is retrieved	acetyl on the CoA thiol, two at a time
fat is burned	acetyl handed into the cycle from a thioester

Sulfur holds the two carbons at every point except while they are sitting still.

1039. What the Notation Loses Here ↩

None of this is in any sequence.

what a genome records	what it does not record
the gene for the enzyme	whether its iron-sulfur cluster was ever installed
the gene for lipoyl synthase	whether the cluster it needed was sacrificed
the gene for aconitase	which of its two jobs it is doing today
the gene for CPT1	whether malonyl-CoA is sitting on it right now

The whole energy system is regulated by whether a sulfur atom arrived, and none of the arrivals are written down.

1040. What This Part Refuses ↩

the claim	the status
pyruvate dehydrogenase requires thiamine, lipoic acid and coenzyme A	established
lipoic acid serves the same role in alpha-ketoglutarate dehydrogenase	established
aconitase carries a [4Fe-4S] cluster with one iron free to bind substrate	established
iron-sulfur clusters carry the electrons through Complexes I, II and III	established, and cited
that sulfur therefore powers the cell	refused. The energy comes from the electrons and from the gradient across the membrane. Sulfur is what carries and routes them. Carrying is not the same as being the source
that a sulfur count predicts metabolic rate	not established, and no such measurement is offered here

1041. What This Part Claims ↩

The claims

1	**The gate from sugar into the citric acid cycle needs three sulfur cofactors — thiamine, lipoic acid and coenzyme A**
2	Lipoic acid is an eight-carbon fatty acid with two sulfurs, and it swings between active sites
3	The same arm serves both decarboxylating steps of the cycle
4	Succinyl-CoA is a thioester, and breaking it is what makes GTP
5	Aconitase holds a [4Fe-4S] cluster with one iron uncoordinated, and becomes an iron regulator when the cluster is lost
6	Complexes I, II and III carry electrons along iron-sulfur clusters to cytochrome c
7	The clusters are built from cysteine sulfur and delivered by a chaperone system whose failure causes human disease
8	Fat is built on one sulfur carrier and taken apart on another, and is stored without sulfur in between
9	Malonyl-CoA closes the door to fat burning, so one thioester controls both directions

What would refute it

the claim	what would kill it
the three cofactors at the gate	a functioning pyruvate dehydrogenase lacking any one of them
lipoic acid as the carrier	a version of either dehydrogenase complex that moves the piece without it
the iron-sulfur relay	a respiratory chain shown to pass electrons through Complexes I to III without cluster involvement
the malonyl-CoA gate	measurement showing CPT1 activity independent of malonyl-CoA levels

And the observation this Part exists to record. A cell's energy system is usually drawn as carbon moving and electrons falling. Draw the same diagram again and mark every place a sulfur atom is holding something, and the marks fall on the gate into the cycle, on two steps inside it, on the wire out of it, on both directions of fat handling, and on the door between them. The carbon is what is being moved. The sulfur is what is doing the moving.

PART ONE HUNDRED AND SIXTEEN · SULFUR AND THE SUGAR AND THE HORMONE

Part One Hundred and Sixteen of the evidence volume, sections 1042 to 1054

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The most abundant steroid in human blood is not a hormone. It is a hormone with a sulfate on it, and it is present at two hundred and fifty times the concentration of the hormone itself. Every sulfation reaction in a human body — on a hormone, on a sugar, on a drug — is paid for by one molecule, PAPS, which is sulfate bolted to an adenosine. And a third of the dry weight of cartilage is a sugar chain covered in sulfate groups. The body's most common way of deciding whether a molecule is active is to put a sulfur on it or take one off.

1042. The Operation This Part Is About ↩

There is one chemical move behind everything in this Part.

a molecule with an -OH or an -NH + PAPS → the same molecule with a sulfate on it

adding the sulfate does one of three things	
turns the molecule off	a hormone with a sulfate on it cannot enter its receptor
makes it dissolve	so the kidney can remove it
makes it recognizable	a sugar chain with sulfates in a particular pattern is read by proteins as an address

And every one of those is reversible. An enzyme called a sulfatase takes the sulfate back off.

This is a switch built out of one atom, and the body uses it on hormones, on sugars, on drugs and on the lining of every blood vessel.

1043. The Currency ↩

PAPS

Nothing gets sulfated for free. The sulfate has to be activated first, and it is activated by being joined to an adenosine.

sulfate → APS → PAPS\n(one ATP) (one more ATP)

the enzymes in a human	PAPSS1 and PAPSS2 — one protein doing both steps
what needs it	all human sulfation pathways, without exception

Part One Hundred and Seven placed PAPS beside SAM and coenzyme A as the third sulfur currency, and noted that all three are adenosine conjugates. This Part is what the third one is for.

1044. The Most Abundant Steroid in Your Blood ↩

DHEA-sulfate	the most abundant circulating steroid in a human being
how much more than the unsulfated form	two hundred and fifty to three hundred times
the enzyme	SULT2A1, which puts the sulfate on carbon three
where it peaks	between the ages of twenty and thirty, and it falls steadily afterward

The most plentiful steroid in your bloodstream is a steroid that has been switched off with a sulfur, and it is being carried around in that state as a reserve.

A sulfatase takes the sulfate off where the hormone is wanted. The active hormone is made at the destination rather than at the source.

1045. And the Same Trick on the Estrogens ↩

estrone sulfate	circulates at far higher levels than estrone itself
what it is for	a reservoir, tapped locally by a sulfatase
why it matters clinically	this is the route some breast tumors use to make their own estrogen, and steroid sulfatase inhibitors were developed to block it

The sulfate is not decoration. It is the difference between a hormone that is stored and a hormone that is acting, and a single enzyme decides which.

1046. Now the Sugars ↩

Section 5 of this volume records that sulfur bonds to nitrogen in a sugar — N-sulfoglucosamine in heparan sulfate. Here is what that is for.

the chain	where it is
heparan sulfate	on the surface of nearly every animal cell
chondroitin sulfate	cartilage

the chain	where it is
keratan sulfate	cornea, cartilage
dermatan sulfate	skin, blood vessels, heart valves
heparin	the most negatively charged molecule the body makes

These are long chains of repeating sugar pairs with sulfate groups attached at particular positions. They are not built from a template. No gene specifies the pattern.

1047. And the Pattern Is the Message ↩

Where the sulfates sit on a heparan sulfate chain decides which proteins will stick to it.

growth factors	bind at particular sulfation patterns and not at others
antithrombin	binds one specific five-sugar sequence with a particular sulfate arrangement — this is why heparin thins blood
viruses	many use heparan sulfate as the first handhold on a cell

A pattern of sulfate groups is being read as information, by proteins, on the outside of every cell in your body. It is written by enzymes rather than copied from a template, so no sequencing method reads it and no gene contains it.

This volume's argument is about a notation that records letters. Here is a whole layer of biological information that has no letters at all.

1048. The Measure of How Much There Is ↩

cartilage, dry weight	a large fraction is proteoglycan — protein cores carrying dozens of sulfated sugar chains each
what the sulfates do there	they hold a negative charge that pulls water in, and the trapped water is what makes cartilage resist compression

A knee works because sulfate groups on a sugar chain hold water. When they are lost, the joint loses its cushion.

1049. And the Diseases That Prove It ↩

When the enzymes that break these chains down fail, the chains build up inside cells.

the group	what fails
the mucopolysaccharidoses	enzymes that take sulfated sugar chains apart
Hunter syndrome	a sulfatase — iduronate-2-sulfatase
Sanfilippo syndrome type A	a sulfamidase, which removes the sulfur-nitrogen group
multiple sulfatase deficiency	the enzyme that activates every sulfatase at once fails, and all of them stop

That last one is the clearest evidence in medicine that sulfation is a single system. One modification enzyme fails and seventeen different sulfatases go dark together.

1050. The Drug Column ↩

The same reaction handles compounds the body did not make.

what happens to many drugs in the liver	a sulfate is added, which makes them dissolve and leave
the enzymes	the SULT family
the competition	sulfation and glucuronidation compete for the same molecules, and which one wins depends on how much PAPS is available

Acetaminophen is the standard example. At ordinary doses it is largely sulfated and removed. At high doses the sulfate supply runs out, and the overflow goes down a route that damages the liver.

A common poisoning is, in part, a sulfur budget running dry.

1051. And the Sugar That Is Itself a Sulfur Compound ↩

Part One Hundred and Nine records sulfoquinovose — a sugar with a sulfonate group bonded straight to carbon, in the membrane of every plant, alga and cyanobacterium, holding an estimated half of the sulfur in the living world.

the sugar	sulfoquinovose
the bond	carbon to sulfur, not an ester — it cannot be taken off by a sulfatase
where it goes	eaten by gut bacteria, which run a whole pathway on it

1052. What the Notation Loses Here ↩

the molecule	what a database records
DHEA	a steroid
DHEA-sulfate	a steroid
a heparan sulfate chain with one pattern	a polysaccharide
the same chain with a different pattern	a polysaccharide
a drug	a drug
the same drug sulfated and on its way out	a drug

In every row, the two entries behave completely differently in a body, and the difference is one sulfate group. There is no letter for it and no sequence contains it.

1053. What This Part Refuses ↩

the claim	the status
DHEA-sulfate is the most abundant circulating steroid	established, and cited

the claim	the status
PAPS is required for all human sulfation	established, and cited
sulfation patterns on heparan sulfate determine protein binding	established
multiple sulfatase deficiency disables all sulfatases at once	established
that sulfation is therefore the body's main regulatory system	refused. Phosphorylation is far more common inside cells. Sulfation dominates outside them and in the liver, and the volume says which is which
that the sulfation pattern is a code in the sense the genetic code is a code	refused. It carries information and it is read. It is not translated, it is not copied, and it is not inherited

1054. What This Part Claims ↩

The claims

1	**All human sulfation runs on PAPS, which is sulfate joined to an adenosine at the cost of two ATP**
2	DHEA-sulfate is the most abundant circulating steroid in a human, at 250 to 300 times the level of DHEA
3	It peaks between twenty and thirty and declines with age
4	Estrone sulfate serves as a local reservoir, and steroid sulfatase inhibitors were built to interrupt it
5	Heparan, chondroitin, keratan and dermatan sulfate carry patterns of sulfate that proteins read
6	Heparin works because antithrombin recognizes one particular sulfated five-sugar unit
7	Cartilage resists compression because sulfate charge holds water
8	Multiple sulfatase deficiency disables every sulfatase at once, through one modification enzyme
9	Acetaminophen toxicity involves the sulfate supply running out
10	None of these patterns is written in any gene

What would refute it

the claim	what would kill it
PAPS as universal	a human sulfotransferase shown to use a different donor

the claim	what would kill it
the DHEA-S ratio	a measurement finding free DHEA at comparable circulating levels
pattern-dependent binding	a demonstration that protein binding to heparan sulfate depends only on chain length
the templateless claim of section 1047	discovery of a template or a gene that specifies sulfation position

And the observation this Part exists to record. A hormone is switched off by adding one sulfur and switched on by taking it away. A sugar chain becomes an address by where its sulfurs sit. A drug leaves the body because one was attached. Not one of these is visible in a sequence, and all of them are the difference between a molecule that acts and one that waits.

PART ONE HUNDRED AND SEVENTEEN · SULFUR AND THE NUCLEIC ACID

Part One Hundred and Seventeen of the evidence volume, sections 1055 to 1067

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

There is no sulfur in a canonical base, no sulfur in the sugar, and no sulfur in the backbone. A picture of DNA contains none. And every deoxyribonucleotide in that picture was made by a sulfur radical, every methyl on it was delivered by a sulfonium, the transfer RNA that reads it carries a thiolated uridine at the wobble position, the enzymes that copy and repair it hold iron-sulfur clusters, and bacteria put sulfur into the backbone itself. The element is absent from the molecule and present at every operation performed on it.

1055. The Absence, Stated First ↩

where sulfur is not	
adenine, guanine, cytosine, thymine, uracil	none
ribose and deoxyribose	none

where sulfur is not	
the phosphate backbone	none

A structure of the double helix contains not one sulfur atom. That is the fact this whole volume starts from, and it is worth printing plainly before the rest of this Part.

1056. And the Enzyme That Made Every Deoxy Sugar ↩

Ribonucleotide reductase

DNA is RNA with one oxygen removed from each sugar. One enzyme family does that removal, and it begins with a cysteine losing a hydrogen and becoming a radical.

what it does	ribonucleotide → deoxyribonucleotide
how it starts	a thiyl radical on a cysteine
the coverage	every deoxyribonucleotide in every strand of DNA in every organism that has ever lived

DNA did not exist until a sulfur radical was available to make it. Part Seven and Part Ten carry the full account.

1057. The Marks on the DNA ↩

Part One Hundred and Three establishes that both epigenetic currencies ride on sulfur.

the mark	the donor	the sulfur
a methyl group	S-adenosylmethionine	a sulfonium — sulfur with three bonds and a positive charge
an acetyl group	acetyl-CoA	a thioester

Every methyl on every cytosine in your genome came off a sulfur. So did every methyl on every histone, and every acetyl.

The writing apparatus of epigenetics has two hands and both are sulfur.

1058. And the Consequence That Made It a Hotspot ↩

Part One Hundred and Three, section 876. A cytosine that loses its amino group becomes uracil, which does not belong in DNA and is cut out. A methylated cytosine that loses its amino group becomes thymine, which does belong and is not.

C→T at a methylated CpG	ten to fifty times the rate of other transitions
share of inherited-disease mutations at CpG sites	about one third

The methyl that regulates the gene is the same chemical event that hides the damage. The methyl came off a sulfur.

1059. The Sulfur in the Transfer RNA ↩

Part One Hundred and Eleven sets out the wobble position. Two of the molecules that sit there carry sulfur.

2-thiouridine	a uridine with a sulfur replacing an oxygen at position 2
5-taurinomethyl-2-thiouridine	the mitochondrial form, carrying both a sulfur and a taurine

When the mitochondrial version fails, the transfer RNA cannot read either of its two codons at all, and the result is a named disease.

The 2-thio group is critical for decoding those codons. Losing one sulfur atom stops translation.

1060. And How That Sulfur Gets There ↩

A relay, and every step is named.

cysteine → IscS → TusA → TusBCD → TusE → MnmA → the uridine at position 34

Part Thirty-Two carries the full chain. The sulfur is pulled off a cysteine and handed along five proteins to arrive at one atom position on one nucleotide.

Five proteins, in a line, to move one sulfur atom onto one base.

1061. The Enzymes That Handle DNA Hold Iron and Sulfur ↩

This is the finding that has grown most in the last twenty years, and the field's own summary is direct.

Iron-sulfur clusters are cofactors in nuclear proteins involved in DNA replication, repair, telomere maintenance, transcription and mitosis. These include DNA polymerases, helicases and glycosylases.

the machine	why it matters
DNA polymerases	the enzymes that copy
helicases	the enzymes that unwind
glycosylases	the enzymes that find and cut out damage
primase	starts each new piece

And the consequence: defects in cluster assembly disrupt cell division and cause genome instability.

The machinery that copies and repairs the genetic material is built around a cofactor made of iron and sulfur, and the genetic material itself contains neither.

1062. The Sulfur in the Backbone ↩

Part Five records this and it belongs here. For fifty-five years the textbooks said there is no sulfur in DNA, and the founding experiment of molecular biology depended on that.

Hershey and Chase, 1952	labeled protein with radioactive sulfur and DNA with radioactive phosphorus precisely because the two do not mix
2007	bacterial gene clusters called dnd were found to replace one backbone oxygen with sulfur, at specific sequences and in a specific three-dimensional orientation
a later survey	1,349 such systems across many bacterial groups, nearly half without the defense machinery first thought to explain them

The separation that proved DNA carries heredity is not absolute. Sulfur is in the backbone of some bacterial genomes, in a defined place, and it changes how efficiently genes are transcribed.

1063. And the Free Bases Are the Wreckage ↩

Part Forty-Two, section 143, from the 1982 chart. Free bases — adenine, guanine, hypoxanthine, xanthine, uracil, thymine drawn without a sugar and without a phosphate — sit almost entirely inside the two boxes ruled PURINE CATABOLISM and PYRIMIDINE CATABOLISM.

In the building direction the ring is assembled on a sugar phosphate that was already there. The free base is not an intermediate.

The four letters name molecules that, in the direction that builds, occur nowhere on the chart.

1064. The One Enzyme That Puts a Sulfur Into the Purine Road ↩

Part Ninety-Five carries MOCOS — molybdenum cofactor sulfurase — the enzyme that installs the terminal sulfur on xanthine oxidoreductase.

what it does	puts a sulfur atom onto the molybdenum cofactor
what fails without it	xanthine cannot be turned into urate
the lesion in humans	CGA to TGA — a methylated CpG transition, the same lesion that disabled uricase

The enzyme that puts sulfur into the purine pathway was disabled by the same chemical event as the enzyme that ends it, and both are the deamination of a methylated cytosine.

1065. What the Notation Loses Here ↩

what is present	what the letter says
a cytosine	C
a cytosine carrying a methyl from a sulfonium	C
a uridine at the wobble	U
a 2-thiouridine at the wobble	U
a normal phosphate in the backbone	nothing — the backbone is not written at all
a phosphorothioate, with sulfur in the backbone	nothing

The backbone is the one part of the molecule the notation does not record at all, and it is the part where bacteria put the sulfur.

1066. What This Part Refuses ↩

the claim	the status
no canonical base, sugar or backbone contains sulfur	established
ribonucleotide reductase runs on a thiyl radical	established
both epigenetic marks are delivered from sulfur carriers	established

the claim	the status
nuclear DNA enzymes carry iron-sulfur clusters	established, and cited
bacterial phosphorothioate DNA is real and widespread	established
that DNA should therefore be described as a sulfur molecule	refused. It is not one. It contains none
that phosphorothioate DNA is common in humans	refused. It is a bacterial system and this volume does not claim otherwise
that the iron-sulfur clusters in polymerases prove sulfur controls replication	refused. They are required for the enzymes to work. Required is not the same as controlling

1067. What This Part Claims ↩

The claims

1	**There is no sulfur in any canonical base, sugar or backbone**
2	Every deoxyribonucleotide was made by an enzyme that starts with a cysteine radical
3	Every methyl and every acetyl mark is delivered from a sulfur carrier
4	C→T at methylated CpG runs ten to fifty times other transitions, and about a third of inherited disease sits there
5	Two of the molecules at wobble position 34 carry sulfur, and losing the 2-thio group stops translation of those codons
6	Five proteins in a line move that one sulfur atom from a cysteine to the base
7	DNA polymerases, helicases, glycosylases and primase hold iron-sulfur clusters
8	Bacterial dnd systems put sulfur in the DNA backbone, 1,349 of them found in one survey
9	Hershey and Chase used the sulfur-phosphorus separation in 1952, and it is not absolute
10	On the 1982 chart the free bases sit almost entirely inside the two catabolism boxes

What would refute it

the claim	what would kill it
the absence	a canonical base, sugar or backbone with sulfur in it

the claim	what would kill it
the radical mechanism	a ribonucleotide reductase working without a thiyl radical
the nuclear clusters	demonstration that these enzymes function with the clusters removed
the backbone survey	a re-analysis finding the dnd systems far rarer than reported

And the observation this Part exists to record. Sulfur is absent from the molecule and present at every operation performed on it — making the sugar, writing the mark, reading the codon, copying the strand, repairing the damage, and in some organisms holding the backbone together. The four letters describe the thing being worked on. They say nothing about the tools.

PART ONE HUNDRED AND EIGHTEEN · SULFUR AND THE DIVIDING CELL

Part One Hundred and Eighteen of the evidence volume, sections 1068 to 1080

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

In 1931 a French biologist proposed that cell division is controlled by sulfur — that thiol groups appear before a cell divides and drive the whole process. The idea was called the sulfhydryl theory of mitosis, it was taken seriously for thirty years, and it was set aside when no single mitotic substance could be found. Ninety-five years later, the machinery that copies the chromosomes, the machinery that repairs them, the pool that holds the cell in its resting condition, and the inspection point that decides whether division may proceed at all have each turned out to depend on sulfur. He was wrong about the mechanism and he was pointing at something real.

1068. The Old Idea, Stated Fairly ↩

Rapkine's sulfhydryl theory

The proposal, in its own terms: proteins partly unfold before a cell divides, which exposes thiol groups that were buried. Those thiols reduce oxidized glutathione. That activates glycolysis, and the metabolic events of division follow.

what the theory got right	what it got wrong
thiols and disulfides do influence progress through the cell cycle	there is no single mitotic substance
glutathione does rise at the onset of division	the causal chain as drawn does not hold
the sulfur pool and division are connected	the direction of the arrow was assumed rather than shown

Chalkley showed in 1942 that certain sulfur compounds could alter when Amoeba proteus began to divide. That is a real experimental result and it is eighty-four years old.

This volume prints the old theory because it was aimed at the right system with the wrong mechanism, and because almost nobody in the field remembers it.

1069. What the Modern Account Actually Says ↩

The field's own summary, from the current literature:

Sulfur is essential for mitosis through thiol-containing proteins, iron-sulfur clusters, and metabolites such as glutathione, which regulate DNA processes, cell cycle control and metabolic activity during cell division.

Three routes. This Part takes them one at a time.

1070. Route One — the Copying Machinery Is an Iron-sulfur Machinery ↩

Part One Hundred and Seventeen, section 1061, records it. It matters most here.

the machine	what it does at division
DNA polymerases	copy the chromosomes
helicases	unwind them

the machine	what it does at division
primase	starts every new piece
glycosylases	find and cut out damage before it is copied
telomere maintenance	protects the ends

All of them carry iron-sulfur clusters. And the consequence is stated plainly in the literature:

Defects in iron-sulfur cluster assembly disrupt cell division and cause genome instability.

A cell cannot copy its own chromosomes if its sulfur delivery system has failed.

1071. Route Two — the Pool ↩

Glutathione

what it is	three amino acids, and the working part is a cysteine thiol
how much	one to ten thousandths of a mole per liter inside a cell
what it does	holds the inside of the cell in the condition where disulfide bridges stay open
at the onset of division	it accumulates

That accumulation is what Rapkine saw. It is real and it is still reported.

Before a cell divides it stocks up on the most abundant thiol it has. What that stockpile is for is a live question, and this volume does not answer it.

1072. And Why a Cell Would Need the Pool Right Then ↩

Two demands land at once.

the demand	why it needs the thiol pool
making the DNA	ribonucleotide reductase runs on a cysteine radical and has to be reset after every single turn. Each of the roughly six billion

the demand	why it needs the thiol pool
	deoxynucleotides in a human S phase resets that enzyme once
handling the damage	copying generates breaks, and the repair enzymes are iron-sulfur proteins

The one enzyme that supplies every building block for the new chromosome is a sulfur enzyme that must be recharged after each unit it makes. A dividing cell needs its thiol supply for the same reason a factory needs a power feed.

1073. Route Three — the Switches ↩

Part Fifty-One records the sulfenyl-amide switch. It is a cell-cycle switch.

the enzyme family	the phosphatases, which remove phosphate groups
the mechanism	an active-site cysteine is oxidized to a sulfenic acid, which turns the enzyme off
the reversal	the glutathione pool turns it back on
what it controls	the balance between adding and removing the phosphates that drive the cell cycle

Whether a phosphatase is working depends on the oxidation state of one cysteine. That is a sulfur atom holding the brake on the cell cycle, and no sequence records which position it is in.

1074. And the One Thing That Must Be Counted Before Division ↩

Part Ninety-Eight of this volume records the finding, and it belongs here.

The DNA damage checkpoint fires on nucleotide pool depletion with no lesion present. Inhibit IMPDH, lose nascent dNTP incorporation, and the cell mounts a full damage response.

what the cell measures before it commits	
how much building material is left in the pool	
how much protein-coated single strand is exposed at a fork	

Neither of those is a letter. Both are amounts.

A cell decides whether to divide by measuring a concentration. The genome it is about to copy tells it nothing about that.

1075. The Mitotic Spindle, and One Honest Limit ↩

A reader will expect this Part to claim the spindle too. It does not.

what the spindle is made of	tubulin, which has cysteines
do those cysteines matter	yes — cysteine-modifying agents disrupt spindle assembly, and this has been known for decades
does that make the spindle a sulfur structure	no. Tubulin polymerization is driven by GTP, not by thiols. The cysteines are targets, and being a target is not the same as being the mechanism

Colchicine and the vinca alkaloids act on tubulin without touching sulfur at all.

1076. And the Place Where Sulfur Supply Limits Division Outright ↩

T cell proliferation	linked to how cysteine sulfur is partitioned
the general finding	sulfur availability influences cell cycle dynamics

A dividing cell needs more sulfur than a resting one, for the reasons in sections 1070 to 1073, and where sulfur is short the division slows.

1077. The Experiment This Part Generates ↩

Experiment Thirty-eight, for Part Twenty-Eight, section 65.

The question. Rapkine claimed the thiol rise causes division. Does it, or does it follow?

Method. In synchronized cells, measure the glutathione pool continuously through one full cycle with a genetically encoded thiol sensor, alongside two markers: the activity of ribonucleotide reductase, and the point at which the cell commits to S phase. Then run three conditions — normal, glutathione synthesis blocked, and the pool artificially raised before commitment. Ask whether raising the pool early moves the commitment point.

Falsification condition, written before the answer. If raising the thiol pool early does not advance commitment, then the rise is a consequence of preparing to divide rather than a cause of dividing, Rapkine's arrow points the wrong way, and this Part should record that the old theory described a correlation. If it does advance commitment, the ninety-five-year-old proposal has a measurement behind it for the first time.

The experiment is cheap, the reagents are ordinary, and the question has been open since 1931.

1078. What This Part Refuses ↩

the claim	the status
iron-sulfur clusters are required by the replication and repair machinery	established, and cited
glutathione accumulates at the onset of division	established
phosphatase cysteines are reversible switches	established
that sulfur controls mitosis	refused. The cycle is driven by cyclins and their kinases. Sulfur is required by the machinery those kinases turn on
that Rapkine was right	refused as stated. He proposed a specific causal chain and no single mitotic substance was found. This volume records that he was aimed at a real system
that the mitotic spindle is a sulfur structure	refused in section 1075

the claim	the status
that raising glutathione would speed up cell division	refused, and section 1077 is written to test it rather than assume it

1079. Why the Old Theory Is Worth Printing Anyway ↩

Rapkine had no way to see an iron-sulfur cluster. The techniques that made those clusters visible did not exist until the late 1950s, and even then the proteins fell apart on contact with air, so the work required sealed chambers and instruments most laboratories did not have.

He was looking at a system whose central components could not be observed with any tool available to him, and he described what he could measure: thiols going up before division. The mechanism he proposed was wrong. The system he identified was correct, and the reason it took ninety-five years to fill in is that the cofactor at the middle of it is destroyed by oxygen.

1080. What This Part Claims ↩

The claims

1	**Rapkine proposed in 1931 that thiol groups drive cell division**
2	Chalkley showed in 1942 that sulfur compounds alter the onset of division in Amoeba proteus
3	DNA polymerases, helicases, primase, glycosylases and telomere maintenance proteins all carry iron-sulfur clusters
4	Defects in cluster assembly disrupt division and cause genome instability
5	Glutathione accumulates at the onset of division
6	Ribonucleotide reductase runs on a cysteine radical and must be reset after every nucleotide
7	Phosphatase cysteines are reversible oxidation switches that the glutathione pool controls
8	The damage checkpoint fires on pool depletion with no lesion present

1	**Rapkine proposed in 1931 that thiol groups drive cell division**
9	The spindle is not a sulfur structure, and this Part says so
10	Sulfur availability influences how fast cells proliferate

What would refute it

the claim	what would kill it
the nuclear cluster requirement	replication and repair shown to proceed normally with cluster assembly disabled
the glutathione rise	measurement across a synchronized cycle finding no accumulation before division
the checkpoint claim	a repetition finding no damage response on pool depletion alone
Rapkine's arrow	Experiment Thirty-eight finding that raising the pool does not move the commitment point

And the observation this Part exists to record. A theory can be aimed correctly and built wrong, and the field will discard both together. Rapkine's mechanism did not survive. His subject did. Ninety-five years later the copying machinery, the repair machinery, the resting condition of the cell, and the brake on the cycle have each turned out to run on sulfur — and the reason nobody could see it in 1931 is that the central piece falls apart in air.

PART ONE HUNDRED AND NINETEEN · THE SYSTEMATIC NAMES

Part One Hundred and Nineteen of the evidence volume, sections 1081 to 1093

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

A reference table published in 1986 makes this volume's central argument in its second column, and makes it without knowing it. The systematic name of orotic acid is uracil-6-carboxylic acid. The systematic name of thymine is 5-methyluracil. Xanthine is 2,6-dioxopurine and hypoxanthine is 6-hydroxypurine, and the molecular weights say the step between them is exactly sixteen — one oxygen atom — and then exactly sixteen again to uric acid. The eight nucleotides are not eight different molecules. They are two ring skeletons carrying a small number of substituents, and the four letters name four of them.

1081. The Eight, Numbered ↩

This volume's numbering, fixed here.

number	base	ring
1	adenine	purine
2	guanine	purine
3	uracil	pyrimidine
4	thymine	pyrimidine
5	cytosine	pyrimidine
6	inosine — the base is hypoxanthine	purine
7	xanthine	purine
8	orotate — the acid is orotic acid	pyrimidine

Four purines, four pyrimidines. Four with letters, four without.

1082. The Source ↩

R. M. C. Dawson and colleagues, Data for Biochemical Research, third edition, Clarendon Press, Oxford, 1986, with the Merck Index, eleventh edition, 1989.

The table gives, for each base: the common name, the systematic name, the molecular formula, the molecular weight, the acid dissociation constants for each ionization stage, and the solubility in grams per hundred grams of solution at a stated temperature.

It is a data table. It makes no argument, takes no position, and was compiled by people with no interest in how many letters the genetic code ought to have.

1083. The Pyrimidine Half, as Printed ↩

common name	systematic name	formula	weight
cytosine	4-amino-2-hydroxypyrimidine	$C_4H_5N_3O$	111.10
5-methylcytosine	4-amino-2-hydroxy-5-methylpyrimidine	$C_5H_7N_3O$	125.13
5-hydroxymethylcytosine	4-amino-2-hydroxy-5-hydroxymethylpyrimidine	$C_5H_7N_3O_2$	141.13
uracil	2,4-dihydroxypyrimidine	$C_4H_4N_2O_2$	112.09
thymine	5-methyluracil	$C_5H_6N_2O_2$	126.11
orotic acid	uracil-6-carboxylic acid	$C_5H_4N_2O_4$	156.10

1084. And the Purine Half ↩

common name	systematic name	formula	weight
adenine	6-aminopurine	$C_5H_5N_5$	135.14
hypoxanthine	6-hydroxypurine	$C_5H_4N_4O$	136.11
guanine	2-amino-6-hydroxypurine	$C_5H_5N_5O$	151.13
isoguanine	6-amino-2-hydroxypurine	$C_5H_5N_5O$	151.13
7-methylguanine	7-methyl-2-amino-6-hydroxypurine	$C_6H_7N_5O$	165.16
xanthine	2,6-dioxopurine	$C_5H_4N_4O_2$	152.11
uric acid	2,6,8-trihydroxypurine	$C_5H_4N_4O_3$	168.11

1085. The Two Names That Settle the Argument ↩

Orotate

Uracil-6-carboxylic acid.

Orotate is uracil carrying a carboxyl group at position six. OMP decarboxylase removes that carboxyl. What is left is uracil.

the gate	orotate
what passes through it	uracil
the difference between them	one carboxyl group

Thymine
5-methyluracil.

Thymine is uracil carrying a methyl at position five. Part Seven records that the enzyme putting it there is a sulfur enzyme.

Two of the eight pyrimidines are uracil with one group added. The code gives one of them a letter and not the other.

1086. And the Purine Ladder Is Arithmetic ↩

Take the molecular weights from the table and subtract.

the step	the change	the difference
adenine → hypoxanthine	amino replaced by hydroxy	about 1
cytosine → uracil	amino replaced by hydroxy	about 1
hypoxanthine → xanthine	one oxygen added	152.11 − 136.11 = 16.00
xanthine → uric acid	one oxygen added	168.11 − 152.11 = 16.00
uracil → thymine	one methyl added	126.11 − 112.09 = 14.02
uracil → orotic acid	one carboxyl added	156.10 − 112.09 = 44.01

Sixteen, then sixteen again. Hypoxanthine to xanthine to uric acid is one oxygen atom at a time, and the table's own numbers say so to two decimal places.

And the two "about one" rows are the same chemical move on the two different rings — an amino group leaving and a hydroxy taking its place. That is deamination, and

Part Two of this volume calls it the conjugate channel. Here it is as a mass difference, on both rings, at the same size.

1087. And Two of Them Are the Same Atoms ↩

	formula	weight
guanine	$C_5H_5N_5O$	151.13
isoguanine	$C_5H_5N_5O$	151.13

Same atoms. Same mass. The only difference is which position carries the amino and which carries the hydroxy — guanine has amino at two and hydroxy at six, isoguanine has them the other way around.

One of them is in the genetic code and one of them is not. No count of atoms distinguishes them. Only the arrangement does, and no letter records an arrangement.

1088. The Acid Constants, and the One That Sits at Body PH ↩

The table gives the pKa for each ionization stage. One number stands out.

base	the pKa values
adenine	<1 · 4.1 · 9.8
hypoxanthine	2.0 · 8.9 · 12.1
guanine	3.3 · 9.2 · 12.3
xanthine	0.8 · 7.4 · 11.1
uracil	0.5 · 9.5 · >13
thymine	9.9 · >13
orotic acid	2.4 · 9.5 · >13

Xanthine's middle pKa is 7.4. That is the pH of blood. Xanthine sits half-charged at body temperature and body acidity, and it is the only base on the sheet that does.

Section 200 of this volume records the correction that follows from it: xanthine is substantially deprotonated at physiological pH, and the deprotonated form pairs better rather than worse.

1089. And the Solubility Column Explains a Disease ↩

base	grams per hundred grams of solution
cytosine	0.76
thymine	0.4
uracil	0.36
orotic acid	0.18
adenine	0.09
hypoxanthine	0.07
xanthine	0.05
isoguanine	0.006
guanine	0.004
uric acid	0.002

The purine pathway ends in the least soluble compound on the sheet. Uric acid is three hundred and eighty times less soluble than cytosine.

Gout is that number. Part Ninety-Five records that human uricase, the enzyme that would take urate further and make it soluble, was disabled in our lineage by a single transition at a methylated CpG site — and that CGA is the only codon in the genetic code that becomes a stop codon by mutating one.

1090. What the Table Shows That the Code Does Not ↩

what the systematic names record	what a letter records
which ring	nothing
which position carries which group	nothing
that thymine is uracil plus a methyl	two unrelated letters, T and U

what the systematic names record	what a letter records
that orotate is uracil plus a carboxyl	one letter and one blank
that xanthine is hypoxanthine plus an oxygen	two blanks
that guanine and isoguanine are the same atoms rearranged	one letter and one blank

The second column of a 1986 data table describes the eight bases as one family with a handful of substitutions. The four-letter code describes four of them as unrelated symbols and does not mention the rest.

1091. What This Part Refuses ↩

the claim	the status
the systematic names are as printed	established — the table is named, dated and obtainable
the molecular weights and their differences	arithmetic, checkable by anyone with the table
xanthine's middle pKa is 7.4	as printed
uric acid is the least soluble compound listed	as printed
that the code ought therefore to have eight letters	refused. The code assigns amino acids to codons and does that correctly. This Part shows that its four symbols do not describe the chemistry of the family they are drawn from
that isoguanine has a biological role equivalent to guanine	not claimed. It is listed in the table and it is not a standard base
that the 1986 table supports this volume's framework	refused. It is a data compilation. It supports nothing. It records measurements, and the measurements are what this Part reports

1092. The Experiment This Part Generates ↩

Experiment Thirty-nine, for Part Twenty-Eight, section 65.

The question. Does the sixteen-mass-unit ladder from hypoxanthine to xanthine to uric acid appear as a measurable series in a real tissue?

Method. Take one tissue by mass spectrometry and measure the three species together in the same sample, without separate assays. Report their molar ratio. Then repeat under conditions where xanthine oxidoreductase is inhibited by allopurinol and where its sulfur has been removed by loss of MOCOS. Public methods, ordinary instrumentation, no novel reagents.

Falsification condition, written before the answer. If the three species cannot be resolved and quantified together in a single run, the ladder is a paper relationship rather than a measurable series, and section 1086 should say that it is arithmetic on a reference table and nothing more.

1093. What This Part Claims ↩

The claims

1	**This volume numbers the eight: adenine 1, guanine 2, uracil 3, thymine 4, cytosine 5, inosine 6, xanthine 7, orotate 8**
2	The systematic name of orotic acid is uracil-6-carboxylic acid
3	The systematic name of thymine is 5-methyluracil
4	Xanthine is 2,6-dioxopurine and hypoxanthine is 6-hydroxypurine
5	Hypoxanthine to xanthine is exactly 16.00 mass units, and xanthine to uric acid is exactly 16.00 again
6	Uracil to thymine is 14.02; uracil to orotic acid is 44.01
7	Guanine and isoguanine share the formula $C_5H_5N_5O$ and the weight 151.13, differing only in which position carries which group
8	Xanthine's middle pKa is 7.4
9	Uric acid is the least soluble compound in the table at 0.002 grams per hundred

What would refute it

the claim	what would kill it
the systematic names	a current authority giving orotate a name that is not built on uracil
the mass ladder	a recalculation from the formulas giving a different difference

the claim	what would kill it
the isoguanine identity	a formula for isoguanine that differs from guanine's
the pKa	a redetermination placing xanthine's second ionization away from physiological pH

And the observation this Part exists to record. Every fact in it was published in 1986 in a reference table that any biochemist can pull off a shelf, and none of it required a new measurement, a new instrument or a new theory. The second column was always there. It says the eight bases are one family, and the code names half of them.

PART ONE HUNDRED AND TWENTY · THE TOOL IS MADE FROM THE TARGET

Part One Hundred and Twenty of the evidence volume, sections 1094 to 1106

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Two enzyme families in a human cell perform the same chemical act on the same atom of the same base, and they are not related in purpose, location, target or disease. One works on transfer RNA at a single position. The other works on messenger RNA, almost entirely inside the repeated stretches called Alu. The literature calls the reaction A-to-I editing in both cases and the shared name hides two different systems. And the gene-editing tool that would repair the disease on the first side was built by directed evolution from a bacterial enzyme that does the first side's job — the same chemistry, on the same position, of the same kind of molecule.

1094. The One Reaction, and the Two Systems That Run It ↩

The chemical act is the same in both. An amino group is removed from adenosine and a water-derived oxygen takes its place. The product is inosine.

adenosine + water → inosine + ammonia

	ADAT2 and ADAT3	ADAR1, ADAR2 and ADAR3
what they work on	transfer RNA	double-stranded messenger

	ADAT2 and ADAT3	ADAR1, ADAR2 and ADAR3
		RNA
where	one position — the wobble, number 34	scattered, mostly inside Alu repeats
how many targets	a handful of transfer RNAs	very large numbers of sites
is it optional	no. Life requires it	no, but for a different reason
the diseases	ADAT3 intellectual disability	Aicardi-Goutières syndrome, a skin disorder, an ALS link

These are two systems with one name. A reader who searches the literature for "A-to-I editing" is handed both and told nothing about which is which.

1095. The First Editor, and Why It Cannot Be Skipped ↩

ADAT2 and ADAT3

Two different proteins that work only as a pair. ADAT2 carries the chemical machinery. ADAT3 has no working active site of its own and is required anyway.

what they make	inosine at position 34 of transfer RNA
why position 34 matters	it is the first letter of the anticodon, the one that meets the third letter of the codon
what inosine does there	reads three different codon endings — A, C and U — with one molecule
can a eukaryote live without it	no

Part One Hundred and Eleven of this volume sets out the wobble position in full. The short version is that inosine at 34 is how a cell covers sixty-one codons with far fewer transfer RNAs.

One enzyme pair, one atom position, and the arithmetic of the whole decoding system depends on it.

1096. The Second Editor, and Where It Actually Works ↩

ADAR

ADAR1	**the broad one. Two forms, one of which patrols the cytoplasm**
ADAR2	the precise one. Its best-known job is a single position in a brain receptor
ADAR3	has no catalytic activity at all. Brain-only, and appears to get in the other two's way

ADAR needs double-stranded RNA to work on. In a human cell, most of that double-stranded RNA is made by accident.

How the accident happens

Alu is a repeated stretch of about three hundred letters. There are more than a million copies in the human genome, and they sit thickly inside the untranslated tails and the interior spacers of ordinary genes.

When two Alu copies land in the same transcript pointing in opposite directions, they are complementary to each other. The RNA folds back and pairs with itself.

——— Alu ———> <——— Alu ———\n\ /\n_____/ a double-stranded hairpin,\nmade by two repeats facing\neach other in one transcript

The overwhelming majority of A-to-I editing events in a human being occur in transcripts derived from Alu repeats. That is where ADAR1 spends its working life.

1097. And What ADAR1 Is Actually For ↩

The cell has a sensor called MDA5 whose job is to detect long double-stranded RNA and raise the alarm, because long double-stranded RNA is what a virus makes.

The accidental Alu hairpins look exactly like that.

the problem	**the cell's own transcripts contain structures indistinguishable from viral RNA**
what ADAR1 does about it	edits them. Each inosine put into the duplex weakens the pairing
the result	the hairpin becomes untidy enough that MDA5 no longer reads it as an invader

the problem	**the cell's own transcripts contain structures indistinguishable from viral RNA**
the name for this	marking the RNA as self

ADAR1 also binds a left-handed form of RNA called Z-RNA, and disrupting only that binding is enough to produce the disease in animals.

ADAR1 is not an editor in the sense of improving a message. It is a marking system. It writes a chemical signature onto the cell's own double-stranded RNA so the cell's own immune sensor will leave it alone.

1098. The Disease on the First Side ↩

ADAT3, and a mutation sixteen centuries old

the change in the gene	**c.382G>A — one letter, G to A**
the change in the protein	valine to methionine at position 144 — V144M
how old it is	about 1,600 years
its standing	the most common cause of inherited intellectual disability in Arabia where both copies are affected
the description in the literature	24 individuals from eight Saudi families, with cognitive impairment and strabismus, and commonly growth failure, small head size, muscle tone abnormalities and epilepsy

What the mutant protein does

does it still bind its partner	**yes. The pair still forms**
does the pair still work	greatly reduced activity
what else goes wrong	the protein clumps together, and is found associating with the cell's folding chaperones

One letter, in one gene, changing one amino acid, in a protein with no active site of its own — and the consequence is less inosine at position 34 across the transfer RNA population, and a named intellectual disability affecting families across a region for sixteen hundred years.

1099. And the Diseases on the Second Side ↩

Aicardi-Goutières syndrome type 6	ADAR1 fails, the self-marking fails, MDA5 reads the cell's own RNA as a virus, and the body mounts a permanent antiviral response against itself
dyschromatosis symmetrica hereditaria	a skin pigmentation disorder, also from ADAR1
the receptor position	ADAR2 edits one site in a brain glutamate receptor. Losing that single edit is fatal in animals

On the ADAR side the failures are not failures of decoding. They are failures of the boundary between self and not-self, and a failure at one position in one brain receptor.

1100. Which of These Is an Editing Target ↩

This is the practical question, and the two sides give opposite answers.

	ADAT3	ADAR1
how many sites are broken	one	the marking of very large numbers of duplexes
what a correction would have to do	change one letter back	restore an entire ongoing process
is the change the right kind	yes — G back to A means A back to G on the other strand, which is the reaction current tools do best	not applicable
is there a defined population	yes, and a founder mutation makes it one edit for many families	no
verdict	a well-formed target	not a target of this kind

And the route that is not editing at all

The same work that characterized the mutant protein found something else: the clumping can be suppressed by supplying more of the partner protein, ADAT2.

If the problem is a protein that misfolds and aggregates rather than a protein that is absent, then more of its partner may rescue it without

touching the gene at all. This volume records that route alongside the editing route and does not rank them.

1101. The Bacterial Enzyme That Does the Same Job ↩

TadA

Bacteria have their own version of this enzyme, and it is simpler than the human one.

the name	TadA — transfer RNA adenosine deaminase
what it does	makes inosine at position 34
on how many transfer RNAs	one. In bacteria, transfer RNA for arginine is the only one carrying this modification
is it essential	yes
its relation to the human enzyme	it is the ancestor of ADAT2, the half of the human pair that carries the chemistry

One enzyme, one transfer RNA, one position, in bacteria. The same enzyme, doubled into a pair and extended to several transfer RNAs, in us.

1102. And the Gene-Editing Tool Was Built From It ↩

This is the finding this Part exists to record.

The adenine base editor — the tool that changes an A to a G in DNA without cutting the double helix — was not designed from scratch. It was made by taking TadA and forcing it to evolve until it would work on DNA instead of transfer RNA.

TadA makes inosine at position 34 of a bacterial transfer RNA\n/\n/ directed evolution in the laboratory\nv\nevolved TadA performs the same deamination on single-stranded DNA\n/\n/ attached to a Cas9 that nicks but does not cut through\nv\nthe adenine base editor changes one A to a G at a chosen place in a genome

Now put the two facts together

the disease	**ADAT3 V144M — the human enzyme that makes inosine at position 34 is broken**
the tool that would fix it	an evolved TadA — the bacterial enzyme that makes inosine at position 34

The instrument that would repair the gene was built out of the bacterial version of that gene's own partner. The tool and the target are the same enzyme, separated by two billion years and one round of laboratory evolution, and the chemistry both of them perform is the removal of an amino group from adenosine at wobble position 34.

Nobody planned this. The base editor was built because TadA was a small, efficient, well-understood deaminase, and its natural substrate was an accident of what the laboratory had on the shelf.

1103. What the Notation Loses Here ↩

what is present	what a sequence records
an adenosine at position 34	A
an inosine at position 34, made deliberately by an enzyme pair	A — the sequencing chemistry reads inosine as G, so it may also read G
an Alu repeat, unedited, being read as viral	the Alu sequence
the same Alu, edited at many positions, marked as self	the same Alu sequence
a working ADAT3	the gene
V144M — the protein binds, barely works, and clumps	one letter different

The distinction between a molecule the immune system attacks and the same molecule it ignores is written in inosines that no sequence file records as inosines. And the enzyme that writes them is read, by the same notation, as a single changed letter.

1104. What This Part Refuses ↩

the claim	the status
ADAT2/ADAT3 makes inosine at wobble position 34 and is essential	established
ADAR edits mostly within Alu-derived duplexes	established, and cited
ADAR1 editing prevents MDA5 from sensing the cell's own RNA as foreign	established, and cited
the ADAT3 mutation is c.382G>A, V144M, about 1,600 years old	established, and cited
the adenine base editor was evolved from TadA	established, and cited
TadA acts at position 34 of bacterial transfer RNA for arginine	established, and cited
that ADAT3 disease has been treated by base editing	refused. It has not. This Part sets out why the target is well formed. That is not the same as a therapy
that ADAR1 disease could be corrected by an editor	refused. The loss is of an ongoing process across very many sites, and no single edit restores it
that the TadA connection was intended by anyone	refused. It is a coincidence of laboratory history, and this Part records it as one
that ADAT and ADAR are one system because they run one reaction	refused. That is the confusion this Part exists to remove

1105. The Experiment This Part Generates ↩

Experiment Forty, for Part Twenty-Eight, section 65.

The question. In cells from a person carrying the ADAT3 V144M change, does correcting the single letter with an adenine base editor restore inosine at position 34 across the transfer RNA population — and does supplying extra ADAT2 do the same thing without touching the gene?

Method. Take patient-derived cells. Run three arms: uncorrected, corrected with an adenine base editor aimed at c.382, and untouched but supplied with additional ADAT2. In each arm measure two things directly — how much inosine sits at position

34, by a method that does not convert it first, and whether the protein still clumps. Report both, per arm.

Falsification condition, written before the answer. If base correction restores the letter but does not restore inosine at position 34, then the letter was not the whole lesion and this Part's account of the mechanism is incomplete. If extra ADAT2 restores the modification as well as the base edit does, then a disease with a clean single-letter target is better treated without editing it, and section 1113 should say so.

The two arms test opposite propositions, and the experiment is written so that either outcome is informative.

1106. What This Part Claims ↩

The claims

1	**Two unrelated enzyme families run the same reaction, and the shared name A-to-I editing hides the difference**
2	ADAT2 and ADAT3 work as a pair at one position — the wobble, number 34 — and eukaryotic life requires it
3	ADAR works on double-stranded messenger RNA, and the overwhelming majority of its sites lie in Alu-derived duplexes
4	Those duplexes form when two Alu copies face each other in one transcript
5	ADAR1 editing marks that RNA as self so MDA5 does not sound the viral alarm
6	Losing that marking is Aicardi-Goutières syndrome — the body running an antiviral response against its own transcripts
7	ADAT3 c.382G>A, V144M, arose about 1,600 years ago and is the commonest inherited intellectual disability in Arabia
8	The mutant still binds ADAT2, has greatly reduced activity, and clumps
9	Extra ADAT2 suppresses the clumping, which is a route that does not involve editing
10	The adenine base editor was made by evolving TadA, the bacterial enzyme that makes inosine at position 34

What would refute it

the claim	what would kill it
the two-system distinction	a demonstration that ADAT and ADAR share targets in a

the claim	what would kill it
	normal cell
the Alu placement	a survey finding the bulk of editing outside Alu-derived duplexes
the self-marking account	animals lacking ADAR1 that do not develop the sensor-driven response
the founder mutation dating	a re-analysis of the shared haplotype giving a substantially different age
the TadA lineage of the base editor	a base editor of this class shown to derive from something other than a transfer RNA deaminase

And the observation this Part exists to record. A cell makes inosine at one position in its transfer RNA so that one molecule can read three codons, and it makes inosine across its own repeated elements so that its immune system will not attack them. Same atom, same reaction, same product, two purposes that have nothing to do with each other. The notation writes both as A, or as G, and never as what they are. And the tool a laboratory would reach for to repair the first system was manufactured out of that system's own bacterial ancestor — which is either a coincidence or an indication of how few ways there are to do this chemistry at all.

PART ONE HUNDRED AND TWENTY-ONE · THE INTERIOR THAT NEVER CHANGED

Part One Hundred and Twenty-One of the evidence volume, sections 1107 to 1119

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The largest chemical change in the history of this planet is dated by sulfur. Not by measuring oxygen, which leaves no direct record, but by watching a sulfur isotope signal switch off in the rock. That signal could only be made in an atmosphere with no oxygen in it, and when it stops, the oxygen has arrived. The event took roughly a hundred and forty million years, it was not the same everywhere at once, and it changed what sulfur could do in a cell. And then every cell that survived it did one thing: it kept the old world inside itself. The inside of a living cell is still chemically reducing, two and a third billion years later, and a sulfur compound is what holds it that way.

1107. The Event Is Dated by the Wrong Element ↩

Section 14 of this volume states the fact. This Part is the whole of it.

what happened	free oxygen accumulated in the atmosphere for the first time
roughly when	about 2.4 billion years ago
how it is dated	by the disappearance of a sulfur isotope signal from sedimentary rock
is oxygen measured directly	no. Oxygen leaves no isotope fingerprint of its own arrival

The most important event in the chemical history of the planet is read off the isotopes of the element this book is about. Not as a metaphor, and not as this volume's interpretation. That is how the people who date it, date it.

1108. Why Sulfur Records It and Oxygen Does Not ↩

Sulfur has four stable isotopes — atoms of the same element with different masses.

sulfur-32	the common one
sulfur-33	
sulfur-34	
sulfur-36	

Ordinary chemistry sorts isotopes by mass, and it sorts them in proportion. If a reaction favors the light one, it favors sulfur-33 by about half as much as it favors sulfur-34, because sulfur-33 is about half as far from sulfur-32 in mass. Everything scales. This is called mass-dependent sorting, and it is what almost every chemical and biological process does.

One kind of process does not obey it.

Certain reactions driven by ultraviolet light sort sulfur isotopes out of proportion to their masses. Sulfur-33 comes out enriched by an

amount that has nothing to do with being half as heavy. This is called mass-independent fractionation, and the measured quantity is written $\Delta^{33}S$.

A nonzero $\Delta^{33}S$ in a rock is a fingerprint. It says light did this, in the gas phase, not chemistry and not life.

1109. The Mechanism — Light, and No Shield ↩

Sulfur dioxide from volcanoes rises into the atmosphere. Ultraviolet light strikes it and breaks it apart, and the breaking sorts the isotopes out of proportion.

$$volcanic\ SO_2 \ + \ ultraviolet\ light \ \rightarrow \ sulfur\ products\ carrying\ a\ nonzero\ \Delta^{33}S$$

But that only works if the ultraviolet light reaches the sulfur dioxide.

what blocks that ultraviolet	ozone — and ozone is made from oxygen
what else erases the signal	an oxygen-bearing atmosphere mixes the sulfur products back into one pool, and the fingerprint averages away

So the signal requires an atmosphere with essentially no oxygen in it. When oxygen appears, an ozone layer forms, the ultraviolet no longer reaches the sulfur dioxide, and the fingerprint stops being made. It never comes back.

The founding measurement is Farquhar and colleagues, in Science, 2000. Laboratory work since has confirmed the mechanism by making the signal on purpose — shining ultraviolet light on sulfur dioxide, hydrogen sulfide and carbon disulfide, and recovering the same out-of-proportion sorting.

1110. What the Record Actually Shows ↩

A reader expects a line: signal present, then signal absent, one date. That is not what the rocks say.

the signal is present	throughout the Archean, in rock after rock
it begins to falter	about 2.45 billion years ago
it is gone	after about 2.31 billion years ago
in between	the signal disappears and returns, more than once

The transition took something on the order of a hundred and forty million years, and it flickered. The atmosphere did not switch. It wandered across a threshold several times before it stayed on the other side.

This volume prints the interval rather than a single number, because the interval is what was measured.

1111. And the Refinement That Came Later ↩

Work published since has found something further, and it matters for how the event should be described at all.

The sulfur isotope signals are not synchronous around the world. Different basins lose the fingerprint at different times, which means the record is partly local — recycled older sulfur, basin conditions, and the path a given sulfur atom took before it was buried.

what this does not overturn	that the signal requires an oxygen-free atmosphere, and that it ends
what it does change	the idea of a single global date. The field has been asked to redefine the event accordingly

This volume states the mechanism as established and the exact global timing as under active revision, which is what the literature currently supports.

1112. The Eight Hundred Meters of Salt ↩

The most direct evidence of what came after is not an isotope ratio. It is a pile of evaporated seawater.

In Russian Karelia, in the Onega Basin, there is a sequence of evaporite rock about two billion years old and roughly eight hundred meters thick — more than a billion years older than the next comparable deposit anyone has found.

the layers, from the bottom	
about 100 meters	halite — common salt
about 500 meters	anhydrite and magnesite — calcium sulfate and magnesium carbonate
about 200 meters	dolomite and magnesite

Five hundred meters of calcium sulfate. To precipitate that, the seawater it evaporated from had to be carrying sulfate, and the minerals constrain how much: at least ten millimoles per kilogram.

The authors put a number on what that means. The sulfate in that one basin represents an oxidizing reservoir equivalent to more than twenty percent of the entire modern ocean and atmosphere's oxidizing capacity — sitting in rock, two billion years old.

And note which two elements built the pile. Sulfate and magnesium.

1113. What the Ocean's Sulfate Did ↩

Sulfate is oxidized sulfur. Before there was oxygen there was very little of it.

	seawater sulfate
the Archean, before the event	extremely low
after the event, at its peak	high enough to precipitate five hundred meters of calcium sulfate
through much of the middle Proterozoic afterward	back down — below 400 micromolar, possibly as low as 100
today	about 28 millimolar

Two things put sulfate into the ocean once oxygen existed: rain and weather attacking sulfide minerals on land and oxidizing them, and a sulfur cycle in the sea that could now run in both directions.

The concentration did not rise once and stay. It rose, fell back, and only reached modern levels much later. The chemistry available to a cell depended on where in that history the cell lived.

1114. And What That Made Possible in a Cell ↩

Part One Hundred and Sixteen of this volume records that every sulfation reaction in a human body is paid for with PAPS, and that PAPS is made from sulfate and two ATP.

$$sulfate \rightarrow APS \rightarrow PAPS\n(one\ ATP)\ \ (one\ more\ ATP)$$

That pathway needs sulfate to exist in quantity. So does assimilatory sulfate reduction — the route by which an organism takes sulfate from its surroundings and turns it into the cysteine that every protein in this volume depends on.

before the event	sulfur was available mostly as sulfide and other reduced forms
after it	sulfate became a bulk resource, and the pathway that activates it became worth having

The hormone switch of Part One Hundred and Sixteen, the cartilage of a knee, the way a drug leaves the liver — all of it runs on activated sulfate, and activated sulfate needs an oxidized world to draw from.

1115. The Bond That Could Not Exist Before ↩

Two cysteines joined by a sulfur-sulfur bridge — the disulfide of Part One Hundred and Fourteen — is an oxidation. Making one releases electrons. It happens readily in an oxidizing environment and it does not happen in a reducing one.

where structural disulfides are found	in secreted and surface proteins — antibodies, insulin, digestive enzymes, the proteins of hair, skin and connective tissue
where they are not found	in the ordinary proteins of the cytoplasm
why not	the cytoplasm will not let them form

The folding bridge that holds a great many proteins in shape is a bond that an oxygen-free world could not have made in quantity. The Great Oxidation Event did not merely change the air. It opened a chemical option, and a large fraction of the proteins outside your cells are held together by it.

1116. And the Interior That Never Changed ↩

This is the observation this Part exists to make.

Oxygen arrived 2.4 billion years ago and filled the atmosphere and the ocean. It did not get inside the cell. Every living cell holds its interior in a reducing condition — the opposite of the world outside it — and it does this with a sulfur compound.

what holds the interior reducing	**glutathione, whose working part is a cysteine thiol**
how much of it	one to ten thousandths of a mole per liter — Part One Hundred and Eighteen, section 1071
the consequence	disulfide bridges do not form there. Thiols stay open
where oxidizing conditions begin	at a membrane. Disulfides are made in a separate compartment, and outside the cell entirely

ARCHEAN CONDITIONS | POST-OXIDATION CONDITIONS\nreducing, thiols open | oxidizing, disulfides form\nheld by glutathione | held by the atmosphere\n---------- membrane ----------\nthe cytoplasm of every cell | the ocean, the air, and the space\nalive today | outside your cells

A cell is a piece of the pre-oxidation world, maintained against the present one by a sulfur compound, continuously, for two and a third billion years. The membrane is where the Archean ends. Nothing in any sequence records which side of that line a given cysteine is on, and which side it is on decides whether it will form a bond or stay open.

1117. What This Part Refuses ↩

the claim	the status
the event is dated by the loss of mass-independent sulfur isotope fractionation	established, and cited
the signal requires an atmosphere effectively free of oxygen	established, and cited
the signal is made by ultraviolet photolysis of sulfur gases	established, reproduced in the laboratory
the transition runs from about 2.45 to about 2.31 billion years ago and flickers	established, and cited
the Onega evaporites constrain sulfate to at least ten millimoles per kilogram	as published
the cytoplasm is held reducing by glutathione and structural disulfides are extracellular	established
that a single global date for the event is secure	refused. The signals are not synchronous between basins and the field has been asked to redefine the event
that sulfur caused the Great Oxidation Event	refused. Oxygenic photosynthesis did. Sulfur is how it is read, not what did it
that the reducing cytoplasm is a deliberate preservation of the Archean	refused as intent. It is the condition the chemistry of the interior requires. That it is also the older condition is an observation, not a purpose
that disulfide bonds were impossible before the event	refused as absolute. They were not available in bulk. Local oxidants existed

1118. The Experiment This Part Generates ↩

Experiment Forty-One, for Part Twenty-Eight, section 65.

The question. If the reducing interior is a maintained condition rather than an incidental one, then the machinery that maintains it should be among the most conserved sulfur machinery in biology — more conserved than the machinery that uses sulfur for anything else.

Method. This is a computational experiment and needs no laboratory. Take three sets of genes: the glutathione system that holds the interior reducing, the disulfide-forming system that operates outside it, and the sulfur-assimilation system that

brings sulfate in. Across a wide sample of sequenced organisms spanning all three domains, measure how universally each set is present and how strongly each is conserved. Then ask which set is oldest by the standard tests.

Falsification condition, written before the answer. If the disulfide-forming machinery is as universal and as conserved as the glutathione machinery, then the interior and exterior systems are of comparable age, the framing of section 1116 as an old interior and a newer exterior is not supported, and this Part should say so. If the sulfur-assimilation machinery proves the most conserved of the three, the ordering this Part implies is wrong in a different way and should be corrected.

The data required is public, the methods are standard, and the result is obtainable without a bench.

1119. What This Part Claims ↩

The claims

1	**The Great Oxidation Event is dated by the disappearance of a sulfur isotope signal, not by measuring oxygen**
2	That signal — nonzero $\Delta^{33}S$ — is made by ultraviolet light breaking sulfur gases in an atmosphere with no oxygen
3	Oxygen ends it twice over: an ozone layer blocks the light, and an oxygenated atmosphere averages the products together
4	The transition runs from about 2.45 to about 2.31 billion years ago and is punctuated rather than sharp
5	The signals are not synchronous between basins, and the field has been asked to redefine the event accordingly
6	The Onega Basin holds about 800 meters of two-billion-year-old evaporite, including roughly 500 meters of calcium sulfate
7	Those minerals constrain seawater sulfate to at least ten millimoles per kilogram, an oxidant reservoir put at more than twenty percent of the modern ocean-atmosphere oxidizing capacity
8	Seawater sulfate rose, fell back below 400 micromolar for much of the middle Proterozoic, and reached today's roughly 28 millimolar much later
9	Activated sulfate chemistry — PAPS, and assimilatory sulfate reduction — needs an oxidized sulfur supply
10	Structural disulfide bonds are found in secreted and surface proteins and not in the cytoplasm
11	The cytoplasm of every living cell is held reducing by glutathione, and the membrane is where the two chemical

1	**The Great Oxidation Event is dated by the disappearance of a sulfur isotope signal, not by measuring oxygen**
	worlds meet

What would refute it

the claim	what would kill it
the dating mechanism	a route to nonzero $\Delta^{33}S$ that operates in an oxygen-bearing atmosphere
the interval	a re-analysis placing the loss of the signal at a single sharp global date
the evaporite constraint	a re-interpretation of the Onega minerals requiring far less sulfate
the compartment claim	a survey finding structural disulfides as common in cytoplasmic proteins as in secreted ones
the conservation ordering	Experiment Forty-One finding the disulfide machinery as old as the glutathione machinery

And the observation this Part exists to record. The planet changed once, permanently, and we know when because sulfur stopped being sorted strangely by sunlight. Everything alive today descends from something that survived that change, and the way it survived was to hold a pocket of the older chemistry inside a membrane and keep it there. Your cells are still doing it. The thing standing between the inside of you and the atmosphere that killed most of what was alive in 2.4 billion years ago is a small molecule with a sulfur atom on it, present in every cell, replaced constantly, and named in no genetic sequence.

PART ONE HUNDRED AND TWENTY-TWO · THE CLIMB, AND WHAT DECIDES WHEN

Part One Hundred and Twenty-Two of the evidence volume, sections 1120 to 1132

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The central dogma is taught as a sequence of molecules. This Part sets it out as a climb through dimensions — a letter, then a line, then a sheet, then a shape that occupies space and has to arrive at a particular place at a particular moment. Everything through the peptide is answered by sequence. Nothing after it is. The

question changes from what comes next to when, and the thing that answers the new question is not the code. And of the eight nucleotides this volume tracks, seven have now been found in material that never touched this planet. One has not, and it is the one at the gate.

1120. The Four Sheets ↩

This Part is drawn from four working sheets, made in sequence. They are described here because the order of them is part of the finding.

the sheet	what it is
the first	the chain written out once, with the enzyme bracketed underneath and the words when · to fold · target · space
the second	the same chain with the counts — 3.2 billion base pairs, 20,000 to 22,000 genes — and the steps numbered one through nine
the third	the shorthand pass, arrows and single words, no sentences
the fourth	the whole thing on one page, with the prebiotic inventory, the sulfur route from RNA to DNA, and the three acts

The sentences disappear between the second sheet and the third. That is usually the point at which a person stops describing a thing and starts seeing its structure.

1121. The Climb Is Dimensional, Not Only Sequential ↩

This is the observation the fourth sheet exists to make.

$$X \quad XY \quad X^2Y\backslash n| \quad | \quad |\backslash n1\ dimension \quad 2\ dimensions \quad 3\ dimensions\backslash n|$$
$$| \quad |\backslash n\text{amino acid} \rightarrow \text{peptide} \rightarrow \text{protein}\backslash n\text{a unit} \quad \text{a chain} \quad \text{a shape that occupies space}$$

the level	what it is	what a sequence can tell you
X	one amino acid, one unit	everything
XY	a chain, in order	everything

the level	what it is	what a sequence can tell you
X²Y	a folded shape with an inside, an outside and a surface	almost nothing

The usual account runs DNA to RNA to protein and treats it as one kind of step repeated. It is not. The first steps are transcription of a symbol string into another symbol string. The last step leaves the string entirely.

The code is a complete description of the first two levels and a partial description of the third. That is not a failure of the code. It is a change of subject that the notation does not mark.

1122. The Nine Steps, Numbered ↩

From the second sheet, with the count at each stage where a count exists.

	the step	what it holds
1	DNA	3.2 billion base pairs · the genetic, genomic and racial memory archive
2	gene	20,000 to 22,000 of them · which message to send
3	messenger RNA	the message, sent
4	transfer RNA	the message, decoded
5	ribosomal RNA	where the decoding happens
6	amino acid	X — one dimension
7	peptide	XY — two dimensions
8	protein	X²Y — three dimensions, spatial fit, rotation
9	the enzyme	when

Steps one through five move symbols. Step six is the first molecule. Steps seven and eight add dimensions. Step nine adds time.

1123. And Where Timing Enters ↩

The sheet asks a question the central dogma does not: at which step does when start to matter?

the step	the question it answers
gene	which message
messenger RNA	what the message says
transfer RNA	which amino acid
ribosome	where the assembly happens
the growing chain	what order
the fold	when
the target	when, and where in space
the enzyme	when the substrate is present, when the timing is right, when the structure fits

Every question up to the peptide is answered by the sequence. Every question after it is answered by conditions — concentration, charge, compartment, temperature, what else is present and what is already occupied. The sequence is silent on all of them.

This is the same boundary Part One Hundred and Twelve reaches from the other side, and the same one the checkpoint of Part One Hundred and Eighteen sits on: a cell commits to dividing by measuring an amount, not by reading a letter.

1124. What Holds the Prebiotic Stretch ↩

A difficulty arises if the enzyme is placed before life. Enzymes are proteins. Proteins require translation. Translation requires ribosomes, transfer RNAs and synthetases — which are the machinery the enzyme would have to build.

The fourth sheet already answers this, in the top right corner.

the word written there	RIBOZYMES
what a ribozyme is	RNA that folds and catalyzes. No protein required
what makes it fold	magnesium, neutralizing the backbone charge — Part One Hundred and Six
what makes the chain long enough to fold	montmorillonite clay, giving oligomers of forty to fifty units

the word written there	RIBOZYMES
the surviving proof	the ribosome's catalytic center is RNA. Peptide bonds are still made by a ribozyme today

The catalyst that precedes protein is not an enzyme. It is a folded RNA held in shape by a metal ion on a clay surface, and the ribosome is the one that never got replaced.

So the word enzyme belongs exactly where the sheet puts it — at step nine, where timing enters — and the whole stretch before it is held by ribozymes.

1125. The Correction — Seven of the Eight Fell Out of the Sky ↩

The fourth sheet divides the bases into what arrived and what was made here. That division is now testable, and the test has been run on material that never touched this planet.

the mission	Hayabusa2, to the carbonaceous asteroid (162173) Ryugu
why it settles the question	the samples were collected in space and returned sealed. Terrestrial contamination is not available as an objection
what was found, in two separate samples	all five canonical nucleobases — adenine, guanine, cytosine, thymine and uracil
the published account	Koga and colleagues, Nature Astronomy, 2026

And the meteorite record adds the two this volume put back:

hypoxanthine and xanthine	long established in the Murchison meteorite
the pattern across bodies	Ryugu carries purines and pyrimidines in nearly equal amount. Murchison is purine-rich; Bennu and Orgueil are pyrimidine-rich

The corrected division

	the eight
arrived from space	hypoxanthine · xanthine · adenine · guanine · uracil · cytosine · thymine
not found off this planet	orotate

Seven of the eight nucleotides this volume numbers have been recovered from asteroids and meteorites. The eighth has not.

1126. And the Same Survey Carried Isoguanine ↩

The 2022 meteorite work that first reported the pyrimidines also reported pairs that biology does not use.

the pair found in meteorites	
isoguanine with isocytosine	a working pair, and not in the genetic code
xanthine with 2,4-diaminopyrimidine	another

Part One Hundred and Nineteen records that guanine and isoguanine share the formula $C_5H_5N_5O$ and the weight 151.13, and differ only in which ring position carries the amino and which the hydroxy.

Space made both. Both arrived. Both can pair. One is in the code and one is not, and no count of atoms distinguishes them — only the arrangement, which no letter records.

1127. Which Leaves Orotate Standing Alone ↩

This is the strongest column on the corrected sheet, and it has one entry.

	orotate
found in meteorites or asteroid samples	not reported
what it is	uracil-6-carboxylic acid — uracil carrying a carboxyl at position six
where it sits	the origin node of every pyrimidine, made on a pathway
the enzyme that opens the gate	OMP decarboxylase, which removes that carboxyl and leaves uracil
that enzyme's standing	a rate enhancement of about 10^{17}, with no cofactor and no metal

Seven of the eight could be delivered. The eighth has to be built, in order, on a pathway, by a cell. It is the one this volume calls the gate, it has no letter, and it is the only one of the eight that metabolism cannot obtain by waiting for it to arrive.

This volume does not claim orotate is absent from space. It claims it has not been reported there, and that the distinction between a delivered molecule and a manufactured one is the distinction the sheet was drawn to make.

1128. The Sulfur Step, Where One World Becomes the Other ↩

The fourth sheet runs a short branch off to the left. It is the smallest thing on the page and it carries the largest transition.

$$SULFUR\backslash n|\backslash nribonucleotide\ reductase\backslash n|\backslash nRNA \longrightarrow DNA$$

what the enzyme does	removes one oxygen from the sugar of a ribonucleotide
how it starts	a cysteine losing a hydrogen and becoming a thiyl radical
the coverage	every deoxyribonucleotide in every strand of DNA in every organism that has ever lived

The RNA world does not become the DNA world by accumulating letters. It becomes the DNA world when a sulfur radical is available to take one oxygen off one carbon. Part Seven and Part Ten carry the full account.

And the sheet then continues correctly: DNA → chromosomes → genes → messenger, transfer and ribosomal RNA → amino acid → peptide → protein. The archive first, then the index, then the message, then the climb.

1129. What the Notation Loses Here ↩

what is present	what a sequence records
a chain of amino acids in order	the sequence

what is present	what a sequence records
the same chain, folded, with a working surface	the same sequence
the same protein, folded at the wrong moment	the same sequence
a base delivered by an asteroid	A, G, C, T or U
the same base built on a pathway	the same letter
guanine	G
isoguanine, same atoms, arrived on the same rock	nothing

The notation is complete through step eight and silent on step nine. It records what a thing is made of and never when it acts, and every disease in the last twenty Parts of this volume is a failure of when.

1130. What This Part Refuses ↩

the claim	the status
all five canonical bases are present in Ryugu samples	established, and cited
Ryugu material was collected in space and returned sealed	established
hypoxanthine and xanthine occur in carbonaceous meteorites	established
isoguanine-isocytosine and xanthine pairs were reported in meteorites	as published
ribonucleotide reductase runs on a thiyl radical	established
the ribosome's catalytic center is RNA	established
that orotate does not exist in space	refused. It has not been reported. Absence of report is not absence
that enzymes existed before life	refused. Enzymes are proteins and require translation. Ribozymes hold that stretch, and this Part says so
that the four letters fail to describe the first eight steps	refused. They describe them completely. The change happens at step nine
that the dimensional ladder	refused. Primary, secondary and tertiary structure are

the claim	the status
is a new discovery about proteins	textbook. What this Part claims is that the ladder and the timing question are the same boundary, and that the notation stops at it

1131. The Experiment This Part Generates ↩

Experiment Forty-Two, for Part Twenty-Eight, section 65.

The question. Orotate is the one of the eight not reported off this planet. Is that a real absence or a search that was never run?

Method. The returned asteroid samples and the carbonaceous meteorite collection have been analyzed for nucleobases down to parts per trillion. Orotic acid is a carboxylated pyrimidine, chemically close to compounds already recovered, and it is not on the target list of the published surveys. Add it — and add dihydroorotate and orotidine — to the analyte panel of an existing method and re-run the archived extracts. No new mission and no new instrument.

Falsification condition, written before the answer. If orotate is found at comparable abundance to uracil in pristine asteroid material, then all eight arrived, section 1127 is wrong, and the distinction between delivered and manufactured collapses for this set. If it is absent while uracil and thymine are present in the same extract, the gate is a molecule biology had to build, and this Part's central column stands.

The samples exist, the method exists, and the compound has simply never been on the list.

1132. What This Part Claims ↩

The claims

1	**The climb from amino acid to protein is a climb through dimensions — one, two, then three**
2	Sequence answers every question through the peptide and none after it
3	Timing enters at the fold, and the enzyme is what answers it

1	**The climb from amino acid to protein is a climb through dimensions — one, two, then three**
4	Ribozymes, not enzymes, hold the prebiotic stretch, and the ribosome's catalytic center is still RNA
5	Magnesium makes the ribozyme fold; clay makes the chain long enough to have a fold
6	All five canonical bases are present in Ryugu, collected in space and returned sealed
7	Hypoxanthine and xanthine occur in carbonaceous meteorites
8	Seven of this volume's eight nucleotides have been recovered from extraterrestrial material
9	Orotate has not been reported there, and it is the gate
10	Meteorites carried isoguanine and its pair, and biology uses one of the two
11	The RNA world became the DNA world at a sulfur radical, in one enzyme, on one oxygen

What would refute it

the claim	what would kill it
the Ryugu inventory	a re-analysis finding one of the five absent, or the samples compromised
the seven-of-eight count	a demonstration that the meteoritic hypoxanthine and xanthine are terrestrial
orotate as the exception	Experiment Forty-Two finding orotate in pristine asteroid material
the timing boundary	a demonstration that fold timing is predictable from sequence alone in the general case
the ribozyme claim	evidence of protein catalysis preceding translation

And the observation this Part exists to record. Seven of the eight arrived. They arrived as free bases, with no sugar, no phosphate, no order and no meaning, and among them came a pair that biology looked at and declined. What had to be built here was the gate, the sugar removal, the order, and the moment. The letters describe what fell. They do not describe what was made of it, and they say nothing at all about when.

Part One Hundred and Twenty-Three of the evidence volume, sections 1133 to 1145

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

This volume is named for an arc that begins at the Big Bang. This is where it begins. One of the seven colored atoms was made in the first minutes of the universe. Three were made inside ordinary stars. Two — phosphorus and sulfur — came out of a single reaction between two oxygen nuclei in the core of a dying massive star, and that reaction made magnesium as well. The seventh, selenium, could not be made by fusion at all and had to be assembled one neutron at a time on the far side of iron. Seven atoms, five different origins, and the reaction that made the two this volume cares about most runs for somewhere between four days and five years before the star that hosts it collapses.

1133. The Arc Has a Beginning, and It Is Not on This Planet ↩

Every Part of this volume before this one begins with matter already present — a base, a sugar, a metal, an ocean. This Part asks where the atoms themselves came from, because the title of the book promises an answer and the reader is entitled to one.

what the Big Bang made	**hydrogen, helium, and a trace of lithium. Nothing else**
what made everything else	stars, and the deaths of stars
how the products got here	they were blown into space and later gathered into a disk, a sun and a set of rocks

Not one atom in a human body heavier than helium was made in the Big Bang. Every carbon, nitrogen, oxygen, phosphorus, sulfur, magnesium and selenium atom in you was manufactured inside a star that no longer exists.

1134. Hydrogen, and Almost Nothing Else ↩

In the first few minutes, the universe was hot and dense enough for nuclei to fuse, and then it expanded and cooled and the window closed.

hydrogen	about three quarters of all ordinary matter, by mass
helium	about one quarter
lithium	a trace
everything else	essentially none

Hydrogen is H1 — the red band of this volume's color index, and the atom that makes every hydrogen bond in every base pair.

The oldest thing in a strand of DNA is the hydrogen. It is the same age as the universe, and it has never been made since in any quantity.

1135. Carbon and Oxygen Come Out of the Helium Fire ↩

When a star exhausts its hydrogen, the core contracts and heats, and helium begins to fuse.

three helium-4 nuclei → carbon-12\ncarbon-12 + helium-4 → oxygen-16

carbon-12	C6 — the blue band. The skeleton of every ring, chain and sugar
oxygen-16	O8 — the orange band. The other half of every base pair, and the ester of every backbone linkage
their relation	parent and child. Oxygen is carbon with one more helium nucleus added

And oxygen-16 has a property that matters two sections from now: it is doubly stable in the nuclear sense — a closed shell of protons and a closed shell of neutrons. It is unusually hard to break.

Neon is heavier than oxygen and burns first, because oxygen is the more stable of the two. The ordering of the fires in a star is not by mass. It is by stability.

1136. Nitrogen Is the Ash of a Catalyst ↩

Nitrogen is not made for its own sake. It accumulates.

In stars heavier than the sun, hydrogen is converted to helium along a loop that uses carbon, nitrogen and oxygen as go-betweens. The carbon, nitrogen and oxygen are not consumed — they are handed the protons and pass them on.

why nitrogen builds up anyway	one step in the loop is much slower than the others, and material piles up in front of it
the step	the one that consumes nitrogen-14
the result	nitrogen-14 accumulates as the loop runs

Nitrogen is N7 — the green band, and every base in the genetic code is a nitrogen heterocycle. Every hydrogen bond that holds a pair together is made at a nitrogen or an oxygen.

The element that makes the bases is the traffic jam in a catalytic cycle that was doing something else.

1137. And Then Two Oxygen Nuclei Collide ↩

This is the section this Part exists for.

In a star heavy enough to reach it — roughly nine solar masses and up — the core eventually gets hot enough to fuse oxygen with oxygen. This requires temperatures between 1.5 and 2.6 billion kelvins.

The branches, with their measured shares

$$^{16}O + {}^{16}O \rightarrow {}^{31}P + p \quad + 7.676\ MeV \qquad 56\ percent \backslash n \rightarrow {}^{28}Si + \alpha \quad + 9.593\ MeV \qquad 34\ percent \backslash n \rightarrow {}^{31}S + n \quad + 1.459\ MeV \qquad 5\ percent \backslash n \rightarrow {}^{30}P + d \quad - 2.409\ MeV \qquad 5\ percent \backslash n \rightarrow {}^{30}Si + 2p \quad + 0.381\ MeV \backslash n \rightarrow {}^{32}S + \gamma \quad + 16.539\ MeV \backslash n \rightarrow {}^{24}Mg + 2\alpha \quad - 0.393\ MeV$$

the single largest branch	phosphorus-31, at 56 percent
the next	silicon-28, at 34 percent
also produced	sulfur-32 · sulfur-33 · sulfur-34 · magnesium-24

Phosphorus and sulfur — the element that holds the backbone together and the element this whole volume is about — are two branches of one reaction between two oxygen atoms. Magnesium

comes out of the same collision. Three of this book's central elements were made in a single event, in a single shell, in a single star.

1138. What That One Reaction Makes, and How Fast It Ends ↩

The inventory

The major products of oxygen burning, as published:

silicon-28 · sulfur-32, 33 and 34 · chlorine-35 and 37 · argon-36 and 38 · potassium-39 and 41 · calcium-40 and 42

of all of these	silicon-28 and sulfur-32 together are ninety percent of the final composition

And the clock

the fuel	roughly how long a massive star burns it
hydrogen	millions of years
helium	hundreds of thousands of years
carbon	centuries
neon	about a year
oxygen	between a few days and five years
silicon	about a day

A star spends millions of years making the carbon and oxygen, and then makes almost all of its sulfur in less time than it takes to write a book. The sulfur in your body was manufactured in a burst that lasted, at the outside, five years.

1139. Selenium Is on the Far Side of Iron ↩

Six of the seven colors can be made by fusion. The seventh cannot.

why fusion stops	**iron is the most tightly bound nucleus. Fusing anything past it costs energy rather than releasing it**
selenium's atomic number	34 — well past iron at 26
so how is it made	one neutron at a time

The two routes

the slow route	**in aging stars on the asymptotic giant branch. Neutrons are released in a thin layer between the hydrogen and helium shells by the reaction carbon-13 plus an alpha particle gives oxygen-16 plus a neutron, and iron-peak nuclei absorb them one at a time**
the fast route	in explosions and in the collision of neutron stars, where nuclei absorb many neutrons in seconds
the split	the fast route accounts for roughly half of the neutron-capture isotopes in the solar system

Selenium is the indigo band of this volume, and it holds the one protein class that could not use sulfur instead. It is also the only one of the seven that no star could make by burning. It had to be built by accretion, neutron by neutron, from an iron seed.

1140. The Seven Colors, and Their Five Origins ↩

band	atom	where it was made
RED	H1	the Big Bang, in the first minutes
BLUE	C6	helium burning — three helium nuclei joined
GREEN	N7	the CNO cycle, accumulating at its slowest step
ORANGE	O8	helium burning — carbon plus one more helium
PURPLE	P15	oxygen burning — the 56 percent branch
YELLOW	S16	oxygen burning — silicon and sulfur are 90 percent of it
INDIGO	Se34	neutron capture, past iron, in aging stars and in collisions
WHITE	Mg12	oxygen burning and carbon burning

Five distinct processes, spread across the life and death of stars of different masses, and the result is a set of eight atoms that can be arranged into a person. Nobody arranged for that. The processes were doing what physics required at each temperature.

1141. Iron Ends the Star, and the Star Delivers ↩

After oxygen comes silicon burning, and silicon burning makes iron.

what iron does to a star	nothing. It cannot be fused for energy
what happens next	the core has no way to hold itself up, and it collapses
what the collapse does	it blows the shells outward

Every layer the star built — the hydrogen shell, the helium shell, the carbon shell, the neon shell, the oxygen shell with its silicon and sulfur, the iron core — is thrown into space.

The star has to die for the atoms to leave it. Sulfur made in a stellar core and kept there is of no use to anyone. What put it into a cloud, and then a disk, and then a rock, and then an ocean, was the failure of the star to hold itself together.

Part One Hundred and Twenty-Two records what arrived at the other end: seven of this volume's eight nucleotides, recovered from asteroids and meteorites, with the eighth still unaccounted for.

1142. What the Notation Loses Here ↩

what is present	what a sequence records
a phosphorus atom in the backbone	nothing — the backbone is not written
the same atom, made in a 56 percent branch of an oxygen collision	nothing
sulfur-32 in a cysteine	the letter for cysteine, if it is in a protein

what is present	what a sequence records
sulfur-33 and sulfur-34 in the same sample	nothing. No sequence records an isotope
a magnesium ion holding ATP	nothing

The notation does not record which isotope, and the isotopes are how the age of the atmosphere is measured. Part One Hundred and Twenty-One dates the Great Oxidation Event on sulfur-33 against sulfur-32 — two numbers set inside a dying star and never written in any genome.

1143. What This Part Refuses ↩

the claim	the status
the Big Bang produced hydrogen, helium and a trace of lithium	established
carbon comes from three helium nuclei, oxygen from carbon plus one more	established
oxygen burning runs at 1.5 to 2.6 billion kelvins	as published
the phosphorus-31 branch is 56 percent and the silicon-28 branch 34 percent	as published, with the branching ratios cited
silicon-28 and sulfur-32 are ninety percent of the products	as published
oxygen fuel is exhausted in about 0.01 to 5 years	as published
selenium is made by neutron capture past iron	established
that the elements were made in order to produce life	refused. Each process is what physics does at that temperature and density. This Part records the sequence, not a purpose
that sulfur is special among the products of oxygen burning	refused. Chlorine, argon, potassium and calcium come out of the same reaction. What is claimed is that phosphorus and sulfur are two branches of one event, which is a fact about that reaction and not a fact about sulfur
that this Part adds new astrophysics	refused. Every number in it is from the stellar evolution literature. What it adds is the alignment of that literature with this volume's color index

1144. The Experiment This Part Generates ↩

Experiment Forty-Three, for Part Twenty-Eight, section 65.

The question. Part One Hundred and Twenty-One dates the Great Oxidation Event on the ratio of sulfur-33 to sulfur-32. Both isotopes were made in the same oxygen-burning shell. Does the ratio the Earth started with match what stellar nucleosynthesis predicts, and if it does not, by how much?

Method. This is a comparison of two published bodies of numbers and needs no instrument. Take the predicted isotope yields for sulfur-32, 33, 34 and 36 from the standard massive-star nucleosynthesis models. Set them beside the measured sulfur isotope composition of the least altered meteorites, which stand for the composition of the solar nebula before the Earth existed. Report the difference per isotope.

Falsification condition, written before the answer. If the meteoritic ratios sit within model uncertainty of the stellar predictions, then the baseline the Great Oxidation Event is measured against is a stellar baseline, and section 1121 of this volume can say so. If they diverge substantially, then processes between the star and the solar nebula reset the ratio, and the statement that the atmospheric clock was set in a dying star is a figure of speech rather than a measurement.

Both datasets are published, neither is proprietary, and the comparison appears not to have been made in the terms this volume asks for.

1145. What This Part Claims ↩

The claims

1	**The Big Bang made hydrogen, helium and a trace of lithium, and nothing heavier in quantity**
2	Hydrogen — H1, the red band — is as old as the universe
3	Carbon is three helium nuclei joined; oxygen is carbon plus one more

1	**The Big Bang made hydrogen, helium and a trace of lithium, and nothing heavier in quantity**
4	Nitrogen accumulates at the slowest step of the CNO cycle, as the ash of a catalyst
5	Oxygen burns at 1.5 to 2.6 billion kelvins, in stars of about nine solar masses and up
6	The largest branch of oxygen burning produces phosphorus-31, at 56 percent
7	Silicon-28 and sulfur-32 together are ninety percent of the final composition
8	Magnesium-24 comes out of the same collision
9	The oxygen fuel is gone in between about four days and five years
10	Selenium lies past iron and cannot be made by fusion, only by neutron capture
11	Iron ends the star, and the collapse is what delivers every shell into space
12	The seven colors of this volume have five different origins

What would refute it

the claim	what would kill it
the branching ratios	a revised measurement moving the phosphorus branch off 56 percent
the ninety percent figure	a model giving silicon and sulfur a substantially smaller share
the timescale	a stellar model in which oxygen burning runs for centuries
the selenium route	a fusion pathway to element 34 operating in stars
the isotope baseline	Experiment Forty-Three finding meteoritic sulfur far from the stellar prediction

And the observation this Part exists to record. Two oxygen nuclei meet in the core of a star that has only a few years left. Fifty-six times in a hundred they make phosphorus. Most of the rest of the time they make silicon and sulfur, and now and then magnesium. Some hundreds of millions of years later the star fails, throws the shell outward, and the phosphorus becomes a backbone, the sulfur becomes the thing that builds and folds and routes everything the backbone carries, and the magnesium holds them both in place. The arc this volume is named for starts there — with a collision between two atoms of the element that would eventually end the flow, producing the two that would carry it.

PART ONE HUNDRED AND TWENTY-FOUR · WOBBLE WAS AN ERROR FIRST

Part One Hundred and Twenty-Four of the evidence volume, sections 1146 to 1158

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

In 2026 a laboratory in Cambridge reported a forty-five-nucleotide piece of RNA that copies its own complementary strand and makes a copy of itself. It is the smallest self-copying molecule anyone has built, it was pulled out of a pool of random sequences, and it works in frozen alkaline brine with magnesium. It is also wrong about six percent of the time, and its errors are not scattered. They fall at three fixed places, and the paper names the cause: the ribozyme accepts a G to U wobble pair where an A to U pair belongs. At the origin of copying, wobble is the defect. Two billion years later the same pairing at one position on a transfer RNA is what lets a cell read three codons with one molecule. It was never invented as an advantage. It was unavoidable, and it was later put to work.

1146. The Smallest Thing That Copies Itself ↩

Gianni, Kwok, Wan, Goeij, Clifton, Attwater and Holliger, at the MRC Laboratory of Molecular Biology in Cambridge. Posted as a preprint in October 2024 and published in Science in 2026.

the molecule	QT45 — forty-five nucleotides
where it came from	a pool of random sequences, by repeated selection
what came before it	polymerase ribozymes of more than two hundred nucleotides
what it does	copies its complementary strand from a mixture of all sixty-four triplets
and	copies itself, using thirteen defined triplets and one six-unit piece
how well	about 0.2 percent yield over seventy-two days, at roughly 94 percent accuracy per unit

Cut further, to forty and then thirty-five nucleotides, it still works — a core of twenty-nine nucleotides held by a three-base-pair stem.

The whole functional machine is twenty-nine nucleotides. The authors' point is not that this molecule is impressive. It is that if a working polymerase is this small, such molecules are far more common in the space of possible sequences than anyone assumed, and the odds of one appearing by chance improve accordingly.

1147. What It Runs On, and Where the Real Shortcut Is ↩

QT45 does not add one nucleotide at a time. It adds three.

the substrate	**trinucleotide triphosphates — "triplets"**
the immediate consequence	one third as many steps to copy a given length
why the authors chose them	they let a folded template be copied at all, and they stop the two strands from sticking back together
their own phrase	triplets "reduce the phenotypic requirements of a polymerase" — the enzyme has less to do

The shortcut in this system is the triplet, not the wobble. Copying in threes cuts the number of operations by two thirds and lowers what the catalyst has to be capable of. That is a real economy and it is the one the paper is built on.

And the unit is three, which is the unit the genetic code would later use. This volume records that and claims nothing from it.

1148. It Made Another Ribozyme, From Scratch ↩

The test that matters most is not whether the molecule copies a repeat. It is whether what it makes works.

the target	**a minimal eighteen-nucleotide hammerhead ribozyme**
from what	the six triplets that spell it — or from a random pool of all sixty-four
the result	the product cut RNA. It was catalytically active

One ribozyme built another ribozyme from a random pool of parts, and the second one worked. That is the shape of the thing the RNA world requires, at a scale small enough to have happened.

1149. And the Errors Are All One Kind ↩

The fidelity is about ninety-four percent per nucleotide, which means roughly one unit in seventeen is wrong. Those errors are not spread evenly.

how many hotspots	three
shared with the older, larger ribozyme	yes — the same three
the stated cause	"a tolerance for a G:U wobble pair in place of the correct A:U pair"
where in the triplet	particularly at the first position

The dominant error mode of the first self-copying molecule is wobble. Not a random misreading — one specific wrong pair, at the same places, in two different ribozymes.

And it is the same pair Crick named in 1966 and the same pair Part Ninety-Four of this volume takes apart: guanine meeting uracil where adenine should have been.

1150. Wobble at the Origin Is a Cost ↩

what it does to the copy	puts the wrong letter in
what it does to fidelity	holds it near ninety-four percent when the chemistry could do better
what it does to survival	a replicator loses its information at this error rate unless the sequence is short

The paper does not treat wobble as a feature. It treats it as the thing standing between this ribozyme and a fidelity high enough for open-ended evolution.

At the beginning, wobble is the leak in the bucket.

1151. Wobble at Position 34 Is an Economy ↩

Part One Hundred and Eleven of this volume sets out the other half.

where	position 34 of a transfer RNA — the wobble position of the anticodon
what sits there	inosine, and six other molecules
what inosine does	reads codons ending in A, C or U with one molecule
the consequence	a cell covers sixty-one codons with far fewer transfer RNAs than sixty-one

And a cell spends real resources to put it there. Part One Hundred and Twenty records ADAT2 and ADAT3, a protein pair that exists to make that one inosine, and a disease that follows when it fails.

At position 34, loose pairing is not tolerated. It is manufactured, deliberately, by an enzyme built for the purpose.

1152. The Same Chemistry, Twice, for Opposite Reasons ↩

This is the observation this Part exists to make.

	in QT45	at anticodon position 34
the pairing	loose — G with U	loose — inosine with A, C or U
is it made on purpose	no. It is tolerated	yes. Enzymes are dedicated to it
what it costs	fidelity — three fixed error hotspots	specificity at the third codon letter
what it buys	nothing	the whole arithmetic of decoding
its status	a defect	a requirement of eukaryotic life

Loose pairing did not appear because it was useful. It appeared because two bases that are not a canonical pair will still hold together if the geometry lets them, and no early copying system could stop it.

It was a property of the chemistry before it was a property of anything alive.

What changed is not the pairing. What changed is that a later system found a position where a tolerance for three different partners is worth more than exactness, put a manufactured base there, and built enzymes to keep making it.

1153. And the Pair in Its Core Has No Letter ↩

The published structure of QT45 shows the base pairs of its stems, and one of them is not a canonical pair.

the pair	C11 with U35 — cytosine against uracil
its status in the figure	listed and annotated separately, as the non-canonical base pair
is it load-bearing	the fitness data says yes. Mutations that keep a base pair score higher than mutations that break one

The smallest molecule anyone has made that copies itself has, in its working core, a base pair that the four-letter notation has no way to write. C and U are both in the alphabet. C against U is not in the grammar.

Part Three of this volume states the general case. Here it is in the most prebiotically relevant object the field has produced.

1154. What Holds It Up — Magnesium, Ice and Clay ↩

The reaction conditions are worth printing, because three of them are already threads in this volume.

magnesium chloride	fifty millimolar, in every reaction — Parts One Hundred and Six and One Hundred and Seven
the temperature	minus seven degrees Celsius, frozen — the ice concentrates the substrates and steadies the ribozyme
the acidity	pH 9, mildly alkaline
potassium chloride	two hundred millimolar

magnesium chloride	fifty millimolar, in every reaction — Parts One Hundred and Six and One Hundred and Seven
in their own bibliography	Ferris, montmorillonite-catalyzed formation of RNA oligomers — the clay of the preface

A folded RNA, held open by magnesium, concentrated by freezing, in alkaline water, descended from chains that clay made long enough to fold. Every element of that sentence is somewhere else in this volume, and here they are together in one published method section.

1155. What the Notation Loses Here ↩

what is present	what a sequence records
a correct A·U pair in the growing copy	A and U
a G·U wobble put there by mistake	G and U — and the copy now reads as though G belonged
the C11 position of QT45	C
the U35 position	U
the pair between them, which is holding the core together	nothing. There is no notation for a pair
one nucleotide added	one letter
three nucleotides added as one triplet	three letters, with no record that they arrived together

The error and the correct product are written in the same alphabet, so the record of a copy cannot say which positions were wobbled and which were read properly. An error rate is measurable only by comparing two sequences. It is not visible in either one.

1156. What This Part Refuses ↩

the claim	the status
QT45 is forty-five nucleotides and was found	established, and cited

the claim	the status
in a random pool	
it copies its complementary strand from all sixty-four triplets, and itself from thirteen and a hexamer	as published
the fidelity is about ninety-four percent per nucleotide	as published
the errors concentrate at three hotspots and are G:U wobble in place of A:U	quoted from the paper
it synthesized a working hammerhead ribozyme	as published
the core contains a non-canonical C11–U35 pair	as published in the figure annotation
that QT45's positions 34 to 37 correspond to the anticodon positions 34 to 37	refused. QT45 is a forty-five-nucleotide molecule numbered from its own 5-prime end. The match is a coincidence of two numbering systems and this volume does not use it
that the paper argues wobble is an advantage	refused. It argues the opposite. Wobble is named as the cause of the poor fidelity
that self-replication has been achieved	refused. A 0.2 percent yield over seventy-two days at 94 percent fidelity is not a replicating system. It is a demonstration that the activity fits in forty-five nucleotides
that the triplet is evidence for the origin of the codon	refused. The unit is three in both, and this volume records the coincidence and draws nothing from it

1157. The Experiment This Part Generates ↩

Experiment Forty-Four, for Part Twenty-Eight, section 65. This volume regards it as the most direct test it has produced.

The question. The dominant error of the first self-copying molecule is a G:U wobble where A:U belongs. There is a known chemical fix for exactly that, and it is a sulfur atom.

The reasoning. Part One Hundred and Seventeen records 2-thiouridine — a uridine with sulfur in place of the oxygen at position 2. That substitution is used by living cells at the wobble position precisely because it strengthens pairing with adenine and discriminates against guanine: the larger sulfur atom does not fit the geometry a G:U pair requires.

Method. Repeat the QT45 fidelity measurement with one change. Synthesize the triplet substrates with 2-thiouridine in place of uridine at the first position, where the paper locates the worst hotspot. Run the standard conditions — frozen at minus seven, pH 9, fifty millimolar magnesium — and sequence the products. Compare the error rate at the three hotspots against the unmodified controls.

Falsification condition, written before the answer. If the hotspots persist at the same rate with 2-thiouridine substrates, then the errors are not a wobble geometry problem and the account in section 1149 is incomplete. If the hotspots fall and overall fidelity rises, then one sulfur atom, added at one position, raises the accuracy of the smallest known self-copying molecule — and the element this volume is named for turns out to be the fix for the defect that stands between a ribozyme and open-ended evolution.

The substrates are commercially available, the assay is published in full, and the modification is one that biology itself uses at the same position for the same reason.

1158. What This Part Claims ↩

The claims

1	**QT45 is a forty-five-nucleotide RNA polymerase ribozyme found in a pool of random sequences**
2	Earlier polymerase ribozymes were more than two hundred nucleotides
3	Its working core is about twenty-nine nucleotides on a three-base-pair stem
4	It copies its complementary strand from all sixty-four triplets, and itself from thirteen triplets and one hexamer
5	It built a working hammerhead ribozyme, including from a random pool of all sixty-four triplets
6	The real step reduction is the triplet — three nucleotides per addition, not one
7	Fidelity is about ninety-four percent, and the errors fall at three fixed hotspots
8	The stated cause is tolerance of a G:U wobble pair in place of A:U
9	The same three hotspots appear in a larger, older ribozyme
10	The core contains a non-canonical C11–U35 pair, and the fitness data shows it is load-bearing

1	QT45 is a forty-five-nucleotide RNA polymerase ribozyme found in a pool of random sequences
11	It runs in frozen alkaline brine at fifty millimolar magnesium
12	Loose pairing is a defect at the origin and an economy at anticodon position 34

What would refute it

the claim	what would kill it
the error account	a re-analysis attributing the hotspots to something other than wobble geometry
the shared hotspots	a finding that the two ribozymes fail at different positions
the non-canonical pair	a revised structure in which C11 and U35 do not pair
the two-valence argument	a demonstration that G:U tolerance confers a measurable benefit in the ribozyme
the sulfur fix	Experiment Forty-Four finding the hotspots unchanged with 2-thiouridine substrates

And the observation this Part exists to record. The first molecule that could copy itself made one kind of mistake, over and over, at the same three places, and the mistake was a pair that is almost right. Nothing could stop it, because nothing about the chemistry forbids it. Very much later, a cell found one position in one molecule where a pair that is almost right is worth more than a pair that is exact, manufactured a base to sit there, and built two proteins whose only job is to keep making it. The chemistry never changed. What changed is that something learned to want it.

PART ONE HUNDRED AND TWENTY-FIVE · THE PARENT, NOT THE WAYPOINT

Part One Hundred and Twenty-Five of the evidence volume, sections 1159 to 1171

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The notation puts inosine between adenine and guanine. Adenosine is edited to inosine, and inosine is read as guanosine, so the letter I appears to be a station on a road running from A to G. The purine pathway says the opposite. IMP is the parent of both. Adenosine and guanosine are its two children, made by two different routes, at two different ring positions, at two different costs. And the distances are not equal

— inosine is one chemical step from adenine and two from guanine, so the convention reads it as the base it is further from, and steps over the base in between. That base is xanthine.

1159. The Claim, Stated First ↩

what the notation implies	A → I → G. A line, with inosine in the middle
what the purine pathway does	IMP is the branch point. AMP and GMP are both made from it
the consequence	the notation inverts a fork into a line, and runs the line the wrong way

Inosine is not a stage between adenine and guanine. It is what both of them are made from.

1160. What the Notation Implies ↩

Two conventions, laid end to end.

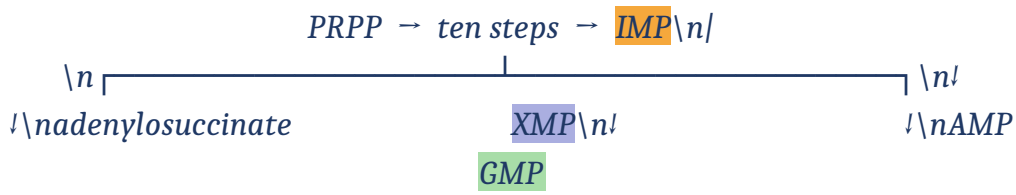
the chemical event	A → I. An enzyme removes the amino group from adenosine. Inosine is the product
the reading convention	I → G. Inosine's pairing face resembles guanine's, so the ribosome and the reverse transcriptase both treat it as G
what appears in the record	A → G
what was actually made	inosine. No guanosine was synthesized at any point

Part One Hundred and Twenty sets out the two enzyme families that perform the first step. Part One Hundred sets out where the second convention is applied.

Put the two conventions together and a molecule that was never made appears in the file, while the molecule that was made does not.

1161. What Metabolism Actually Does ↩

The de novo purine pathway builds one ring system and then splits.



what is built first	IMP — inosine monophosphate
what is made from it	AMP, by one route. GMP, by another
is either made from the other	no

The first complete purine nucleotide a cell makes is inosine monophosphate. Adenine and guanine are both later, and neither is on the way to the other.

1162. The Two Distances Are Not Equal ↩

From Part One Hundred and Nineteen, the systematic names.

	systematic name	difference from hypoxanthine
hypoxanthine	6-hydroxypurine	—
adenine	6-aminopurine	one change, at position 6
xanthine	2,6-dioxopurine	one change, at position 2
guanine	2-amino-6-hydroxypurine	two changes, both at position 2

Inosine is one step from adenine and two steps from guanine. The reading convention assigns it to guanine — the base it is further from — and the step it skips over is xanthine.

1163. The Editing Reverses a Biosynthesis ↩

This is the exact relation, and it is worth printing plainly.

to make AMP from IMP	adenylosuccinate synthetase joins aspartate at position 6, spending a GTP; adenylosuccinate lyase releases fumarate, leaving an amino group
the net effect	an amino group is installed at carbon 6
what A-to-I editing does	removes an amino group from carbon 6

A-to-I editing is the chemical reversal of the last two steps of adenine synthesis, performed on an RNA that has already been assembled. The cell spends two enzymes and a GTP putting the amino group on, and later a different enzyme takes it off again.

Neither enzyme is confused. They are doing opposite things at the same carbon for different reasons — one to make a nucleotide, the other to change how a finished RNA is read.

1164. And the Other Direction Erases Xanthine ↩

Getting from inosine to guanosine is not one step and does not happen in RNA at all.

the step	the enzyme	what it does
IMP → XMP	IMP dehydrogenase	adds an oxygen at position 2
XMP → GMP	GMP synthase	replaces it with an amino group, spending an ATP

The reading convention that lets an instrument write G where an inosine sits is the same convention that removes xanthine from the account. Xanthine is the obligate intermediate between them, it is this volume's number seven, and "I reads as G" steps over it as though it were not there.

Part One Hundred and Nineteen records that the step from hypoxanthine to xanthine is exactly sixteen mass units — one oxygen atom — and that the step from xanthine to uric acid is exactly sixteen again. Neither appears in any sequence.

1165. And the Two Routes Pay Each Other ↩

The costs are not symmetric, and the asymmetry is the regulation.

	what it spends
making AMP from IMP	a GTP
making GMP from IMP	an ATP

Adenine synthesis is paid for in guanine currency and guanine synthesis is paid for in adenine currency. If one pool runs low the branch that consumes it slows, and the other branch is favored. The balance between the two purines is held by making each one buy its way in with the other.

That mechanism is a fact about two molecules and a phosphate. It is nowhere in a sequence, and it is the reason the two letters exist in the proportions they do.

1166. The Start Codon, Downgraded Rather Than Broken ↩

Part One Hundred and Twenty-Four records that the dominant error of the QT45 ribozyme is a G:U pair where an A:U pair belongs, worst at the first position of a triplet. That substitution has a specific consequence in the code.

the first letter	the codon	what it is
A	AUG	methionine, and the start codon
G	GUG	valine, and also a start codon
U	UUG	leucine, and also a start codon

In Escherichia coli, of the genes whose starts are known: AUG about 83 percent, GUG about 14 percent, UUG about 3 percent. And genes beginning with AUG are on average expressed at significantly higher levels than genes beginning with GUG, which in turn exceed those beginning with UUG.

An A-to-G change at the first position of a start codon does not abolish the start. It exchanges one working start for a weaker one. Nothing breaks, nothing reports an error, and the gene is simply made less.

This volume records the arithmetic and makes no claim that the ribozyme's substrate error and the codon are the same event. The triplets in that experiment are chemical feedstock, not codons.

1167. The Salvage Direction Inverts It Again ↩

This Part would be one-sided without the following, which cuts the other way.

Cells do not only build purines from scratch. They recover them.

the enzyme	what it takes back
HGPRT — hypoxanthine-guanine phosphoribosyltransferase	hypoxanthine → IMP, and guanine → GMP. One enzyme, both bases
APRT — adenine phosphoribosyltransferase	adenine → AMP. A separate enzyme

In salvage, hypoxanthine and guanine share an enzyme and adenine does not. So the notation's habit of grouping inosine with guanine is not baseless — it is correct for the recovery direction and wrong for the building direction.

Part Ninety-Five records what happens when HGPRT fails: Lesch-Nyhan syndrome. The enzyme that handles both hypoxanthine and guanine is the one whose loss is catastrophic.

1168. Where the Confusion Actually Lives ↩

This Part does not claim that cells make mistakes here.

does the ribosome misread inosine	no. Inosine's pairing face genuinely resembles guanine's. The decoding is correct chemistry
do the editing enzymes err	no. They deaminate the adenosines they are aimed at

does the ribosome misread inosine	**no. Inosine's pairing face genuinely resembles guanine's. The decoding is correct chemistry**
does the pathway confuse its branches	no. IMP dehydrogenase and adenylosuccinate synthetase have different active sites and different substrates
what is confused	the record, and everything built on the record

The cell knows exactly which molecule it made. The file does not, because the file has four characters and the cell used a fifth. Every downstream inference — that a position "changed from A to G," that a variant exists, that two transcripts differ — inherits a molecule that was never present.

1169. What the Notation Loses Here ↩

what is present	what the record says
an inherited guanosine	G
an inosine made by deamination of an adenosine	G
IMP, the first complete purine a cell builds	no letter at all
XMP, the obligate step from inosine to guanosine	no letter at all
a GTP spent to make an AMP	nothing
the branch point itself	nothing. A fork cannot be written in a linear alphabet

Three of the molecules in this Part — IMP, XMP and the branch between them — carry the whole architecture of purine supply, and not one of them has a symbol.

1170. What This Part Refuses ↩

the claim	the status
IMP is the first complete purine nucleotide of de	established

the claim	the status
novo synthesis	
AMP and GMP are both made from IMP by separate routes	established
AMP synthesis consumes GTP and GMP synthesis consumes ATP	established
hypoxanthine differs from adenine at position 6 and from guanine at position 2, by two changes	established, from the systematic names in Part One Hundred and Nineteen
XMP is the obligate intermediate from IMP to GMP	established
HGPRT accepts both hypoxanthine and guanine; APRT accepts adenine	established
AUG, GUG and UUG all initiate in bacteria, at about 83, 14 and 3 percent	as published
that cells confuse inosine with guanosine	refused. They do not. The pairing is genuine and the decoding is correct
that A-to-I editing is a metabolic step in purine synthesis	refused. It acts on assembled RNA. The claim is that it is the chemical reverse of a biosynthetic step, at the same carbon, and nothing more
that the notation's grouping of I with G is simply wrong	refused. It is wrong for de novo synthesis and right for salvage, and this Part prints both
that the QT45 substrate error is a start-codon mutation	refused. Those triplets are feedstock. The codon arithmetic is stated separately and claimed separately

1171. The Experiment This Part Generates ↩

Experiment Forty-Five, for Part Twenty-Eight, section 65.

The question. Edited RNA is eventually broken down. The inosine it contains is released as hypoxanthine, and hypoxanthine has exactly two fates: recovery to IMP by HGPRT, or oxidation to xanthine and then to urate. Is the quantity large enough to measure?

Why it matters. If it is, then a process the record writes as "A to G" is in fact a route that feeds the purine catabolic pathway — and its output is urate, the least soluble compound on the reference sheet.

Method. Take a cell line. Run three arms: normal, ADAR1 suppressed, and ADAR1 overexpressed. Confirm the editing level by direct sequencing in each arm. Then measure, by mass spectrometry in the same samples, the intracellular hypoxanthine, xanthine and urate. Ask whether the three species track the editing level.

Falsification condition, written before the answer. If hypoxanthine and urate do not move with the editing level, then the flux from edited RNA is negligible against bulk RNA turnover, and this Part should record that the connection between editing and the purine pool is formal rather than quantitative. If they do move, then RNA editing is a measurable input to purine catabolism, and the same chemical event has one name in molecular biology and no name at all in metabolism.

What this Part claims

1	**IMP is the parent of both AMP and GMP, not an intermediate between them**
2	The notation implies a line, A to I to G, where the pathway has a fork
3	Inosine is one chemical step from adenine and two from guanine
4	The reading convention assigns it to the base it is further from
5	A-to-I editing removes at carbon 6 the amino group that adenylosuccinate synthetase and lyase install
6	Going from IMP to GMP requires two enzymes and passes obligately through XMP
7	"I reads as G" therefore steps over xanthine, this volume's number seven
8	AMP synthesis is paid for in GTP and GMP synthesis in ATP, which is how the two pools are balanced
9	In salvage, HGPRT takes both hypoxanthine and guanine while adenine has its own enzyme — so the I-with-G grouping is right for recovery and wrong for building
10	Neither the cell nor its enzymes are confused. The record is

What would refute it

the claim	what would kill it
the branch architecture	a demonstrated route from AMP to GMP or the reverse that does not pass through IMP
the two distances	a systematic name placing hypoxanthine one step from guanine
the reversal	a mechanism for adenosine deaminases acting somewhere other than carbon 6
the reciprocal cost	a measurement showing AMP synthesis does not consume GTP
the flux claim	Experiment Forty-Five finding hypoxanthine and urate

the claim	what would kill it
	unchanged across editing levels

And the observation this Part exists to record. A cell builds one purine first and makes the other two from it. The notation gives letters to the two children and none to the parent, then borrows the parent's reading from one of its own offspring, and in doing so deletes the molecule that stands between them. Every A-to-G call in every editing dataset ever published is a record of a molecule that was not made, standing in for one that was, on a branch the alphabet cannot draw.

PART ONE HUNDRED AND TWENTY-SIX · THE VERDICT IS NOT IN THE CODON

Part One Hundred and Twenty-Six of the evidence volume, sections 1172 to 1184

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

A cell decides thousands of times a second whether to keep a message or destroy it. The system that decides is called nonsense-mediated decay, and it is the best-studied surveillance pathway in eukaryotic biology. It does not read the stop codon. It reads how the stopping went — how slowly, how far from the end, what proteins were nearby, how long the tail was. The same three letters, UAA, are a normal ending in one message and a death sentence in another. And in one documented case the verdict turns on whether the cell has enough of a single element: the codon UGA inserts selenocysteine when selenium is present and triggers destruction of the message when it is not. Same letter. Same position. Different mineral in the medium.

1172. What This System Actually Decides ↩

The name of the review that anchors this Part states the finding: nonsense-mediated decay begins where translation ends.

when the decision is made	at the moment the ribosome stops
what is decided	whether the message survives for more rounds of translation, or is cut up

when the decision is made	at the moment the ribosome stops
who carries it out	UPF1, once phosphorylated, recruiting SMG6 to cut the message and SMG5 with SMG7 to strip its tail
how it ends	the fragments are decapped and eaten from both directions

The published summary of normal termination is three steps: recognize the signal, release the finished protein, take the ribosome apart. When any of that goes badly, the message is condemned.

The system is not a proofreader of sequence. It is a witness to an event.

1173. The Same Codon, Two Verdicts ↩

	a normal stop	a premature stop
the letters	UAA	UAA
what the ribosome does	terminates cleanly	terminates slowly and awkwardly
what happens next	the message is reused	UPF1 is phosphorylated and the message is cut

Nothing about the three letters differs. The verdict is opposite. Whatever decides it is not in the codon.

1174. The Experiment That Settles It ↩

Amrani and colleagues, Nature, 2004. The paper is titled for its own device: a false tail.

They took a normal, correctly positioned stop codon and changed only what lay downstream of it — giving the message an artificial three-prime tail with the wrong composition.

the stop codon	correct, and in the right place
what was altered	only the region after it

the stop codon	correct, and in the right place
the result	the message was destroyed

And the companion finding, from Boehm and colleagues in 2014: the length of that tail and the proteins sitting on it determine how efficiently the cutting enzyme works.

A correct stop codon was condemned because of what came after it. The letter was right. The surroundings were wrong.

1175. The Signal Is Slowness ↩

This is the mechanism the field has converged on, and it is a statement about time.

Kinetically slow translation termination, caused by the absence of factors that normally speed termination, may be the signal that triggers destruction.

what triggers the decision	how long termination takes
the best-characterized accelerator	poly-A binding protein, which speeds the arrival of the release factors
what that means	a message with the protein nearby stops fast and lives. The same message without it stops slowly and dies

Part One Hundred and Twenty-Two of this volume records that the question changes from what to when at the fold. Here it changes at the stop, and the cell is measuring a duration.

There is no letter for how long something took.

1176. And the Distance Is Measured in Space ↩

The review states the following, and this volume prints it without embellishment.

The efficiency with which destruction is suppressed correlates with the physical distance between the termination codon and the tethered poly-A binding protein.

the variable	physical distance
not	number of letters, identity of letters, or reading frame

And the marker complex that flags a stop as premature is deposited by the splicing machinery at a measured offset — twenty to twenty-four nucleotides upstream of each exon junction.

a long tail	more than about a thousand nucleotides in mammalian cells can trigger destruction
a short reading frame upstream of the main one	can trigger it
the field's own hedge	these features "can — but not always do" trigger it

Distance, length, offset and occupancy. Four physical measurements, and the alphabet records none of them.

1177. Selenium, and a Codon That Changes Meaning With a Mineral ↩

This is the finding this Part exists for.

The codon UGA is normally a stop. In a small number of human genes it does not mean stop — it means insert selenocysteine, the twenty-first amino acid, whose side chain carries a selenium atom in place of sulfur.

Whether it means one or the other depends on whether the cell has selenium.

selenium available	UGA is read as selenocysteine. The protein is made
selenium absent	UGA is read as a stop. Termination happens early, the message is judged defective, and nonsense-mediated decay destroys it
the published case	Moriarty and colleagues, 1998 — selenium deficiency reduces the messenger RNA for a selenium-dependent enzyme by a mechanism dependent on that UGA

The same three letters, at the same position, in the same gene, in the same person. In one nutritional state they specify an amino acid. In the other they condemn the message to destruction. The variable is the concentration of an atom, and the atom appears nowhere in the sequence.

Selenium is Se34, the indigo band of this volume's color index — the element of Part Sixteen, the one residue class that could not use sulfur instead. Here it is deciding, by its presence or absence, what a codon means.

1178. Where Wobble Enters ↩

Three routes, and they are not equally strong. This Part rates them.

the route	how firm
Readthrough suppresses the decision. If a near-cognate transfer RNA occupies the stop codon, termination does not happen there, so no verdict is reached	firm. The review cites work from 2001 on the same surveillance proteins modulating readthrough of nonsense transcripts
Decoding speed upstream affects the state in which the ribosome arrives at the stop. The signal is slowness, and modified wobble bases set the pace of decoding	plausible and stated as such. This volume does not claim it has been measured
The selenocysteine case	firm, and documented — see the previous section

The first and third are established. The second is a proposition this Part offers and does not assert.

1179. The Medicine That Works by Causing an Error ↩

Premature stop codons are a substantial cause of inherited disease. One therapeutic strategy for them is to make the ribosome ignore the stop.

how the oldest such compounds work	aminoglycoside antibiotics bind the decoding center of the ribosome and reduce its fidelity, so a near-cognate transfer RNA is more likely to be accepted at the premature stop
the consequence	translation continues past the stop, no premature termination occurs, and the message escapes destruction
the clinical record	mixed. Compounds in this class have been developed and trialed for nonsense-mutation forms of muscular dystrophy and cystic fibrosis, with contested efficacy. This volume records the strategy, not a verdict on any product

The mechanism is a deliberate decoding error at the wobble position, induced on purpose, so that the cell's own surveillance system does not destroy a message it would otherwise judge defective.

Part One Hundred and Twenty-Four records that wobble is the dominant error of the first self-copying molecule. Here the same event is a therapy.

1180. What the Field Says About Its Own Understanding ↩

From the opening sentence of the review, published in 2019 after four decades of work on this pathway:

"Fundamental questions concerning the molecular mechanism of target RNA selection remain unsolved."

And the same abstract records that the system does not only destroy defective messages:

It also targets many messages encoding perfectly good full-length proteins.

so it is not only a quality filter	it is also a regulator of ordinary gene expression
and the rule that separates the two cases	not known

This volume takes that sentence at face value. It is not a criticism of the field. It is a description of what happens when the deciding variables are duration, distance, occupancy and the concentration of an element, and the record being searched contains letters.

1181. What the Notation Loses Here ↩

what decides the verdict	what a sequence records
how long termination took	nothing
the physical distance to the nearest poly-A binding protein	nothing
whether an exon junction marker sits downstream	nothing — it is deposited after splicing
the length of the untranslated tail	recoverable, but not treated as functional
whether the cell has selenium today	nothing
the codon itself	UGA — identical in every case above

Six variables decide whether a message lives. One of them is in the sequence, and it is the same in every outcome.

1182. What This Part Refuses ↩

the claim	the status
the decision is made at translation termination	established, and cited
a correct stop codon with an altered downstream region is destroyed	as published — Amrani and colleagues, 2004
three-prime tail length and bound proteins set the cutting efficiency	as published — Boehm and colleagues, 2014
slow termination is the proposed trigger	as reviewed. The field states it as a proposal, and so does this Part
suppression correlates with physical distance to tethered poly-A binding protein	quoted from the review
UGA specifies selenocysteine when selenium is present and triggers decay when it is absent	as published — Moriarty and colleagues, 1998

the claim	the status
that wobble modifications have been shown to control this decision	refused. Readthrough suppressing the decision is established. A quantitative effect of wobble modification on the decision has not been demonstrated and this Part does not claim it
that nonsense-mediated decay is a defective system	refused. It is a functioning surveillance pathway that also regulates ordinary expression. What this Part records is that its deciding variables are physical
that readthrough therapy is effective	refused as a general claim. The strategy is real; the clinical results are mixed and contested, and this volume says so

1183. The Experiment This Part Generates ↩

Experiment Forty-Six, for Part Twenty-Eight, section 65.

The question. The proposed trigger is slow termination. Wobble modifications set the speed of decoding. Does removing a wobble modification change which messages get destroyed?

Method. Take cells in which a single wobble-modifying enzyme can be switched off — the enzyme that places the sulfur at position 34 is the obvious first choice, since Part One Hundred and Seventeen records the five-protein relay that installs it. Switch it off. Then measure two things in the same samples: the abundance of known targets of nonsense-mediated decay, and the ribosome's dwell time at termination codons, by ribosome profiling.

Falsification condition, written before the answer. If removing the modification leaves target abundance and termination dwell time unchanged, then wobble chemistry does not reach this decision, the second route in section 1178 is dead, and this Part should say so plainly. If targets shift, then a sulfur atom on a transfer RNA helps decide which messages a cell keeps — and the deciding variable is one no sequence records.

Both measurements are standard. The novelty is running them together and asking whether the modification layer touches the surveillance layer, which appears not to have been asked.

1184. What This Part Claims ↩

The claims

1	**Nonsense-mediated decay decides at the moment translation ends, not from the codon**
2	The same codon, UAA, produces opposite verdicts in different contexts
3	A correct stop codon is destroyed if only the downstream region is altered
4	Tail length and bound proteins determine the efficiency of destruction
5	The proposed trigger is slow termination — a measurement of duration
6	Suppression correlates with physical distance to a tethered protein
7	The exon junction marker is deposited twenty to twenty-four nucleotides upstream of each junction
8	UGA means selenocysteine when selenium is present and triggers decay when it is absent
9	Readthrough prevents termination and therefore prevents the verdict
10	One therapeutic strategy for premature stops is to induce a decoding error on purpose
11	The field states that target selection remains unsolved after four decades

What would refute it

the claim	what would kill it
the false-tail result	a failure to reproduce Amrani and colleagues
the timing model	a demonstration that termination speed does not correlate with the verdict
the distance correlation	a re-analysis finding suppression independent of separation
the selenium case	a demonstration that the message loss under selenium deficiency proceeds by another route
the wobble route	Experiment Forty-Six finding no change in targets when the modification is removed

And the observation this Part exists to record. A cell holds a message up, looks at how the reading ended, and decides whether to keep it. It is measuring how long the stop took, how far the nearest anchor protein sat, whether a marker was deposited downstream during splicing, how long the tail is — and in at least one documented case, whether there is enough of a particular element in the body that day.

Every one of those is a physical quantity. The codon is identical in every outcome. A record made of letters can hold the one variable that does not vary, and none of the ones that do.

PART ONE HUNDRED AND TWENTY-SEVEN · THE ATOM THAT MAKES THYMINE, AND THE ATOM THAT POISONS IT

Part One Hundred and Twenty-Seven of the evidence volume, sections 1185 to 1197

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Thymine carries the yellow band in this volume because thymine cannot be made without a sulfur atom bonding itself to the ring. One enzyme performs that step, an active-site cysteine attacks carbon six of the pyrimidine, and the methyl that distinguishes thymine from uracil can only be delivered afterward. The most widely used chemotherapy of the twentieth century works by trapping that attachment permanently. And there is a second relationship running the other way: put sulfur into the ring in place of an oxygen and the base becomes easier to ionize, absorbs light the canonical bases ignore, and turns into a poison activated by daylight. That is not a laboratory curiosity. It is what happens in the skin of every transplant patient taking azathioprine, and it carries a hundred- to two-hundred-fold increase in skin cancer.

1185. Why Thymine Is the Yellow Band ↩

This volume assigns thymine to sulfur in its color index. The reason is mechanical, not thematic.

thymine's systematic name	5-methyluracil — Part One Hundred and Nineteen
so what distinguishes it	one methyl group at position five
the enzyme that installs it	thymidylate synthase, the only route
how that enzyme starts	by forming a covalent bond between a cysteine and the ring

Thymine is uracil that a sulfur atom held still long enough for a methyl to be attached.

1186. The Enzyme, and the Covalent Step ↩

The mechanism is textbook and worth stating in order, because the order is the point.

1. an active-site cysteine attacks carbon 6 of the pyrimidine ring\n2. a covalent bond forms — the enzyme and the base are now one molecule\n3. that attack makes carbon 5 reactive\n4. the methyl is transferred from methylenetetrahydrofolate to carbon 5\n5. the cysteine is eliminated and thymidylate is released

the substrate	**deoxyuridine monophosphate**
the product	deoxythymidine monophosphate
what makes step four possible	step one
is the cysteine conserved	yes, across the enzyme family

The methyl cannot be delivered to an unactivated ring. The sulfur is not a bystander in this reaction. It is the thing that makes the ring willing to accept a methyl at all.

Every thymine in every strand of DNA in every organism was made by a sulfur atom temporarily bonding itself to a pyrimidine and then letting go.

1187. And the Drug That Traps It ↩

Fluorouracil is one of the most prescribed cancer drugs ever made. Its mechanism is the reaction above, stopped in the middle.

what the cell makes from the drug	**5-fluoro-deoxyuridine monophosphate**
what happens in the active site	the cysteine attacks carbon 6 exactly as it should
what cannot then happen	the elimination that releases the enzyme. The fluorine at carbon 5 will not leave
the result	a stable complex of enzyme, drug and folate. The enzyme is dead

what the cell makes from the drug	5-fluoro-deoxyuridine monophosphate
the consequence for the cell	no new thymidylate, so no DNA replication

The drug works by gluing a sulfur atom to a pyrimidine ring and refusing to let go. A cancer therapy in daily use worldwide is a deliberate sabotage of the sulfur–thymine bond.

1188. The Second Relationship — Sulfur Substituted Into the Ring ↩

The first relationship is sulfur making thymine. The second runs the other way: sulfur placed into the base, replacing an oxygen.

4-thiothymine	the oxygen at position four replaced by sulfur
2-thiothymine	the oxygen at position two replaced by sulfur
2,4-dithiothymine	both replaced

These are called thiobases. They are not exotic — 4-thiouridine is a standard laboratory reagent used to tag newly made RNA, because it crosslinks to protein when illuminated. Favre and colleagues described the class in 1998 as intrinsic photoaffinity probes.

What makes them useful in a laboratory is what makes them dangerous in a person.

1189. The Numbers, From the Calculation ↩

Yermolina and Papadantonakis, 2019, computed the energies. The title of the paper states the consequence: these species can alter and distort double-helix DNA structure.

the base	aqueous adiabatic ionization energy
thymine	4.95 eV
2-thiothymine	4.99 eV
2,4-dithiothymine	4.94 eV

the base	aqueous adiabatic ionization energy
4-thiothymine	4.81 eV

Replacing one oxygen with sulfur at position four lowers the energy needed to strip an electron from the base by about 0.14 electron volts. The base becomes measurably easier to ionize.

And the reverse measurement, for the doubly substituted base:

2,4-dithiothymine, aqueous adiabatic electron affinity	2.67 eV
what the authors propose from it	that it may be a potent radio-chemotherapeutic agent — a molecule that captures the electrons produced by ionizing radiation

1190. And What the Excited State Does ↩

The calculated absorption spectra of the radical cations are strongly shifted toward the red, and the paper reports that they show the characteristics of noncanonical structures.

an ordinary thymine absorbing ultraviolet light	returns to its ground state very fast, and does nothing
a thiothymine absorbing light	crosses to a long-lived excited state and has time to react
the shift in wavelength	into the range that reaches living tissue

Pollum and colleagues published 2,4-dithiothymine as a potent ultraviolet-A chemotherapeutic agent in 2014, and dithionated bases as photodynamic agents against human carcinoma cells in 2018.

One atom substituted at one ring position converts a base that harmlessly discards ultraviolet energy into one that holds onto it long enough to do damage. The letter T covers both.

1191. The Third Relationship — a Drug That Puts Sulfur Into a Patient's DNA ↩

This is not a proposal. It is standard care, and it has been for decades.

the drug	azathioprine, the most widely prescribed immunosuppressant in transplant medicine
what the body makes of it	6-thioguanine — guanine with sulfur replacing the oxygen at position six
where the 6-thioguanine goes	it is incorporated into the patient's own DNA

And then the patient goes outside.

canonical DNA bases and ultraviolet-A	they barely absorb it
6-thioguanine sitting in DNA	a strong ultraviolet-A absorber
what it becomes	a Type II photosensitizer, generating reactive oxygen where it sits

1192. What That Costs, in People ↩

The published consequences of that combination:

DNA strand breakage	yes
crosslinking of the two strands to each other	yes
oxidation of neighboring bases	yes
covalent attachment of proteins to the DNA	yes — including the repair and replication proteins themselves
the epidemiology	a hundred- to two-hundred-fold increase in skin cancer incidence with long-term use after organ transplant
its regulatory classification	azathioprine is classed by the International Agency for Research on Cancer as a human carcinogen

A sulfur atom substituted onto one base, delivered by prescription, turns a patient's own genome into a photosensitizer. The proteins sent to repair the damage are welded to the DNA by the same reaction.

1193. And It Is Reversible ↩

The most important clinical fact in this Part, and the reason it is not a counsel of despair.

what happens when azathioprine is replaced with a different immunosuppressant	the ultraviolet-A photosensitivity reverses, and the measured DNA damage falls

The sulfur leaves. The DNA stops absorbing the light. The risk changes.

This volume records the harm and the remedy in the same section, because the remedy exists and is in the literature.

1194. What the Notation Loses Here ↩

what is present in the molecule	what the sequence record says
thymine	T
4-thiothymine, ionizing more easily by 0.14 eV	T
2,4-dithiothymine, an electron trap proposed for radiotherapy	T
guanine	G
6-thioguanine in a transplant patient's skin cells	G
a thymidylate synthase caught mid-reaction, covalently bonded to its substrate	nothing. There is no notation for an enzyme joined to a base

A hundredfold change in cancer risk, invisible to the record. The oncologist knows because they know what the patient is taking, not because anything in the genome says so.

1195. What This Part Refuses ↩

the claim	the status
thymidylate synthase forms a covalent bond between an active-site cysteine and carbon 6	established
fluorouracil traps that complex and inactivates the enzyme	established
the ionization energies as listed	as computed and published, 2019
2,4-dithiothymine has an aqueous adiabatic electron affinity of 2.67 eV	as computed
thiobases are used as photoaffinity probes	established since at least 1998
azathioprine leads to 6-thioguanine in patient DNA	established
DNA 6-thioguanine is an ultraviolet-A chromophore and Type II photosensitizer	established, and cited
the hundred- to two-hundred-fold skin cancer figure, and the carcinogen classification	as published
that the ionization energies have been measured rather than computed	refused. The 2019 values are density functional calculations. This volume prints them as calculations and says so
that thiobases in DNA explain cancers other than the thiopurine case	refused. The transplant case is documented. Nothing here extends beyond it
that sulfur is therefore harmful to DNA	refused. Sulfur makes thymine possible. The same element in a different ring position is the hazard. The position is the whole story
that fluorouracil should be reconsidered	refused. It works, and this Part records why

1196. The Experiment This Part Generates ↩

Experiment Forty-Seven, for Part Twenty-Eight, section 65.

The question. A patient on azathioprine carries 6-thioguanine in their DNA, and the amount determines their photosensitivity. How much is in there? At present the

answer is estimated indirectly, from thiopurine metabolites measured in red blood cells.

Why it should be measurable directly. Nanopore sequencing reads the native molecule rather than a copy, and distinguishes bases by the current they block. A guanine carrying a sulfur atom is a physically different obstruction than a guanine carrying an oxygen.

Method. Take skin or blood samples from patients on long-term azathioprine and from matched controls. Sequence directly, without amplification. Ask whether positions occupied by 6-thioguanine produce a distinguishable signal, and whether the amount tracks the clinical photosensitivity and the red-cell metabolite level.

Falsification condition, written before the answer. If 6-thioguanine cannot be distinguished from guanine in the raw signal, the measurement is not available by this route and this Part should say so. If it can, then the sulfur load in a patient's own DNA becomes a direct, personal measurement of skin cancer risk — and it is being read by the one instrument that does not copy the molecule first.

Part One Hundred and Twenty-Two records that the standard method erases the chemistry at the first step. Here is a case where a patient's risk is that chemistry, and the instrument that does not erase it already exists.

1197. What This Part Claims ↩

The claims

1	**Thymine is 5-methyluracil, and one enzyme makes it**
2	That enzyme begins by forming a covalent bond between an active-site cysteine and carbon 6 of the ring
3	The methyl cannot be transferred until that bond activates carbon 5
4	Fluorouracil works by making that bond permanent and killing the enzyme
5	Replacing the oxygen at position 4 of thymine with sulfur lowers the ionization energy from 4.95 to 4.81 eV
6	2,4-dithiothymine has a computed electron affinity of 2.67 eV and has been proposed as a radio-chemotherapeutic
7	Thiobases have been used as photoaffinity probes since the 1990s

1	**Thymine is 5-methyluracil, and one enzyme makes it**
8	Azathioprine places 6-thioguanine into patient DNA
9	Canonical bases barely absorb ultraviolet-A; DNA 6-thioguanine absorbs it strongly
10	The combination breaks DNA, crosslinks strands, and welds proteins to the double helix
11	Long-term use carries a hundred- to two-hundred-fold increase in skin cancer, and the drug is classed as a human carcinogen
12	Replacing the drug reverses the photosensitivity

What would refute it

the claim	what would kill it
the covalent mechanism	a thymidylate synthase shown to methylate without the cysteine adduct
the ionization ordering	an experimental measurement placing 4-thiothymine above thymine
the photosensitizer account	a demonstration that the transplant skin cancer excess is unrelated to DNA 6-thioguanine
the reversal	a study finding photosensitivity persists after the drug is withdrawn
the measurement	Experiment Forty-Seven finding 6-thioguanine indistinguishable from guanine in direct reading

And the observation this Part exists to record. The same element appears twice in the life of one base and does opposite things. At carbon six of the enzyme's cysteine it is what allows thymine to exist at all. At position four of the ring it is what turns the base into something that catches daylight and breaks the strand it sits in. The difference is not the atom. It is where the atom is — and a letter records neither.

PART ONE HUNDRED AND TWENTY-EIGHT · TWO, ONE, ZERO

Part One Hundred and Twenty-Eight of the evidence volume, sections 1198 to 1210

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The most consequential common variant in human medicine is a count of sulfur atoms. The three apolipoprotein E alleles differ at exactly two positions in a protein

of two hundred and ninety-nine residues, and at both of them the choice is between cysteine and arginine. The protective allele carries two cysteines. The common allele carries one. The allele that raises Alzheimer's risk carries none. And the consequence is not abstract: the two cysteine-bearing forms make disulfide-linked dimers in blood, in cerebrospinal fluid and in human frontal cortex, and the third form cannot, because it has nothing to bond with. A genotyping test reads two letters and returns a name. It does not report whether the bond those letters permit has actually formed.

1198. The Count ↩

allele	residue 112	residue 158	sulfur atoms in the protein
ε2	cysteine	cysteine	two
ε3	cysteine	arginine	one
ε4	arginine	arginine	none

Two positions. Two hundred and ninety-nine residues in the protein. Everything else identical.

The three forms of apolipoprotein E are not three different proteins. They are one protein carrying two sulfur atoms, one sulfur atom, or none — and the one carrying none is the risk allele.

1199. What the Two Letters Actually Change ↩

The two variants are named rs429358 at codon 112 and rs7412 at codon 158, and both are cysteine-arginine interchanges.

codon 112 TGC (cysteine) <--> CGC (arginine)\ncodon 158 CGC (arginine) <--> TGC (cysteine)

what the letter change is	one base, at the first position of the codon, in both cases
what the amino acid change is	a thiol side chain exchanged for a positively charged one

what the letter change is	one base, at the first position of the codon, in both cases
what the atom change is	a sulfur atom present, or absent

1200. And the Bond That ε4 Cannot Make ↩

A cysteine can do something no other residue can. It can bond to another cysteine.

apoE3 and apoE2	form disulfide-linked dimers — in plasma and in cerebrospinal fluid
the partners	another apoE molecule, and also apolipoprotein A-II
apoE4	cannot form them. It has no cysteine

Part One Hundred and Twenty-One of this volume records that structural disulfides form outside the cell, where conditions are oxidizing, and not in the reducing interior. ApoE is secreted. The bond forms where the chemistry permits it.

The difference between the alleles is not only which amino acid sits at position 112. It is whether this protein can join to another protein at all.

1201. How Much of It There Is ↩

This is not a trace phenomenon.

in samples from ε3 homozygotes	
apoE present as a homodimer	about twelve percent
apoE present as a heterodimer with apolipoprotein A-II	about two percent

And the dimers are not confined to blood. They have been found in human frontal cortex and hippocampus — the tissue where the Alzheimer's association lives.

In a person carrying ε3, roughly one apoE molecule in eight is joined to another molecule by a sulfur-sulfur bond. In a person carrying two copies of ε4, that number is zero, and no test they will ever be given reports it.

1202. What the Arginine Does Instead ↩

The story is not only what ε4 lacks. It is also what the substitute residue adds.

arginine at 112 in apoE4	contributes to salt bridges — arginine 61 to glutamate 255, and arginine 112 to glutamate 109
the consequence	the amino-terminal and carboxy-terminal domains of the protein interact with each other
in apoE3 and apoE2	that domain interaction does not occur

This is the standard structural account of why the isoforms behave differently, and it is a statement about folding, not about sequence.

And the receptor behavior differs again in the other direction: Weisgraber and colleagues showed in 1982 that apoE2, with cysteine at both sites, binds poorly to cell surface receptors, while apoE3 and apoE4 bind well.

Three alleles, three behaviors, and none of the three behaviors is a property of a letter. One is a bond that can or cannot form. One is a fold that does or does not close. One is a binding affinity at a receptor.

1203. Where the Wobble Question Ends ↩

This volume examined whether the apolipoprotein E variants involve the wobble position. They do not, and this Part says so before anyone else does.

the wobble position	the third base of the codon
rs429358	first base of codon 112
rs7412	first base of codon 158

Neither apolipoprotein E variant is a wobble event. Any account claiming otherwise is wrong, and this volume declines it.

One adjacent observation is offered as a proposition and not as a finding. Arginine's CGN codons are decoded by a transfer RNA carrying inosine at position 34. So apoE4 requires two inosine-dependent decoding events where apoE2 requires none. That is true — and it is equally true of every arginine in every protein, so it distinguishes nothing. It is recorded here only so that no reader mistakes it for a claim.

1204. What the Genotyping Assay Reads ↩

Apolipoprotein E genotyping is among the most requested genetic tests in medicine. The common method is probe-based allele discrimination — a fluorescent probe for each variant, read on a plate.

what it interrogates	two positions
what it reports	a genotype call: ε3/ε4, ε2/ε3, and so on
how well it agrees with sequencing	complete concordance is the marketed figure
is it a good test	yes. It measures what it measures, accurately and cheaply

This volume takes no issue with the assay. It works.

1205. And What It Cannot Read ↩

what determines the biology	what the genotype call reports
is that cysteine free, oxidized, or in a disulfide?	nothing
is this person's apoE a monomer or a dimer today?	nothing — and about one molecule in eight is a dimer in an ε3 carrier
is it joined to another apoE, or to apolipoprotein A-II?	nothing
is the domain interaction engaged?	nothing
what is the redox state of	nothing

what determines the biology	what the genotype call reports
the compartment it was secreted into?	

The genotype is a statement about which bond is permitted. The biology is which bond has formed. Two people with identical ε3/ε3 results may differ in every row of this table, and the test returns the same three characters for both.

1206. Someone Else Is Arriving Here ↩

This volume records convergence when it finds it.

In 2025 a paper appeared, framed explicitly as a hypothesis, arguing that lipid-protecting disulfide bridges are the missing molecular link between apoE4 and sporadic Alzheimer's disease in humans.

what that means	the sulfur account of the apolipoprotein E risk is live in the current literature
what this volume does about it	cites it, and claims no priority over it

A hypothesis published by others in 2025 and the reasoning in this Part point at the same atom. That is what independent convergence looks like, and it is a reason to move rather than a reason to argue.

1207. What the Notation Loses Here ↩

what is present	what the record says
apoE3, one free cysteine, monomeric	ε3
apoE3, that cysteine bonded to another apoE molecule	ε3
apoE3, that cysteine bonded to apolipoprotein A-II	ε3
apoE3, that cysteine oxidized and unable to bond	ε3

what is present	what the record says
apoE4, no cysteine, domain interaction engaged	ε4

Four chemically distinct species share one genotype call. The distinction between them is a sulfur-sulfur bond, and there is no field in any clinical report for whether a bond exists.

1208. What This Part Refuses ↩

the claim	the status
the three alleles differ at residues 112 and 158 by cysteine-arginine interchange	established
ε2 carries two cysteines, ε3 one, ε4 none	established
apoE3 and apoE2 form disulfide-linked dimers; apoE4 cannot	established, and cited
about twelve percent homodimer and two percent heterodimer in ε3 homozygotes	as published
apoE dimers occur in human frontal cortex and hippocampus	as published
arginine 112 contributes to salt bridges producing domain interaction	as published
apoE2 binds cell surface receptors poorly — Weisgraber and colleagues, 1982	established
that the apolipoprotein E variants are wobble-position events	refused in section 1203. Both are first-position changes
that the inosine decoding of arginine codons distinguishes the alleles	refused. It applies to every arginine and distinguishes nothing
that the missing disulfide is the cause of the ε4 risk	refused as a claim by this volume. It is a live published hypothesis, cited in section 1206, and the evidence is not settled
that apolipoprotein E genotyping is inadequate or	refused. The assay is accurate. What this Part records is that the genotype and the protein state are different

the claim	the status
should be replaced	measurements, and only one of them is made

1209. The Experiment This Part Generates ↩

Experiment Forty-Eight, for Part Twenty-Eight, section 65.

The question. About twelve percent of apoE is dimeric in an ε3 homozygote. Is that number the same in every ε3 homozygote? Nobody appears to have asked, because the genotype is treated as the measurement.

Why it might vary. A disulfide forms or does not form depending on the oxidizing conditions where the protein is secreted. Part One Hundred and Twenty-One records that the interior of a cell is held reducing by glutathione and the exterior is not. The dimer fraction is therefore a redox measurement, and redox status differs between people, with age, and with illness.

Method. Take plasma and, where available, cerebrospinal fluid from a cohort of ε3 homozygotes — people with identical genotype calls. Run non-reducing separation and measure the dimer fraction in each. Report the spread. Then ask whether the spread correlates with anything: age, oxidative stress markers, cognitive measures.

Falsification condition, written before the answer. If the dimer fraction is tightly clustered around twelve percent in every ε3 homozygote, then the genotype does predict the protein state, this Part's central complaint does not apply to apolipoprotein E, and section 1205 should say so. If the fraction varies widely between people with identical genotypes, then a measurement that matters is being left unmade in one of the most-ordered genetic tests in medicine.

The separation method is decades old and costs almost nothing. What is new is asking the question of people whose genotypes are the same.

1210. What This Part Claims ↩

The claims

1	**The three apolipoprotein E alleles differ only at residues 112 and 158**
2	At both positions the choice is cysteine or arginine
3	ε2 carries two cysteines, ε3 one, ε4 none
4	The allele associated with raised Alzheimer's risk is the one with no sulfur
5	apoE3 and apoE2 form disulfide-linked dimers; apoE4 cannot
6	About twelve percent of apoE is homodimer in ε3 homozygotes, and about two percent heterodimer with apolipoprotein A-II
7	Those dimers occur in human frontal cortex and hippocampus
8	Arginine 112 in apoE4 produces a domain interaction the other isoforms lack
9	apoE2 binds cell surface receptors poorly, as shown in 1982
10	Neither variant is a wobble-position event
11	The genotyping assay reads two positions accurately and reports nothing about bond state

What would refute it

the claim	what would kill it
the cysteine count	a re-determination of the isoform sequences
the dimer claim	a demonstration that apoE4 forms the same complexes by another route
the twelve percent	a larger measurement finding a substantially different fraction
the domain interaction	a structure showing the same interaction in apoE3
the variability proposition	Experiment Forty-Eight finding the dimer fraction identical across ε3 homozygotes

And the observation this Part exists to record. A person is told they carry ε4 and that this raises their risk. What they carry is a protein missing two sulfur atoms, and therefore missing the ability to join itself to another molecule — a bond that in a person with the common allele accounts for about one molecule in eight, in their blood, in their spinal fluid and in their frontal cortex. The test that told them reads two letters. The thing the letters decide is whether a bond can exist, and no one has measured whether it did.

PART ONE HUNDRED AND TWENTY-NINE · THE TETRAD WITH A HOLE IN IT

Part One Hundred and Twenty-Nine of the evidence volume, sections 1211 to 1223

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Four guanines can lock into a flat square held by eight hydrogen bonds, stack that square on two more, seat a potassium ion down the middle, and produce the most stable small structure nucleic acids make. It sits in telomeres, in promoters, in the untranslated leaders of messenger RNA, and in the repeat expansion that causes one form of amyotrophic lateral sclerosis. Half of the hydrogen bonds that hold each square together are donated by one atom group — the amino group at carbon two of guanine. Inosine is guanine without that group. And inosine is what the cell's own editing enzyme makes, in messenger RNA, on purpose. A sequencing machine reports inosine as guanine. So the structure a computer predicts from the sequence and the structure the molecule actually builds are not required to be the same object, and no read in any database records the difference.

1211. The Structure This Part Is About ↩

A G-quadruplex is not a helix. It is a stack of squares.

the unit	four guanines in a plane, hydrogen bonded in a cycle — a G-tetrad
the stack	two, three or four tetrads, one on top of another
the ion	a potassium ion seated between each pair of planes, coordinated by eight carbonyl oxygens
where they occur	telomeres, promoters, replication origins, the untranslated leaders of messenger RNA
what they do	regulate transcription and translation, and mark the ends of chromosomes

One disease example makes the stakes concrete. The expanded GGGGCC repeat in the C9orf72 gene, the commonest genetic cause of amyotrophic lateral sclerosis and frontotemporal dementia, forms these structures in RNA. This is not a curiosity of the test tube.

1212. What Holds a Tetrad Together ↩

Each guanine in the square donates two hydrogen bonds to its neighbor and accepts two from the other.

bond one N1 - H . . . O6 (from the ring nitrogen to the carbonyl)\nbond two N2 - H . . . N7 (from the AMINO GROUP AT CARBON TWO)

hydrogen bonds per pair	two
pairs in one tetrad	four
hydrogen bonds per tetrad	eight
how many of those eight come from the carbon-two amino group	four. Exactly half

The same amino group also lines the narrow groove of the assembled structure, where it faces the loops and the solvent and helps decide which of several possible foldings the molecule adopts.

1213. And What Inosine Takes Away ↩

Inosine is guanine minus the amino group at carbon two. That is the entire chemical difference.

	guanine	inosine
carbonyl at carbon six	present	present
ring nitrogen N1 with its hydrogen	present	present
N7, the Hoogsteen acceptor	present	present
amino group at carbon two	present	absent
hydrogen bonds it can contribute to a tetrad	two	one

Put one inosine into a G-run and that position keeps its carbonyl and loses its donor. The tetrad it sits in has a hole in it. And the volume records what follows, which is not what a reader would guess.

1214. The Substitution Has Been Done, Position by Position ↩

Workers at the RNA Institute at the University at Albany took the human telomeric repeat and put inosine at every guanine position in turn, then read out the folding by circular dichroism and melting in both sodium and potassium.

sequence	what folded
(GGG) — unmodified	antiparallel in sodium; hybrid in potassium
(IGG) and (GGI) — one inosine, at an end	still fold, antiparallel, in both ions
(GIG), (IGI), (GII)	fold, but parallel — the topology changes
(IIG) and (III)	no detectable conformation in sodium or potassium

the reading	
one hole	tolerated, and often changes which fold is chosen
two holes	generally abolishes the structure altogether
the ion matters	potassium confers more thermodynamic stability than sodium in most of these cases

Earlier work at Southampton had already shown that the relative cost of an inosine at each position is different in sodium than in potassium — the substitution is not a fixed penalty, it is a penalty that depends on which ion is in the channel.

So the effect of removing this one atom group is not a simple weakening. It is a switch. It can leave the structure, redirect it into a different fold, or delete it.

1215. And the Edit Can Build a Quadruplex That Was Not There ↩

The reverse case is the one that matters most, and it has been demonstrated.

A group at the Federal Institute of Technology in Zurich, publishing in 2021, showed that adenosine-to-inosine editing can complete a quartet that was incomplete. Their title states it plainly: inosine substitutions in RNA activate latent G-quadruplexes.

what they found	
the mechanism	A-to-I editing fills an incomplete G-quartet with inosine
the product	a GI-quadruplex — a real, characterized structure
its topology	parallel
its ion	stabilized by potassium
its stability	moderately reduced relative to an all-guanine quadruplex — reduced, not abolished
where it works	verified in cells, not only in a cuvette
their own summary	a previously unrecognized structural motif that may contribute to the regulation of gene expression

An adenine sitting in a run of guanines breaks the quartet. The editing enzyme deaminates that adenine to inosine. Inosine keeps the carbonyl and the N7. The quartet closes. A structure that the genome does not encode now exists in the messenger RNA, and it regulates that message.

1216. The Editor Binds the Structure It Can Create ↩

The connection is not incidental. It is physical.

A 2025 review sets out strong evidence that the editing enzyme's own Z-beta domain binds G-quadruplexes — the ones formed co-transcriptionally by Alu repeats and inside R-loops.

the enzyme	the double-stranded RNA editing enzyme, in its two major isoforms
what the Z-alpha domain binds	left-handed Z-form DNA and RNA
what the Z-beta domain binds	G-quadruplexes
the consequence reported	it suppresses Alu-mediated alternative splicing, generates most of the reported protein-changing edits, and helps resolve R-loops

Part Sixty of this volume is about the Alu engine. Part Fifty-Nine is about the editor. This is the same machinery, seen from the structural side.

The enzyme that makes inosine binds quadruplexes. The inosine it makes can create quadruplexes. The two facts belong to one mechanism.

1217. And the Editor Is Itself Governed by One ↩

The loop closes.

A group in Hong Kong and Guangzhou identified a thermostable G-quadruplex in the untranslated leader of the editing enzyme's own messenger RNA, and showed that it holds down the translation of that message. A specialized helicase unwinds it, and translation goes up.

the structure	**an RNA G-quadruplex in the 5′ leader of the editing enzyme's transcript**
its effect	inhibits translation of the enzyme
what removes it	a G-quadruplex-specific helicase

The enzyme that converts adenine to a base that can complete a quadruplex has its own production controlled by a quadruplex. Whatever else that is, it is a regulator wired to its own product.

1218. What the Sequencing Read Cannot See ↩

Now the point this Part exists to make.

Reverse transcriptase inserts cytosine opposite inosine. That is not a defect — it is the entire basis on which editing is detected, since an edited site appears in the data as an apparent A-to-G change. It follows that in every sequence database, inosine is written as the letter G.

Every published survey of quadruplex-forming sequences is a computation over those letters.

what the algorithm scans	what may actually be there	what the algorithm concludes
a run of G in a transcript read	a run containing one or more inosines	a quadruplex — but the real molecule has a hole in a tetrad, may adopt a different topology, and may not fold at all
a run in the genome broken by an A	a completed quartet in the edited transcript	no quadruplex — and it is there

The prediction fails in both directions at once. It over-calls structures the cell does not build, and it misses structures the cell builds on purpose. Neither error is visible in the data, because the notation has already thrown away the distinction between the two molecules before the algorithm ever runs.

And a database has now been assembled that presupposes the point: a 2026 registry of RNA modification sites falling inside putative quadruplex-forming sequences, whose authors validated the influence of methylation and of A-to-I editing on those sequences and named the idea a modification switch. The catalog of where this happens is being built. What is missing is a measurement of what the molecule does when it happens.

1219. The Guanine in Every Tetrad Was Inosine Two Steps Earlier ↩

Part One Hundred and Twenty-Five of this volume establishes that inosine monophosphate is the parent of purine biosynthesis, not a waypoint. That result meets this Part directly.

IMP ------> XMP ------> GMP ------> guanine in a tetrad\n(IMPDH) (GMP synthase)

guanines in one tetrad	four
how many passed through inosine monophosphate	four
how many steps separate them from it	two

A G-quadruplex is four molecules of the parent purine, each carried two enzymatic steps forward, assembled into a square. The base that

dissolves the structure when it appears in the finished RNA is the base every guanine in that structure came from.

1220. The Structure Does Not Assemble Tetrad by Tetrad ↩

Everything above this section describes a finished tetrad and what inosine takes out of it. It says nothing about how the structure gets built, and the order of construction turns out to matter to the argument.

Monsen, Sabo, Gray, Hopkins and Chaires reported time-resolved small-angle X-ray scattering on the folding of human telomeric quadruplexes in Nucleic Acids Research in 2025. The measurement runs from one millisecond, and it caught a step nobody had seen.

the first event in quadruplex folding	Monsen et al., Nucleic Acids Research 2025;53:gkaf043
radius of gyration, unfolded	24.3 angstroms
radius of gyration, after the first step	12.6 angstroms
maximum particle dimension, unfolded to folded	83 angstroms to 38
how long the step takes	monophasic, complete in under 600 milliseconds
measured relaxation time for the collapse	187 milliseconds by one fit, 268 to 290 by others
what the authors call it	a rapid collapse, analogous to molten globule formation seen in proteins

The chain collapses first. The tetrads form afterward, inside the collapsed particle, by what the authors describe as a confined conformational search for native contacts. Assembly is not four guanines finding each other in open solution and then stacking. It is a globule forming and then sorting itself out internally.

1221. Which Means the Amino Group Is Not the Builder ↩

Section 1212 counts eight hydrogen bonds per tetrad and shows that four of them come from the amino group at carbon two. That count is unchanged and it remains the reason inosine cannot hold a tetrad.

But the count describes a finished object, and the timing says the finished object is assembled last. If the collapse happens first and the native contacts are found inside it, then those four hydrogen bonds are not what pulls the structure together. Something else does that, and the authors name it.

what actually pulls the chain in	
what drives the collapse	burial of hydrophobic surface
surface area removed, by their estimate	about 2,477 square angstroms
the entropic cost being overcome	for a twenty-four-residue chain, R times the natural log of seven to the twenty-third, or 88.6 calories per kelvin per mole
what does the work at this stage	base stacking and the hydrophobic effect
what the carbon-two amino group does instead	selects, from within an already-collapsed particle, which of several possible foldings is adopted

So the amino group at carbon two is not the mason. It is the referee. It does not build the structure; it decides which structure the collapsed particle is allowed to become, and it does that after the chain has already stopped being extended.

This sharpens the Part rather than weakening it. Inosine's missing amine does not fail to attract - it fails to discriminate. A collapsed inosine chain would still collapse. What it could not do is find the eight-bond square at the end of the search.

1222. And the Field's Standard Unfolded Control Is Not Unfolded ↩

The same paper contains a methodological correction that should be recorded here because this volume has cited quadruplex work throughout.

Lithium is routinely substituted for potassium in quadruplex experiments on the assumption that it will not support the fold, giving an unfolded reference state. The scattering says otherwise.

three states, measured the same way	
folded, potassium chloride at pH 7.2	radius of gyration 12.27 angstroms, maximum dimension 38
lithium chloride at pH 7.2, the usual unfolded control	11.92 angstroms, maximum dimension 43
genuinely unfolded, alkaline pH 11.5	24.26 angstroms, maximum dimension 83
the authors' phrasing	unfolding was complete at alkaline pH, but not in LiCl solution as is often claimed

A lithium sample is as compact as a folded one. Any experiment that used lithium as its unfolded arm was comparing a folded structure against something very nearly as folded, and would have reported a small difference where the real difference is a factor of two in radius.

This volume does not know how many published results are affected and does not speculate. It records the correction because it bears on evidence the volume relies on, and because a reader checking the quadruplex literature should encounter it here rather than after the fact.

1223. The Unfolded State Was Never Empty ↩

One more result changes the picture the earlier sections assume. The starting material is not a random chain.

Ensemble Optimization Method analysis of the scattering describes the unfolded state as a dynamic population of flexible chains carrying a variety of transient hairpin structures. Base pairing is already happening before any tetrad exists, and the collapse proceeds from hairpins rather than from an open coil.

Which means the sequence of events runs: transient hairpins, then hydrophobic collapse to a compact particle, then a confined search inside that particle for the eight-bond tetrad geometry. Three stages, and the carbon-two amino group is load-bearing only in the third.

Part One Hundred and Forty-Four argues that the chemical stratum precedes the molecular one. Here is that ordering inside a single molecule, timed. The hydrophobic effect and base stacking - chemistry, entropy, surface area - do the first two stages in under six hundred milliseconds. The specific hydrogen-bond pattern

that makes a guanine tetrad a guanine tetrad, and that inosine cannot supply, arrives last.

1224. What the Notation Loses Here ↩

what is present in the cell	what the record says
a run of four genuine guanines that folds	GGGG
the same run with one inosine — folds, different topology	GGGG
the same run with two inosines — does not fold at all	GGGG
a run broken by adenine, no structure	GGAG
that run after editing — a completed GI-quadruplex	GGGG

Five chemically distinct outcomes. Two printed strings. And the two strings do not sort the five outcomes — the row that folds and the row that cannot fold carry the same four letters.

1225. What This Part Refuses ↩

the claim	the status
a G-tetrad is held by two hydrogen bonds per pair, N1-H to O6 and N2-H to N7	established
inosine lacks the carbon-two amino group and can donate only one of those two	established
single inosine substitution is tolerated and can redirect the topology; two generally abolish folding	as published, University at Albany, 2024
the penalty depends on whether sodium or potassium is in the channel	as published, Southampton, 2005

the claim	the status
A-to-I editing can complete an incomplete quartet and activate a latent quadruplex in cells	as published, Zurich, 2021
the editing enzyme's Z-beta domain binds G-quadruplexes	as published, 2025
a quadruplex in the editing enzyme's own leader inhibits its translation	as published, 2022
reverse transcriptase reads inosine as guanine, so sequence records cannot distinguish them	established, and it is the basis of editing detection
that A-to-I editing is a mutation	refused. The DNA is not changed. These are two molecules from one sequence, which is a stronger statement and a true one
that quadruplex mis-prediction has been shown to cause any named disease	refused. No such demonstration exists, and this volume does not assert one
that existing quadruplex surveys are worthless	refused. They are computations over letters, correct as computations. What this Part records is that the letters do not carry the distinction the structure depends on
that the effect of inosine on a quadruplex is simple destabilization	refused by the evidence itself. It can preserve, redirect, abolish, or create

1226. The Experiment This Part Generates ↩

Experiment Forty-Nine, for Part Twenty-Eight, section 65.

The opportunity. In January 2025 a group from the University of Louisville, working at the Biophysics Collaborative Access Team beamline operated by Illinois Institute of Technology at the Advanced Photon Source, published the first time-resolved small-angle X-ray scattering study of G-quadruplex folding. Using continuous laminar flow and a pH jump they captured a previously unknown rapid collapse of the unfolded strand.

what they measured, on the human telomeric hybrid-1 sequence	
radius of gyration, unfolded → collapsed	24.3 Å → 12.6 Å

what they measured, on the human telomeric hybrid-1 sequence	
maximum interparticle distance	83 Å → 48 Å
the collapse	monophasic, complete in under 600 milliseconds
relaxation time by scattering	187 ± 13 ms
relaxation times by stopped-flow absorbance	104 ± 4 ms and 260 ± 20 ms
what follows	slower steps spanning 1 to 10,000 seconds
their description of the collapsed state	analogous to the molten globule of protein folding, followed by a confined conformational search inside the collapsed particle

That apparatus can answer the question this Part raises, and nothing else can.

Arm A — does the collapse need the amino group?

Run the identical pH-jump protocol on the same telomeric sequence carrying a single inosine at each of the positions already shown to fold — the terminal substitutions and the interior ones. Measure the radius of gyration against time and extract the relaxation time for each.

outcome	what it would mean
collapse time unchanged, endpoint unchanged	the initial collapse is nonspecific — driven by charge screening and stacking — and the carbon-two amino group matters only for the slow search that follows. The molten globule would be shown to be indifferent to the base identity
collapse slowed or the endpoint radius enlarged	hydrogen bonding participates in the collapse itself, and half the tetrad bonding is missing from the first millisecond onward

Either result is a finding, and neither is currently known.

Arm B — watch an edit switch a fold on

Take a sequence with an adenine breaking a G-run — a latent quadruplex of the kind shown in 2021 to be activated by editing — and synthesize two oligonucleotides: the unedited strand, and the same strand with inosine at that position, which is the edited product. Run both through the same apparatus.

prediction, written before the measurement	
unedited strand	no collapse to the folded radius
inosine strand	collapse, on the sub-second timescale

That measurement would be the first direct structural observation of an RNA editing event switching on a fold in real time. The existence of the product is established. Nobody has watched it form.

Why this is cheap. Inosine phosphoramidite is a standard commercial reagent and the substituted oligonucleotides are ordered the same way the originals were. The buffer, the pH jump, the flow cell and the analysis pipeline already exist and are validated on exactly these sequences. The only variable changed is one atom group on one base.

Falsification condition, written before the answer. If the single-inosine strands collapse indistinguishably from the unmodified strand and the latent strand collapses without editing, then the carbon-two amino group is not structurally decisive on this timescale, sequence-based prediction is adequate for the folding step, and this Part's argument is confined to equilibrium stability rather than kinetics. That is a real way to lose, and it is the reason the experiment is worth running.

1227. What This Part Claims ↩

The claims

1	**A G-tetrad is held by eight hydrogen bonds, and four of the eight are donated by the amino group at carbon two of guanine**
2	Inosine is guanine without that group and can donate only one bond per pair instead of two
3	A single inosine is tolerated and frequently changes which topology the molecule adopts
4	Two inosines generally abolish the fold outright
5	The cost of the substitution depends on whether sodium or potassium occupies the channel
6	A-to-I editing can complete an incomplete quartet and switch on a quadruplex that the genome does not encode, and this has been shown in cells
7	The editing enzyme binds G-quadruplexes through its Z-beta domain
8	The editing enzyme's own translation is held down by a G-quadruplex in its leader
9	Reverse transcriptase reads inosine as guanine, so no sequence record distinguishes the two

1	**A G-tetrad is held by eight hydrogen bonds, and four of the eight are donated by the amino group at carbon two of guanine**
10	Therefore quadruplex prediction from sequence over-calls structures that do not fold and misses structures that do, and neither error is detectable in the data
11	Every guanine in every tetrad passed through inosine monophosphate two enzymatic steps earlier

What would refute it

the claim	what would kill it
the bonding count	a redetermination of G-tetrad hydrogen bonding
the position-dependent folding results	a larger substitution series contradicting the Albany and Southampton data
latent activation	a demonstration that the 2021 GI-quadruplexes are artifacts of the synthetic system
the invisibility argument	a sequencing chemistry that distinguishes inosine from guanine directly, applied at transcriptome scale — which would not refute the argument so much as end the problem, and this volume would welcome it
the kinetic proposition	Experiment Forty-Nine, Arm A, finding the collapse identical with and without the amino group

And the sentence this Part exists to put on the record. The most stable structure nucleic acids build is held together by an atom group that the cell's own editing enzyme removes on purpose, in messenger RNA, in living cells — and the machine that reads the sequence writes the base with the group and the base without it using the same letter. Every map of where these structures occur has been drawn from that letter.

PART ONE HUNDRED AND THIRTY · THE PAWL IS MADE OF SULFUR

Part One Hundred and Thirty of the evidence volume, sections 1224 to 1237

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The protein that moves the ribosome forward one codon at a time belongs to a family older than bacteria, older than archaea, older than the split that produced them. It is present in all three domains, which is the standard evidence that it was

present in their common ancestor. In archaea and in us — but not in bacteria — that protein carries at its working tip a single rebuilt histidine called diphthamide, and diphthamide is made by two enzymes that each hold a four-iron four-sulfur cluster. Structural work published in 2024 shows what that residue does: it stabilizes correct Watson-Crick pairing between codon and anticodon, and it restricts wobble geometry at the second base pair. Remove it and the ribosome slips its reading frame. So the boundary between the position where wobble is permitted and the position where wobble is an error is enforced by a residue that sulfur chemistry builds — and the lineage that added it is the same lineage that expanded inosine decoding from one transfer RNA to eight.

1228. The Family, and How Old It Is ↩

Dr. Berger's own download from the protein archive returns two hundred and fifty-nine human members of one family: the classic translation factor GTPases, TRAFAC class.

the classification, as the archive prints it
TRAFAC class translation factor GTPase superfamily
Classic translation factor GTPase family
EF-G / EF-2 subfamily
Translational GTPases · Ribosomal factors

domain	the elongation GTPase it uses
bacteria	EF-G
archaea	aEF-2
eukaryotes	eEF-2

The same protein, doing the same job, in all three domains of life. That is the ordinary evidence that it was there before the domains separated. This family predates the last universal common ancestor's descendants — it predates prokaryotes and eukaryotes as categories, because those categories are what happened afterward.

And the family carries a member this volume has already met. Among the two hundred and fifty-nine is the selenocysteine-specific elongation factor, the dedicated

machine for the twenty-first amino acid discussed in Part One Hundred and Twenty-Six.

1229. What LUCA's Chemistry Was Made Of ↩

In 2016 a group at Düsseldorf sorted two hundred and eighty-six thousand five hundred and fourteen protein clusters and found three hundred and fifty-five families that trace to the last universal common ancestor by phylogenetic criteria. Their portrait of that organism is specific.

what they concluded LUCA was	
anaerobic	no oxygen
thermophilic	hot
carbon dioxide fixing, hydrogen dependent	the Wood-Ljungdahl pathway
nitrogen fixing	
its biochemistry	replete with iron-sulfur clusters and radical reaction mechanisms

That last line is the one this Part is built on. The chemistry of the organism at the root was iron, sulfur and radicals. Not a metaphor — the reconstructed enzyme inventory.

1230. The Pawl ↩

A pawl is the tooth in a ratchet that lets the wheel turn one way and not the other.

That is the word structural biologists chose for this protein. The 2021 crystal structure of the eukaryotic ribosome caught in the act of moving describes elongation factor 2 as a pawl defining the directionality of translocation.

what the ribosome must do	
move the messenger RNA and both transfer RNAs together	by exactly three bases

what the ribosome must do	
not two, not four	a slip of one base destroys every amino acid after it
and never backward	

And the shape of the tool is the second surprise. The tip of domain four of this protein is a molecular imitation of a transfer RNA anticodon loop. The factor that checks the anticodon is shaped like one.

1231. The Residue at the Tip, and Which Domains Carry It ↩

At the very tip of that imitated anticodon sits one histidine, rebuilt into something found nowhere else in biology.

name	diphthamide
position, human	histidine 715 of a 858-residue protein
position, yeast	histidine 699
what it is famous for	it is the target diphtheria toxin ADP-ribosylates in order to kill you

And here is the distribution, which is the heart of this Part.

domain	diphthamide on the elongation GTPase
bacteria	absent. Bacterial EF-G does not carry it, and bacteria have no genes to make it
archaea	present, in most lineages
eukaryotes	present, in most lineages

A 2018 genome survey adds the necessary caution, and this volume prints it rather than hide it. The ability has been lost more than once: some archaea — the Asgard superphylum, Geoarchaea, Korarchaeota — and some eukaryotes — the parabasalids — have no diphthamide genes at all. Several of those archaea carry instead a second copy of the elongation factor that lacks the residues the modification requires.

And one detail from that same survey is worth its own line. The Heimdallarchaeota, the archaeal group argued to be the closest relatives of the ancestor of eukaryotes, keep the diphthamide genes

and a single ordinary elongation factor. The lineage that became us kept the guard.

1232. Sulfur Builds It ↩

The first step of diphthamide biosynthesis is catalyzed by two proteins acting together.

the enzymes	DPH1 and DPH2
what they carry	a four-iron four-sulfur cluster each
what they do	transfer a three-carbon group from S-adenosylmethionine onto the histidine ring
the chemistry class	radical, of the kind reconstructed as ancestral in section 1225

the sulfur inventory of this one step	
sulfur atoms in the two iron-sulfur clusters	eight
plus the sulfur in the S-adenosylmethionine donor	one, per turnover

Iron-sulfur clusters build the residue that keeps the reading frame. That sentence contains no interpretation. It is the pathway.

1233. What It Does at the Second Base Pair ↩

Until 2024 nobody could say what diphthamide was for. Ten high-resolution reconstructions of the translocating ribosome, published from Strasbourg, answered it.

Their conclusion, in their own summary: diphthamide not only stabilizes correct Watson-Crick codon-anticodon pairing, but also restricts wobble geometry of the second base pair.

codon position	is wobble allowed there?	who enforces that
first	no	the decoding center, and this

codon position	is wobble allowed there?	who enforces that
		residue
second	no	this residue, explicitly
third — the wobble position	yes. This is the whole basis of the code's degeneracy	permitted

The genetic code permits wobble at one position out of three and forbids it at the other two. Something physical has to draw that line. The 2024 structures say the thing drawing it, at the second position, is a residue that iron-sulfur enzymes built.

And the earlier 2021 structure showed it does not work alone: the network stabilizing the codon-anticodon duplex includes diphthamide together with a hypermodified base at position 37 of the transfer RNA — one modification on the protein, one on the RNA, meeting at the same three base pairs.

Take diphthamide away and the measured result is unambiguous, across four laboratories and three organisms: minus-one ribosomal frameshifting rises at ordinary, non-program d sites during normal elongation; ribosomes drop off; translation terminates early at stop codons in the wrong frame.

1234. The Other Sulfur, at the Wobble Seat ↩

There is a second sulfur atom in this system, and it is not on the protein. It is in the transfer RNA, at the wobble base itself.

the modification	5-methoxycarbonylmethyl-2-thiouridine at position 34
where the sulfur sits	at carbon two of the uracil ring — in the base, in the pairing face
who puts it there	a sulfur relay running through the protein Urm1 and the Elongator complex

Work from Kassel, published in 2016, separated the two halves of that modification and tested them independently.

what was removed	what happened
the methoxycarbonylmethyl group alone	plus-one frameshifting rose

what was removed	what happened
the sulfur atom alone	plus-one frameshifting rose
both	synergistically worse

And one further observation from that work belongs in this volume above almost anything else in this Part. The thiolation pathway is heat-sensitive. Raise the temperature moderately and wild-type cells — not mutants, ordinary cells — begin to frameshift, and that heat-induced slippage depends on Urm1, the sulfur carrier.

Warm a cell and it loses a sulfur atom from the wobble base, and the reading frame starts to slip.

1235. One tRNA in Bacteria, Eight in Us ↩

Now the inosine.

Position 34 is the wobble seat. It can carry the sulfur described above. It can also carry inosine — adenine deaminated in place, after the transfer RNA is made.

domain	how many transfer RNAs carry inosine at position 34
bacteria	one — the arginine transfer RNA, and by present evidence that is all
eukaryotes	eight

A 2017 survey from Barcelona established the count and its consequence: the widespread use of inosine at 34 shaped eukaryotic genome evolution in transfer RNA gene abundance and in codon usage itself, and in humans the codons read by inosine-carrying transfer RNAs are preferred in genes of highly skewed amino acid composition. The same survey found candidate substrate transfer RNA genes, previously undescribed, in two bacterial phyla.

Bacteria: one. Eukaryotes: eight. Part Seventy of this volume argues the case for eight on other grounds entirely. Here the number arrives by a different road.

1236. The Advancement, Stated Plainly ↩

Set the three facts side by side and the shape of the advancement is visible.

	bacteria	archaea	eukaryotes
the translocating GTPase	EF-G	aEF-2	eEF-2
sulfur at the wobble base, position 34	yes	yes	yes
diphthamide on the GTPase — the second-position guard	NO	yes, mostly	yes
transfer RNAs carrying inosine at 34	one	—	eight

Read down the last two rows.

The domain that has only one inosine transfer RNA has no diphthamide. The domains that acquired diphthamide are the domains where inosine decoding expanded. Eukaryotes went from one loose reading to eight, and they did it carrying a sulfur-built guard on the second base pair that bacteria do not have.

This volume states that as a proposition and not as a demonstrated cause. What it claims is the pattern, which is a fact of distribution, and the mechanism that makes the pattern intelligible, which is published structure. A cell that reads eight of its codon families loosely at the third position needs the first and second positions held harder than a cell that reads one that way. In archaea and in eukaryotes there is a residue that does exactly that, and in bacteria there is not.

1237. Where the Whole Apparatus Fails ↩

Both guards are sulfur. Sulfur bonds are what oxidation and heat take first. So both fail in the same conditions, and this has been measured on both sides.

the stress	what is lost	what follows
oxidative stress	plants accumulate elongation factor 2 with the diphthamide missing	the second-position guard weakens
moderate heat	yeast loses the sulfur at wobble position 34	wild-type cells frameshift

Part One Hundred and Twenty-One of this volume records that every cell keeps an Archean reducing interior, held by glutathione, because its inherited chemistry requires it. This is what that interior is protecting. Not a metaphor about origins — two sulfur atoms, on a protein and on a base, that hold the reading frame and that oxygen removes.

1238. What the Notation Loses Here ↩

what is present	what the sequence record says
eEF2 with diphthamide at 715	…D A I H R G G G Q…
eEF2 with an ordinary histidine at 715, guard absent	…D A I H R G G G Q…
a transfer RNA with sulfur at wobble 34	U
the same transfer RNA after heat, sulfur gone	U
a transfer RNA with adenine at 34	A
the same transfer RNA after deamination — inosine	G, once sequenced

Six states. Three printed forms. The modification that keeps the frame, the atom that keeps the frame, and the base that loosens the pairing are all invisible to the letters — and the third one is not merely invisible, it is printed as a different letter than the one it is.

1239. What This Part Refuses ↩

the claim	the status
the classic translation factor GTPases occur in all three domains	established
a protein family universal to all three domains is inferred present in their common ancestor	standard inference, and stated as such

the claim	the status
the 2016 reconstruction found LUCA's biochemistry replete with iron-sulfur clusters and radical mechanisms	as published
diphthamide is present in archaeal and eukaryotic EF-2 and absent in bacteria	as published, 2018
that diphthamide is universal in archaea and eukaryotes	refused. It has been lost independently in Asgard archaea, Geoarchaea, Korarchaeota and parabasalids
Heimdallarchaeota, closest to the eukaryotic ancestor, retain it	as published
DPH1 and DPH2 are four-iron four-sulfur cluster proteins	established
diphthamide stabilizes Watson-Crick codon-anticodon pairing and restricts wobble geometry at the second base pair	as published, 2024
loss of diphthamide raises minus-one frameshifting at non-program d sites	established across four laboratories
loss of the sulfur at wobble 34 raises plus-one frameshifting, and heat does this in wild-type cells	as published, 2016
bacteria carry inosine at 34 on one transfer RNA; eukaryotes on eight	as published, 2017
that diphthamide was present in the last universal common ancestor	refused. Bacteria do not have it, so it was not there. It is a later acquisition and this Part says so
that the expansion of inosine decoding caused the acquisition of diphthamide, or the reverse	refused as a causal claim. Section 1232 states it as a proposition and section 1236 supplies the test
that inosine at position 34 causes frameshifting	refused. No one has shown it. What is shown is that sulfur at that seat prevents frameshifting and that inosine occupies the same seat

1240. The Experiment This Part Generates ↩

Experiment Fifty, for Part Twenty-Eight, section 65. It requires no laboratory, no reagent and no beam time. It is a computation over public genomes, and it can be run this month.

The question. Section 1232 proposes that loose reading at the third position and hard guarding at the second position travel together. If that is true, then organisms that lost the guard should differ in their inosine decoding from organisms that kept it.

The two published halves. The 2018 survey already lists which archaea and eukaryotes have lost the diphthamide genes. The 2017 survey already gives a method for counting inosine-substrate transfer RNA genes and for measuring codon adaptation to them. Nobody has crossed the two tables.

Method.

step	
1	For every sequenced archaeal and eukaryotic genome, score presence or absence of the diphthamide biosynthesis genes
2	For the same genomes, count transfer RNA genes with adenine at anticodon position 34 — the substrates for deamination
3	For the same genomes, measure codon usage bias toward the codons those transfer RNAs read
4	Test whether steps 2 and 3 differ between the genomes that kept the guard and the genomes that lost it

The single sharpest test, on one named organism. Trichomonas vaginalis is a parabasalid. It is a eukaryote, and it has no diphthamide. Does it carry the eukaryotic complement of eight inosine-substrate transfer RNAs, or fewer?

result	what it would mean
fewer, or reduced codon adaptation to them	a eukaryote that dropped the guard also dropped the looseness — the two are coupled
the full eight, unchanged	the coupling proposition fails, and section 1232 must be withdrawn as written

The second outcome is a real way to lose, it is cheap to reach, and this volume prints the prediction before the answer rather than after.

A second prediction, for the archaeal side. The 2018 survey reports that several diphthamide-lacking archaea carry a second elongation factor paralog missing the

residues the modification needs. If the coupling holds, those genomes should also show reduced inosine-substrate transfer RNA content relative to their diphthamide-carrying relatives.

1241. What This Part Claims ↩

The claims

1	**The translocating GTPase is present in all three domains and therefore predates their divergence**
2	The reconstructed chemistry at the root was iron, sulfur and radical mechanisms
3	This protein acts as a pawl, making translocation one-directional and three bases long
4	Its working tip imitates a transfer RNA anticodon loop
5	At that tip, in archaea and eukaryotes but not bacteria, sits diphthamide — histidine 715 in the human protein
6	Diphthamide is built by two four-iron four-sulfur cluster enzymes
7	It stabilizes Watson-Crick codon-anticodon pairing and restricts wobble geometry at the second base pair
8	Removing it raises minus-one frameshifting during ordinary elongation
9	A second sulfur atom sits in the wobble base itself, and removing that one raises plus-one frameshifting
10	Moderate heat removes that second sulfur in wild-type cells and they begin to slip
11	Position 34 is the seat that holds either the sulfur or the inosine
12	Bacteria carry inosine there on one transfer RNA; eukaryotes on eight
13	The domains that acquired the sulfur-built guard are the domains in which inosine decoding expanded

What would refute it

the claim	what would kill it
the distribution of diphthamide	a bacterium found to carry it
the iron-sulfur dependency	a diphthamide pathway shown to run without the clusters
the second-base-pair function	a structure contradicting the 2024 reconstructions

the claim	what would kill it
the frameshifting results	failure to reproduce in a fourth organism
the coupling proposition	Experiment Fifty finding no difference in inosine decoding between genomes that kept and lost the guard

And the sentence this Part exists to put on the record. The oldest machine in the cell moves the message forward three letters at a time and must never move it two or four. In our lineage the tooth that holds it is a histidine rebuilt by iron-sulfur enzymes, and what that tooth does is forbid wobble at the second position while permitting it at the third. The permission at the third position is what inosine exists to use. So the atom that draws the line and the base that lives on the far side of it are the two halves of one arrangement — and the arrangement is four billion years old on one side and invisible to every letter we write on the other.

PART ONE HUNDRED AND THIRTY-ONE · THE HIDING PLACE

Part One Hundred and Thirty-One of the evidence volume, sections 1238 to 1250

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

A tumor has a problem. Its own transcription is disordered, and disordered transcription makes double-stranded RNA, and double-stranded RNA is what the innate immune system was built to detect. The tumor solves this problem with inosine. The editing enzyme deaminates adenine inside those duplexes, the duplex loses its regularity, and the sensors stop firing. In 2018 a group at Dana-Farber showed what happens when you take that enzyme away: the tumor becomes visible again, and checkpoint blockade begins to work in animals where it had failed. They called the enzyme an inhibitory checkpoint. And on the other side of the same cell, an enzyme called NFS1 strips sulfur off cysteine and hands it to iron-sulfur clusters and to transfer RNA, and it is overexpressed across many cancers, and until 2025 nobody had a selective inhibitor for it. One atom hides the tumor. The other keeps it alive.

1242. What a Tumor Has to Hide ↩

what disordered transcription produces	double-stranded RNA, from repeats read in both directions
what detects it	PKR, which shuts down translation; MDA5, which raises interferon
what those sensors evolved for	viruses
the tumor's difficulty	its own transcriptome starts to look like an infection

Part Sixty of this volume describes the Alu engine — the inverted repeats that pair with themselves and make exactly this kind of duplex. Every human cell carries a million of them.

1243. And the Atom It Hides Behind ↩

In 2018, in Nature, Ishizuka and colleagues reported the result in one sentence: loss of function of the RNA-editing enzyme ADAR1 in tumor cells profoundly sensitizes tumors to immunotherapy and overcomes resistance to checkpoint blockade.

what happens without the editor	
A-to-I editing of interferon-inducible RNA falls	the duplexes keep their regularity
PKR senses them	growth inhibition
MDA5 senses them	tumor inflammation
and the consequence	resistance to PD-1 blockade caused by loss of antigen presentation is overcome

Their own framing is the line this Part is built on: effective anti-tumor immunity is constrained by inhibitory checkpoints such as ADAR1 that limit the sensing of innate ligands.

Inosine is the tumor's camouflage. Each edited adenine puts one mismatch into a duplex, and enough mismatches make the duplex stop looking like a virus. The immune system is reading base pairing, and the tumor is editing the base pairing.

1244. The Editor Cuts Both Ways ↩

This volume does not permit itself a simple story where the evidence is not simple.

A 2025 review of the field states the position plainly: ADAR1 and ADAR2 act in a context-dependent way, as oncogenic drivers in some settings and tumor suppressors in others; they also act through mechanisms that do not involve editing at all, by binding RNA and by binding proteins.

the editor in cancer	
as a driver	edits oncogene transcripts, reprograms the transcriptome, hides duplexes
as a suppressor	in other tissues and other tumors
without editing at all	RNA binding and protein-protein interaction
in therapy resistance	modifies drug targets and survival pathways

The atom is the same everywhere. What it does depends on which transcript it lands in. That is precisely the argument of this volume — the letter does not carry the outcome, the molecule and its position do.

1245. The Other Atom, and the Enzyme That Moves It ↩

Now the sulfur side of the same cell.

One human enzyme takes sulfur off cysteine and delivers it into the rest of the cell's chemistry. It is called NFS1, a cysteine desulfurase.

what NFS1 supplies sulfur to	
iron-sulfur cluster biosynthesis	every Fe-S protein in the cell
transfer RNA thiolation	including the sulfur at wobble position 34

Part One Hundred and Thirty of this volume identified two sulfur guards on the reading frame: the four-iron four-sulfur enzymes that build diphthamide, and the sulfur atom in the wobble base. Both are downstream of this one enzyme.

NFS1 is the single upstream source for both guards. One enzyme, one atom, two defenses of the reading frame.

1246. And It Is Overexpressed in Cancer ↩

A 2025 report, publishing the first selective small-molecule inhibitor of the human enzyme, states the position of the field.

NFS1 expression in tumors	overexpressed in a variety of cancers
its standing as a target	considered a promising anti-tumor therapeutic target
inhibitors available before 2025	none. To date, no inhibitors targeting NFS1 have been identified
what the new compound did	inhibited lung cancer cell proliferation, raised cellular iron by disrupting Fe-S cluster assembly
and in combination with a glutathione reductase inhibitor	triggered ferroptotic cell death

Ferroptosis is iron-dependent death by lipid oxidation. It arrives when the cell's reducing capacity fails. Part One Hundred and Twenty-One of this volume describes that reducing interior as the inheritance of an anoxic world. Here is what happens when a tumor loses it.

1247. The Two Atoms in One Cell ↩

	inosine	sulfur
what it does for the tumor	hides double-stranded RNA from the innate sensors	builds the iron-sulfur clusters and thiolated transfer RNAs the tumor needs to grow
the enzyme	ADAR1	NFS1
what happens if you remove it	the tumor becomes visible; checkpoint blockade starts working	iron accumulates; Fe-S assembly fails; ferroptosis

	inosine	sulfur
drug status	no approved inhibitor; heavy pharmaceutical interest	first selective inhibitor reported 2025

Both of these are camouflage and both are chemistry. Neither is written in the tumor's DNA sequence. A tumor genome, fully sequenced, does not report how much of its double-stranded RNA has been edited, and does not report how much sulfur its desulfurase is moving.

1248. What the Tumor Sequence Does Not Say ↩

Tumor sequencing is now standard care. What it reports is mutations.

what is measured in the clinic	what is not
point mutations, insertions, deletions	the editing level of the tumor's double-stranded RNA
copy number	whether the innate sensors are being screened or exposed
tumor mutational burden	the flux through the cysteine desulfurase
microsatellite instability	the thiolation state of the tumor's transfer RNAs

And one measurement is worse than absent — it is misreported. An edited site appears in RNA sequencing as an A-to-G difference from the genome. Pipelines that do not explicitly model editing can score it as a variant.

A tumor's camouflage, read by a sequencer, is printed as a mutation.

1249. Where the Purine Arm Already Works ↩

The clinic already treats cancer through both of this volume's atoms, without describing it that way. Part One Hundred and Twenty-Seven set out the thiopurines in detail.

agent	what it does	which atom
6-mercaptopurine, 6-thioguanine	sulfur substituted into the purine ring, incorporated into DNA	both
azathioprine	converted to 6-thioguanine in the patient	both
mycophenolate	inhibits IMPDH, the committed step from inosine toward guanine	purine
methotrexate	starves purine synthesis of one-carbon units	purine
cisplatin	binds guanine at N7; inactivated by cellular thiols	both

Cisplatin deserves its own line. It attacks guanine and is disarmed by sulfur. Resistance to it rises with the cell's thiol content. One of the most-used cytotoxics in medicine is a contest between the two atoms in this volume's title.

1250. What the Notation Loses Here ↩

what is present in the tumor	what the record says
an unedited duplex, visible to MDA5	A
the same duplex after editing, invisible	G — in RNA sequencing, indistinguishable from a mutation
a transfer RNA with wobble sulfur, frame held	U
the same transfer RNA unthiolated under stress	U
a cysteine in the free thiol state	C
the same cysteine after desulfuration	C

1251. What This Part Refuses ↩

the claim	the status
loss of ADAR1 sensitizes tumors to checkpoint blockade in the models tested	as published, Nature, 2018
ADAR1 limits innate sensing of double-stranded RNA by PKR and MDA5	as published
ADARs act as drivers in some cancers and suppressors in others, and act partly without editing	as published, 2025 review
NFS1 supplies sulfur to iron-sulfur clusters and to transfer RNA thiolation	established
NFS1 is overexpressed across many cancers and had no selective inhibitor before 2025	as published
cisplatin binds guanine N7 and is inactivated by cellular thiols	established
that inhibiting ADAR1 is a proven cancer therapy in humans	refused. It is not. The published work is preclinical and the clinical question is open
that NFS1 inhibition is a treatment	refused. One compound, one cell line, 2025
that editing level should replace tumor mutational burden as a biomarker	refused. This volume proposes it be measured, not that it replace anything
that these two atoms explain cancer	refused, and firmly. Cancer is not one thing and this volume does not claim it is

1252. The Experiment This Part Generates ↩

Experiment Fifty-One, for Part Twenty-Eight, section 65.

The question. Tumors that respond to checkpoint blockade and tumors that do not have been compared by mutational burden, by antigen presentation, and by immune infiltrate. They have not been systematically compared by how much of their double-stranded RNA is edited.

Why it is answerable now. The data already exist. Large public tumor cohorts contain matched whole-genome and RNA sequencing with treatment outcomes. Editing level is computable from those files by comparing RNA to the patient's own genome at Alu positions.

step	
1	For each tumor with matched genome and transcriptome, compute the editing index across inverted repeat regions
2	Score interferon-stimulated gene expression in the same tumors
3	Compare editing index between responders and non-responders to checkpoint blockade
4	Test whether editing index adds information beyond mutational burden

Prediction, written before the answer. Non-responders will carry the higher editing index — more camouflage, less sensing.

result	what it means
editing index separates responders from non-responders	a cheap biomarker computable from data already collected on every sequenced patient
no separation	the camouflage model does not scale from mouse to human cohorts, and this Part's clinical reading is withdrawn

A second arm, on the sulfur side. In the same cohorts, score NFS1 expression and test whether it tracks with transfer RNA thiolation signatures and with response. Nobody has crossed the editing index with the desulfurase.

1253. What This Part Claims ↩

1	**Disordered transcription in tumors produces double-stranded RNA that innate sensors are built to detect**
2	A-to-I editing degrades the regularity of those duplexes and reduces sensing
3	Removing the editor sensitizes tumors to immunotherapy in published animal work
4	The editor's role is context-dependent and partly independent of editing
5	One human enzyme supplies sulfur to both iron-sulfur clusters and transfer RNA thiolation

1	Disordered transcription in tumors produces double-stranded RNA that innate sensors are built to detect
6	That enzyme is overexpressed across many cancers and was undrugged until 2025
7	Cisplatin attacks guanine and is disarmed by thiols
8	Neither the editing level nor the sulfur flux appears in any clinical tumor report

What would refute it

the claim	what would kill it
the camouflage model	failure to replicate the 2018 sensitization result
the desulfurase claim	a second independent sulfur source for tRNA thiolation
the clinical proposition	Experiment Fifty-One finding no difference in editing index between responders and non-responders

And the observation this Part records. Every solid tumor sequenced in the last decade has had its mutations counted, and not one has had its edits counted — although the edits are in the same files, already paid for, and although the published animal work says the edits are what let the tumor stay out of sight.

1254. The Name of This Part ↩

GeneCards, cataloging the elongation factor this volume examined in Part One Hundred and Thirty, lists a functional category called cancer-related genes. It is the first of eight such categories. This Part is the first of seven that walk through them, and it establishes the pattern the rest will follow.

the pattern	
there is an inosine story in the category	it concerns what the base pairing does or fails to do
there is a sulfur story in the category	it concerns a bond that forms or fails to form
they are the same cell	and usually the same few enzymes
and neither is in the record	because the record is written in letters

---

PART ONE HUNDRED AND THIRTY-TWO · ONE GENE, TWO DISEASES

Part One Hundred and Thirty-Two of the evidence volume, sections 1251 to 1263

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Lose both working copies of the inosine editor and a child develops a severe inflammatory brain disease in which the body behaves as though it has a permanent viral infection. Lose one copy, in a particular way, and a child develops a freckling disorder of the hands and feet and is otherwise well. Same gene. Same enzyme. Same atom. The difference between a devastating interferonopathy and a cosmetic pigment condition is which copies are affected and how much editing survives. That is not a letter. It is a dose of chemistry. And on the sulfur side the pattern repeats: one missing atom transfer produces a child who cannot process the sulfur amino acids, and a different missing atom transfer produces a newborn who seizes within days and does not recover.

1255. The First Disease ↩

name	Aicardi-Goutières syndrome
what it is	an interferonopathy — the innate immune system running as though a virus were present when none is
the presentation	severe early neurological disease, calcification of the basal ganglia, white matter loss
the gene, in one form of it	ADAR1, the inosine editor
the mechanism	without enough editing, the cell's own double-stranded RNA is read as foreign

Part One Hundred and Thirty-One of this volume describes a tumor using inosine to hide its own duplexes from the innate sensors. This is the same mechanism, in a child, failing.

A healthy cell is full of RNA that looks like a virus. Inosine is what keeps it from being treated as one. Remove enough of the inosine and the immune system attacks the child's brain.

1256. The Second Disease ↩

name	dyschromatosis symmetrica hereditaria
what it is	mixed light and dark macules on the backs of the hands and the tops of the feet
the gene	ADAR1 — the same gene
the inheritance	dominant; one altered copy
the prognosis	it is a pigment condition. It is not a brain disease

	Aicardi-Goutières	dyschromatosis
gene	ADAR1	ADAR1
outcome	catastrophic	cosmetic
what differs	how much editing capacity survives	

Two named diseases, in two different chapters of two different textbooks — dermatology and pediatric neurology — and one enzyme. A report that says "ADAR1 variant" has not told the family which of these two lives their child will have.

1257. And a Third, on the Transfer RNA ↩

Part One Hundred and Twenty of this volume records the finding in full. It belongs here as well.

the enzyme	ADAT3, half of the heterodimer that makes inosine at position 34 of transfer RNA
the variant	a single base change producing valine to methionine at residue 144
what it causes	intellectual disability, with strabismus and microcephaly in many
how many families	eight Saudi families, twenty-four individuals in the founding report
the age of the founder variant	roughly sixteen hundred years

The inosine at position 34 that Parts One Hundred and Twenty-Nine and One Hundred and Thirty examine as chemistry is, in these families, a diagnosis.

1258. The Sulfur Diseases Are the Same Shape ↩

Now the other atom. The pattern is identical: one transfer of one atom fails, and the failure is named after the organ it wrecks rather than after the chemistry.

disease	the failed step	the atom
classical homocystinuria	cystathionine beta-synthase — the entry to transsulfuration	sulfur, not delivered to cysteine
molybdenum cofactor deficiency	the cofactor that sulfite oxidase requires	sulfur, not oxidized to sulfate
isolated sulfite oxidase deficiency	the enzyme itself	the same step

the sulfite oxidase failure	
what accumulates	sulfite
when it presents	days after birth
what it looks like	intractable seizures, and severe neurological injury

Sulfur that cannot complete its journey to sulfate poisons a newborn's brain within a week. The disease is not named for sulfur. It is named for a metal cofactor, or for a urine finding.

1259. And the Purine Diseases ↩

disease	the failed step	what accumulates
Lesch-Nyhan syndrome	HPRT — the salvage enzyme that returns hypoxanthine and guanine to the nucleotide pool	uric acid
adenosine deaminase deficiency	the enzyme that makes inosine from adenosine	deoxyadenosine, toxic to lymphocytes
the second one's other name	severe combined immunodeficiency — the "bubble boy" disease	

Read the second row again. A child with no immune system at all, because the enzyme that makes inosine is missing. Part Ninety-Five of this volume treats inosine as the last purine. Here it is a newborn screening result.

And note the shape of it. Adenosine deaminase failure destroys immunity by letting a substrate accumulate. ADAR1 failure destroys a brain by letting a structure go unedited. Both enzymes make inosine. They fail in opposite directions and neither failure is visible in a letter.

1260. The Common Form of All of Them ↩

what is inherited	a sequence change
what is broken	a chemical transfer
what the clinic measures	the sequence change
what determines severity	how much transfer survives

Every disease in this Part is a dosage disease. The letter is binary and the chemistry is continuous, and the outcome follows the chemistry.

1261. Why the Same Variant Gives Different Children Different Lives ↩

Clinical genetics has a standing difficulty it names openly: variable expressivity and incomplete penetrance. The same variant, in two people, produces two outcomes.

This volume offers a mechanism for part of it, and offers it as a proposition.

what varies between two people carrying one variant	
residual enzyme activity	not measured in most clinics
the redox state of the compartment the enzyme works in	not measured at all
the supply of the atom being transferred	sulfur supply varies with diet, with age, with illness

what varies between two people carrying one variant	
the thiolation state of their transfer RNAs	heat-sensitive, as Part One Hundred and Thirty records

Two children with the same printed variant may differ in every one of these, and none of them appears on the report.

1262. The Measurement That Is Not Ordered ↩

For most of the diseases in this Part, an assay of the actual chemistry exists and is not routinely performed.

disease	the letter that is measured	the chemistry that is not
ADAR1 disorders	the variant	the patient's editing index
ADAT3 disorder	the variant	inosine content at position 34
homocystinuria	the variant, plus plasma homocysteine	the flux through transsulfuration
sulfite oxidase deficiency	the variant, plus urine sulfite	residual enzyme activity

1263. What the Notation Loses Here ↩

what is present in the child	what the record says
ADAR1 with one altered copy, editing largely intact	ADAR1 variant
ADAR1 with both copies impaired, editing collapsed	ADAR1 variant
a transcript edited at ninety percent of sites	G at those positions
the same transcript edited at ten percent	G at those positions, in the same read pileup
a cysteine that reached its destination	C
a cysteine whose sulfur never left it	C

1264. What This Part Refuses ↩

the claim	the status
ADAR1 variants cause Aicardi-Goutières syndrome	established
ADAR1 variants also cause dyschromatosis symmetrica hereditaria	established
ADAT3 V144M causes intellectual disability in the described families	established
CBS deficiency causes classical homocystinuria	established
molybdenum cofactor and sulfite oxidase deficiencies present neonatally with seizures	established
HPRT deficiency causes Lesch-Nyhan; adenosine deaminase deficiency causes severe combined immunodeficiency	established
that editing index predicts severity in ADAR1 disease	refused as a claim. It is proposed in section 1262 and has not been tested at scale
that redox state explains variable expressivity	refused as a claim. It is one candidate among several and this Part says so
that these diseases are misdiagnosed	refused. They are correctly diagnosed. What this Part records is that severity is not predicted, and that the quantity which would predict it is not measured
that anyone should change management on the strength of this Part	refused, without qualification. Nothing here is clinical advice

1265. What This Part Claims ↩

1	**One gene, ADAR1, produces both a catastrophic interferonopathy and a benign pigment disorder**
2	The difference between them is how much editing capacity survives, not which letter changed
3	Inosine failure at transfer RNA position 34 is itself a named human disease

1	**One gene, ADAR1, produces both a catastrophic interferonopathy and a benign pigment disorder**
4	The failure to make inosine from adenosine abolishes immunity outright
5	Sulfur transfer failures present as homocystinuria and as neonatal seizure disorders
6	All of these are dosage diseases dressed as letter diseases
7	In most of them the chemical quantity that would predict severity exists as an assay and is not ordered

1266. The Experiment This Part Generates ↩

Experiment Fifty-Two, for Part Twenty-Eight, section 65.

The question. Does the editing index predict severity within ADAR1 disease?

The cohort. Patients carrying ADAR1 variants span the whole distance from Aicardi-Goutières syndrome to dyschromatosis with no neurological involvement. They are already identified, already sequenced, and already followed in specialist registries.

Method.

step	
1	From existing blood RNA, compute each patient's editing index across inverted repeat regions, against their own genome
2	Score the interferon signature in the same samples, which is already standard in this disease
3	Rank patients by clinical severity, blind to the first two measures
4	Test the correlation

Prediction, written before the answer. Editing index will track severity more closely than the variant class does.

result	what it means
editing index tracks severity	a family receiving an ADAR1 result could be told which disease is coming
no correlation	the dosage model fails for this gene, and section 1257 is withdrawn

Cost. The RNA is banked. The computation is the one described in Part One Hundred and Thirty-One's experiment. There is no new sample to collect.

1267. What This Part Claims About the Category ↩

The gene card lists disease-related genes and human disease-related genes as two categories. They are the same category, and this Part treats them as one rather than pad the volume with a distinction the source does not sustain.

And the finding that runs through both: in this category, the letter names the gene and the chemistry names the outcome. A family is given the first and lives with the second.

PART ONE HUNDRED AND THIRTY-THREE · WHAT CANNOT BE DELETED

Part One Hundred and Thirty-Three of the evidence volume, sections 1264 to 1276

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

There is a short list of human genes that no cell line can lose. It was assembled the hard way, by deleting every gene in turn across hundreds of cell lines and recording which deletions kill. The list is called the common essentials, and it is the closest thing biology has to a statement of what a human cell cannot do without. This Part looks at where the sulfur enzymes and the purine enzymes fall on that list. They fall on it. The enzyme that strips sulfur off cysteine is there. The enzyme that makes the deoxyribonucleotides is there, and it works by generating a radical and quenching it with a pair of thiols. The committed step from inosine toward guanine is there. And what unites them is not that they are important — everything on the list is important. It is that each of them moves an atom that no letter records.

1268. What Essential Means, Exactly ↩

The word is used loosely. It has an operational meaning and this Part uses only that one.

how the list was made	systematic gene-by-gene deletion across large panels of human cell lines
what is scored	whether the cells stop growing or die
common essential	required in essentially every line tested, whatever its tissue of origin
what the term does not mean	that the gene is required in every cell of a living person, in every condition

This volume states the limit at the front rather than the back. A cell line in a dish with unlimited glucose is not a neuron. Essentiality is measured in one setting and generalized carefully or not at all.

1269. The Sulfur Enzyme on the List ↩

Part One Hundred and Thirty-One introduced it. Here is why it belongs in this category.

the enzyme	NFS1, cysteine desulfurase
what it does	removes sulfur from cysteine and hands it onward
what depends on it	iron-sulfur cluster assembly, and transfer RNA thiolation
how many alternatives the cell has	for these purposes, this is the route

Count what fails downstream if it stops.

downstream of the desulfurase	
the respiratory chain	complexes I, II and III carry iron-sulfur clusters
the citric acid cycle	aconitase is an iron-sulfur enzyme
DNA replication and repair	several polymerases and helicases carry clusters
the diphthamide guard on the reading frame	built by two four-iron four-sulfur enzymes
the wobble sulfur on transfer RNA	Part One Hundred and Thirty

One enzyme, one atom, and beneath it: breathing, the cycle, replication, repair, and both guards on the reading frame. That is what a single sulfur transfer is holding up.

1270. The Radical Enzyme, and Its Pair of Thiols ↩

the enzyme	ribonucleotide reductase
what it does	converts ribonucleotides to deoxyribonucleotides — the only route to DNA precursors
how it works	it generates a protein radical and uses it to abstract a hydrogen from the sugar
what closes the cycle	a pair of cysteine thiols, which form a disulfide and must then be reduced again

the sulfur accounting, per nucleotide made	
thiols consumed and regenerated	two, forming one disulfide
who regenerates them	thioredoxin or glutaredoxin — themselves thiol proteins
who regenerates those	NADPH, through reductases

Every deoxyribonucleotide in every human genome was made by an enzyme that closes a sulfur-sulfur bond and then opens it again. The DNA in a cell is the product of a thiol cycle turning several billion times.

And the radical mechanism is the one section 1225 of this volume identified as ancestral: the reconstructed chemistry at the root was iron, sulfur and radicals.

1271. The Purine Enzyme on the List ↩

the enzyme	IMPDH — inosine monophosphate dehydrogenase
what it does	the committed, rate-limiting step from inosine monophosphate toward guanine
why it is essential	there is no other route to guanine nucleotides by synthesis
where this volume has met	Part One Hundred and Twenty-Five: the parent, not the

the enzyme	**IMPDH — inosine monophosphate dehydrogenase**
it	waypoint

The parent purine has two children. The step toward one of them is on the list of things a human cell cannot lose.

1272. And the Editor ↩

the enzyme	**ADAR1**
in the mouse	deletion is embryonic lethal
why	unedited self double-stranded RNA triggers the innate response, and the response is fatal
the demonstration	the lethality is rescued by removing the sensor — the enzyme is essential because of what it prevents, not what it produces

That is an unusual kind of essential and it is worth naming. The editor is not required to build anything. It is required so that a molecule the cell already has does not read as an enemy. The essential function of inosine, in a mammal, is disguise.

1273. What the List Has in Common ↩

enzyme	the atom it moves	what it is doing with it
cysteine desulfurase	sulfur	handing it to clusters and to transfer RNA
ribonucleotide reductase	sulfur	opening and closing a disulfide, several billion times
IMPDH	the purine ring	committing inosine toward guanine
ADAR1	inosine	disguising the cell's own duplexes
the iron-sulfur assembly machinery	sulfur	building the clusters everything else runs on

The essential list is not a list of information-carrying genes. It is largely a list of enzymes that move atoms — and the two atoms that come up most in it are the two this volume is about.

1274. Why This Matters for the Argument ↩

A gene is called essential because deleting it kills the cell. But deletion is a letter operation — the crudest one there is. It removes the whole gene.

what the essentiality screen tests	what it does not test
is this gene needed at all?	how much of it is needed
yes or no	whether the atom it moves is in adequate supply
a gene	a flux

A cell can have every essential gene present and intact and still be starved of the atom those genes move. Essentiality is measured in letters. Sufficiency is measured in chemistry, and nobody measures it.

1275. What the Notation Loses Here ↩

what is present	what the record says
the desulfurase gene, expressed, with adequate cysteine	NFS1 — present, essential
the same gene, expressed, cysteine supply limiting	NFS1 — present, essential
the reductase with its thiol pair reduced and cycling	RRM1 — present, essential
the same enzyme with the pair stuck oxidized	RRM1 — present, essential

The screen would score these identically, and they are not the same cell.

1276. What This Part Refuses ↩

the claim	the status
large-scale deletion screens have produced a set of common essential human genes	established practice
NFS1 supplies sulfur to iron-sulfur clusters and to transfer RNA thiolation	established
ribonucleotide reductase uses a radical mechanism and a cysteine pair	established
IMPDH catalyzes the committed step from inosine monophosphate toward guanine	established
ADAR1 deletion is embryonic lethal in the mouse and the lethality is sensor-dependent	established
that essentiality in cell lines equals essentiality in a person	refused, and this Part states the limit in section 1264 rather than at the end
specific numerical essentiality scores	not asserted. This Part names enzymes and mechanisms, and does not quote scores it has not recomputed
that the essential gene list is mostly sulfur and purine enzymes	refused as stated. The list contains the ribosome, the spliceosome, the proteasome and much else. What section 1269 claims is that these two atoms recur in it, not that they dominate it

1277. The Experiment This Part Generates ↩

Experiment Fifty-Three, for Part Twenty-Eight, section 65.

The question. Essentiality screens delete genes. Nobody has run one while varying the supply of the atom.

Method.

step	
1	Take a standard cell line and a standard genome-wide deletion screen

step	
2	Run it in parallel under three cysteine conditions: replete, limited, and supplemented
3	Score which genes change from non-essential to essential, and which change the other way

What it would show. The set of genes whose essentiality depends on sulfur supply. That set has never been enumerated.

Prediction, written before the answer. The genes that become essential under cysteine limitation will be enriched for the iron-sulfur assembly machinery, for transfer RNA thiolation, and for the diphthamide pathway — the three sulfur consumers named in Parts One Hundred and Thirty and One Hundred and Thirty-One.

result	what it means
the essential set shifts with sulfur supply	essentiality is not a property of a gene. It is a property of a gene and a chemical condition, and every published list carries an unstated condition
the set does not shift	sulfur supply is buffered well enough that gene lists are condition-independent, and this Part's section 1270 is withdrawn

Why it is affordable. The screen is standard and commercial. The only modification is the culture medium.

1278. What This Part Claims ↩

1	**Essentiality is defined operationally, by deletion in cell lines, and that is a narrower statement than the word suggests**
2	The cysteine desulfurase sits above respiration, the citric acid cycle, replication, repair, and both reading-frame guards
3	Every deoxyribonucleotide in every genome was made by an enzyme that opens and closes a disulfide
4	The committed step from the parent purine toward guanine cannot be deleted
5	The inosine editor is essential in mammals because of what it prevents, not what it builds
6	Deletion screens test whether a gene is needed, never whether the atom it moves is in supply

What would refute it

the claim	what would kill it
the desulfurase's singular position	a second, independent sulfur route to clusters and thiolated tRNA
the reductase mechanism	a redetermination of its catalytic cycle
the editor's essentiality mechanism	failure of the sensor-knockout rescue to replicate
the sufficiency argument	Experiment Fifty-Three finding the essential set unchanged across sulfur conditions

1279. And One Honest Limit ↩

A reader may object that this Part has selected its examples. It has. The essential gene set contains several hundred entries and most of them are ribosome, spliceosome, proteasome and polymerase subunits, which are not about either of this volume's atoms.

The claim is not that the list is made of sulfur and purines. The claim is that the list contains them at its foundation — and that for the ones it contains, the screen that put them there could not have detected the difference between the gene being present and the atom being available.

1280. The Third Category, Closed ↩

Essential proteins is the third of the gene card's functional categories. What it yields, on this volume's axes, is a short and specific finding.

The things a human cell cannot live without include the enzyme that moves sulfur, the enzyme that spends sulfur to make DNA, the enzyme that commits inosine to guanine, and the enzyme that turns adenine into inosine so the cell is not mistaken for an infection. That is four of this volume's subjects on the shortest list biology has.

PART ONE HUNDRED AND THIRTY-FOUR · THE PHARMACY IS BUILT FROM TWO ATOMS

Part One Hundred and Thirty-Four of the evidence volume, sections 1277 to 1289

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Take down the approved drug list and mark every agent whose action runs through a purine ring or a sulfur atom. The result is not a corner of the pharmacopoeia. It is transplant medicine, immunosuppression, gout, leukemia, several viral diseases, the platinum chemotherapies, and the oldest antibiotic class in the world. Physicians have been prescribing these compounds for seventy years without describing them as a family, because the family is defined by chemistry and the categories in a formulary are defined by indication. And now the front edge has arrived: three oligonucleotide drugs are in human trials whose entire mechanism is to recruit the patient's own inosine-making enzyme to a chosen site and change one letter of one message. The atom this volume has tracked for a thousand pages is being turned into a delivery system.

1281. The Thiopurines ↩

Part One Hundred and Twenty-Seven treats these in full. Here they are as a class.

agent	what it is	where it is used
6-mercaptopurine	a purine with sulfur in place of an oxygen	childhood leukemia maintenance
6-thioguanine	guanine with sulfur in place of the six-oxygen	leukemia
azathioprine	a prodrug converted to 6-mercaptopurine in the patient	transplant, autoimmune disease, inflammatory bowel disease

what they do	
the mechanism	they are incorporated into DNA as false purines
why sulfur matters	the substitution changes how the base absorbs light and how it reacts
the cost, recorded in Part 127	a hundred- to two-hundred-fold rise in skin cancer, and it is reversible on withdrawal

The name says it. Thio-purine. Sulfur and a purine, in one molecule, given to children.

1282. The Enzyme at the Parent Purine ↩

agent	target	what the target does
mycophenolate mofetil	IMPDH	the committed step from inosine monophosphate toward guanine
ribavirin	IMPDH, among other actions	the same step

mycophenolate's indication	transplant rejection prophylaxis, and autoimmune disease
why it works as an immunosuppressant	lymphocytes depend on synthesis of purines rather than salvage, so blocking the committed step hits them first
ribavirin's other feature	it is a nucleoside analog whose base resembles inosine

Part One Hundred and Twenty-Five of this volume argues that inosine monophosphate is the parent of purine synthesis rather than a waypoint. Two approved drug classes act on the step immediately after it.

1283. The Molybdenum Enzyme, and the Oldest Gout Drug ↩

the drug	allopurinol
the target	xanthine oxidase
what that enzyme does	oxidizes hypoxanthine to xanthine, and xanthine to uric acid — the end of the purine road
what the enzyme is built from	a molybdenum cofactor with a terminal sulfur, plus two iron-sulfur clusters and a flavin

Read that last line again. The enzyme that finishes purine catabolism is an iron-sulfur protein with a sulfur atom on its metal center. Allopurinol, in use since 1966 and on every formulary in the world, is

a purine analog inhibiting a sulfur-metal enzyme at the last step of purine breakdown.

And Part One Hundred and Thirty-Two of this volume records what happens when that molybdenum cofactor cannot be made: a newborn who seizes within days. The same cofactor.

1284. The Platinum Drugs, and the Atom That Disarms Them ↩

the drug	cisplatin, and its relatives carboplatin and oxaliplatin
what it binds	guanine, at the nitrogen in position seven
what it forms	cross-links between adjacent guanines, which the cell cannot replicate past
what inactivates it	cellular thiols — glutathione and metallothionein

the clinical consequence	
tumors with high thiol content	resist platinum
the reason	the sulfur reaches the platinum before the guanine does

One of the most used cytotoxic drugs in medicine attacks a purine and is disarmed by a sulfur atom. The contest inside a treated tumor is between the two subjects of this volume.

1285. And the Oldest One of All ↩

penicillin	a beta-lactam fused to a thiazolidine ring — with a sulfur atom in it
cephalosporins	the same, with a six-membered sulfur ring
captopril	the first oral drug for hypertension; it works through a free thiol binding the enzyme's zinc
N-acetylcysteine	the antidote for paracetamol poisoning, and a mucolytic; it works by donating sulfur

The first antibiotic, the first oral antihypertensive, and the standard antidote in every emergency department are all sulfur compounds. This is not a coincidence to be explained. It is what happens when a chemistry central to life is used as a lever.

1286. The Front Edge — Recruiting the Editor ↩

Now the part that is new, and that changes what this volume is arguing about.

Three oligonucleotide drugs are in human trials whose mechanism is to guide the patient's own ADAR enzyme to a chosen adenine in a chosen transcript and let it make an inosine there. The ribosome then reads that inosine as guanosine, and the protein comes out corrected.

program	condition	phase, as registered
WVE-006	alpha-1 antitrypsin deficiency, PiZZ	Phase 1 completed; Phase 1b/2a active, nine sites
KRRO-121	urea cycle disorders	Phase 1/2 registered
RC001	Dravet syndrome, children aged 2 to 18	Early Phase 1, recruiting

what these drugs are, chemically	
the drug	a short chemically modified RNA
the enzyme	the patient's own, not delivered
the edit	one adenine to one inosine
what makes it work	the fact that the ribosome cannot tell inosine from guanosine

A pharmaceutical industry is now being built on the exact ambiguity this volume has spent a thousand pages documenting. The drug works because the machinery reads an eighth letter as though it were one of the four. That is not a criticism of the drugs. It is the strongest possible confirmation that the ambiguity is real, and that it is exploitable.

1287. And What That Means for the Argument ↩

gene editing changes the DNA	permanent, heritable in tissue, irreversible
this changes the RNA	temporary, dose-dependent, and it stops when the drug stops
what the genome shows afterward	nothing. It is unchanged
what a sequencing panel would show	an apparent A-to-G change in the transcript, which is not a mutation

A patient on one of these drugs, sequenced by a laboratory that does not know it, would be reported as carrying a variant they do not have.

1288. The Table of the Whole Category ↩

indication	agent	purine	sulfur
leukemia	6-mercaptopurine, 6-thioguanine	yes	yes
transplant	azathioprine, mycophenolate	yes	yes / part
gout	allopurinol	yes	yes, in the target
viral disease	ribavirin	yes	—
solid tumors	cisplatin	yes, as the target	yes, as the antagonist
infection	penicillins, cephalosporins	—	yes
hypertension	captopril	—	yes
poisoning	N-acetylcysteine	—	yes
genetic disease, in trials	ADAR-recruiting oligonucleotides	yes — inosine is the product	—

1289. What the Notation Loses Here ↩

what is present in the patient	what the record says
a purine incorporated into DNA with an oxygen	G

what is present in the patient	what the record says
the same position carrying a thiopurine	G
a transcript with adenine at the target site	A
the same transcript after therapeutic editing	G — reported as a mutation the patient does not carry
a tumor with low glutathione, platinum-sensitive	no field
the same tumor with high glutathione, platinum-resistant	no field

1290. What This Part Refuses ↩

the claim	the status
thiopurines are sulfur-substituted purines incorporated into DNA	established
mycophenolate and ribavirin act on IMPDH	established
allopurinol inhibits xanthine oxidase, a molybdenum and iron-sulfur enzyme	established
cisplatin binds guanine N7 and is inactivated by cellular thiols	established
penicillins, captopril and N-acetylcysteine are sulfur compounds acting through that sulfur	established
three ADAR-recruiting oligonucleotide programs are in registered human trials	as registered on the public trials registry, and phases quoted as registered
that these trials have shown clinical benefit	refused. They are early-phase safety and pharmacology studies and this Part claims nothing about outcomes
that the fraction of the pharmacopoeia governed by these two atoms is large	refused as a numerical claim. This Part names agents; it does not count the formulary
that any of this constitutes advice about any medicine	refused absolutely. Nothing here is clinical guidance

the claim	the status
that ADAR-recruiting drugs are unsafe because of the notation problem	refused. Section 1283 records a reporting hazard, not a safety claim

1291. The Experiment This Part Generates ↩

Experiment Fifty-Four, for Part Twenty-Eight, section 65.

The question raised in section 1283 is testable and it is a patient-safety question, not a theoretical one. When a patient is receiving a therapeutic RNA edit, does any standard clinical sequencing pipeline distinguish the induced inosine from a germline or somatic G?

Method.

step	
1	Prepare synthetic RNA carrying inosine at a defined position, and matched RNA carrying genuine guanosine
2	Submit both, blinded, through standard clinical RNA sequencing and variant-calling pipelines
3	Record what each pipeline reports
4	Repeat with the corresponding DNA absent the change, as the real patient's DNA would be

Prediction, written before the answer. Every pipeline will report the inosine as a G, and pipelines that compare RNA to DNA will flag it as an RNA-DNA difference of unknown significance.

result	what it means
pipelines cannot distinguish them	a laboratory reporting standard is needed before these drugs are widely used, and it does not exist
some pipeline does distinguish them	that pipeline should be identified and named, and this section becomes a recommendation rather than a warning

This is the cheapest experiment in the volume and the one with the shortest path to affecting a patient. Two synthetic oligonucleotides and a blinded submission.

1292. What This Part Claims ↩

1	**A large, named group of approved medicines acts through a purine ring, a sulfur atom, or both**
2	The thiopurines are sulfur substituted directly into a purine and are given to children
3	Two approved classes act on the step immediately after the parent purine
4	The gout drug's target is a molybdenum and iron-sulfur enzyme at the end of purine catabolism
5	The platinum drugs attack guanine and are disarmed by thiols
6	The first antibiotic, the first oral antihypertensive and the standard antidote are sulfur compounds
7	Three drugs now in human trials work by recruiting the patient's own enzyme to make an inosine
8	Those drugs work because the translation machinery cannot distinguish inosine from guanosine
9	And no clinical reporting standard yet exists for distinguishing a therapeutic edit from a mutation

What would refute it

the claim	what would kill it
the mechanisms named	any of them being redetermined
the trials	withdrawal or reclassification of the registered studies
the reporting hazard	Experiment Fifty-Four finding that standard pipelines already flag inosine correctly

1293. The Fourth Category, Closed ↩

A physician writing for azathioprine, allopurinol, mycophenolate, cisplatin, penicillin or N-acetylcysteine is prescribing this volume's chemistry. None of those prescriptions describes itself that way, and none of them needs to. But the drugs now entering trials do need to — because their whole mechanism is the eighth letter, and the record has no column for it.

PART ONE HUNDRED AND THIRTY-FIVE · THE TWO CURRENCIES

Part One Hundred and Thirty-Five of the evidence volume, sections 1290 to 1302

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

A cell runs two accounts that most textbooks keep on separate pages. One is the purine account, which begins at inosine monophosphate and branches to adenine on one side and guanine on the other. The other is the sulfur account, which begins at methionine, passes through the universal methyl donor, and either recycles or is spent forward into cysteine and glutathione. They are drawn as separate maps. They are not separate. The methyl donor that carries the sulfur is built from adenosine, so every methylation in the body spends a purine; and the folate cycle that regenerates it is the same cycle that supplies two of the carbons in every purine ring the body makes. The two accounts share a treasury, and a cell that is short of one is short of the other.

1294. The First Account ↩

Part One Hundred and Twenty-Five states the correction this volume insists on: inosine monophosphate is the parent, not an intermediate.

ribose-5-phosphate\n|\nten enzymatic steps\n|\nIMP <-- the parent\n/ \ \n(IMPDH) (adenylosuccinate)\n/ \\nXMP AMP\n|\nGMP

steps to build the ring from scratch	ten
carbons donated by the folate cycle	two
the committed branch toward guanine	IMPDH — an essential enzyme, and a drug target
the salvage route back in	HPRT, whose failure is Lesch-Nyhan syndrome

1295. The Second Account ↩

methionine\n|\n(+ ATP) | <-- a purine is spent here\nv\nS-adenosylmethionine ----> a methyl group, to DNA, RNA, protein, lipid\n|\nS-adenosylhomocysteine\n| \nhomocysteine\n/ \\n(remethylate) (transsulfuration)\n| |\nmethionine cystathionine\n|\ncysteine\n|\nglutathione, taurine, sulfate, Fe-S clusters

what is at the top	an amino acid carrying a sulfur atom
what the branch point is	homocysteine — recycle the sulfur, or spend it forward
what forward spending buys	glutathione, the reducing interior of Part One Hundred and Twenty-One
what backward recycling requires	folate and vitamin B twelve

1296. Where They Meet, First ↩

Look at the second line of the sulfur diagram.

to make the universal methyl donor	methionine is joined to the adenosine of ATP
so every molecule of it contains	a whole adenine nucleoside
and every methylation in the body	consumes one

The cell's methyl currency is a purine with a sulfur atom on it. That is not an analogy. That is the structure of S-adenosylmethionine: adenine, ribose, and a positively charged sulfur carrying the methyl group it is about to give away.

Part Thirty-Nine of this volume treats methyl and acetyl as sulfur currencies. This is the molecular basis of that Part, stated in one sentence.

1297. And Where They Meet Again ↩

the folate one-carbon cycle	**supplies methyl groups to regenerate methionine from homocysteine**
the same folate cycle	supplies two of the carbons in every purine ring built from scratch
the consequence	a folate shortage starves both accounts at once

And the clinic already exploits it. Part One Hundred and Thirty-Four lists methotrexate as a purine starver; it is a folate antagonist. The same drug perturbs the sulfur cycle, which is why homocysteine rises on it.

One vitamin deficiency, two collapsing accounts. That is what a shared treasury looks like.

1298. And a Third Time, at the Parent ↩

inosine monophosphate is made from	**ribose-5-phosphate, glycine, glutamine, aspartate, formate, carbon dioxide**
glycine's other job	it is one of the three amino acids in glutathione
the third glutathione residue	cysteine — the sulfur

Glycine is drawn into the purine ring and into the tripeptide that keeps the cell reduced. The two accounts compete for the same amino acid.

1299. The Enzyme That Spends Both ↩

Part One Hundred and Thirty-Three names ribonucleotide reductase as essential. Here is why it belongs in this Part.

what it consumes, per deoxyribonucleotide	
a purine or pyrimidine ribonucleotide	from the first account
two thiols, forming and	from the second

what it consumes, per deoxyribonucleotide	
then breaking a disulfide	

Every base pair in every human genome cost one nucleotide from the purine account and one disulfide cycle from the sulfur account. The genome is a joint expenditure.

1300. What the Metabolic Map Does Not Show ↩

Metabolic charts are drawn as boxes and arrows. What they do not carry is state.

what the chart shows	what it omits
glutathione, as a node	whether it is reduced or oxidized, and in which compartment
cysteine, as a node	whether its sulfur is free, in a disulfide, or persulfidated
inosine monophosphate, as a node	the concentration, which decides which branch runs
an arrow labeled IMPDH	the flux through it, which is what a drug changes

A pathway diagram is a statement about what can happen. Metabolism is a statement about what is happening, and the difference between them is the whole of clinical medicine.

1301. The Measurement Problem, Stated Precisely ↩

what is routinely measured in a person	what is not
serum uric acid — the end of the purine account	the flux through IMPDH
plasma total homocysteine	the split between recycling and transsulfuration
total glutathione, in research settings	the reduced-to-oxidized ratio, compartment by compartment
nothing about tRNA thiolation	the wobble sulfur of Part One Hundred and Thirty

Part One Hundred and Thirty-Six of this volume takes up the one exception — a sulfur state that is measurable cheaply in blood today and is not measured.

1302. What the Notation Loses Here ↩

what is present	what the record says
S-adenosylmethionine, loaded, ready to donate	SAM
S-adenosylhomocysteine, spent, and an inhibitor of the enzymes SAM feeds	SAH
glutathione, reduced, protecting	GSH
glutathione, oxidized, no longer protecting	GSSG
and the ratio between them, which is the actual physiology	not on any standard panel

1303. What This Part Refuses ↩

the claim	the status
inosine monophosphate is the branch point of purine synthesis	established, and argued in Part 125
S-adenosylmethionine is built from methionine and the adenosine of ATP	established
every methyl transfer consumes one such molecule	established
the folate cycle supplies both purine ring carbons and methionine remethylation	established
glycine is used in both the purine ring and glutathione	established
ribonucleotide reductase spends a nucleotide and a disulfide per deoxyribonucleotide	established

the claim	the status
that purine and sulfur metabolism are one pathway	refused. They are two pathways with shared inputs, and this Part claims the sharing, not an identity
specific flux numbers through any of these steps in a human	not asserted. This Part names the couplings and does not quote fluxes it has not measured
that measuring these ratios would change any patient's care today	refused. No such demonstration exists, and section 1301 proposes the study rather than assuming its result

1304. The Experiment This Part Generates ↩

Experiment Fifty-Five, for Part Twenty-Eight, section 65.

The question. The two accounts share folate, glycine and the adenosine of the methyl donor. If they share a treasury, then perturbing one should move the other, measurably, in a person.

Method — the cleanest available design, using a drug already given to millions.

step	
1	In patients starting mycophenolate — an IMPDH inhibitor, blocking the purine account at the committed step — collect blood before and after
2	Measure the purine account: uric acid, and guanine nucleotide pools in lymphocytes
3	Measure the sulfur account: total homocysteine, cysteine, and the reduced-to-oxidized glutathione ratio
4	Test whether blocking the purine branch moves the sulfur measures

Prediction, written before the answer. Blocking IMPDH will shift the methyl donor ratio and move homocysteine, because the guanine branch and the methyl cycle draw on shared inputs.

result	what it means
the sulfur measures move	the coupling is real in a person, not only on a chart, and a drug given for one account is silently perturbing the other
they do not move	the accounts are buffered independently in vivo, and this Part's central claim is confined to the diagram

Why it is feasible. These patients are already having blood drawn on a schedule. The added cost is three assays that already exist.

1305. What This Part Claims ↩

1	**Purine synthesis begins at inosine monophosphate and branches to adenine and guanine**
2	Sulfur metabolism begins at methionine and branches at homocysteine between recycling and forward spending
3	The methyl donor common to all methylation is a purine carrying a charged sulfur
4	Every methylation in the body therefore spends a purine
5	The folate cycle supplies both purine ring carbons and methionine regeneration
6	Glycine is drawn into the purine ring and into glutathione
7	Every base pair of DNA cost one nucleotide and one disulfide cycle
8	What is measured clinically is the end of each account, not the flux, and not the redox state

What would refute it

the claim	what would kill it
the structural couplings	redetermination of SAM's structure or the folate cycle's inputs
the shared-treasury proposition	Experiment Fifty-Five finding no movement in the sulfur measures on IMPDH blockade

1306. The Fifth Category, Closed ↩

Metabolic proteins is the fifth of the gene card's functional categories.

What it yields is the plainest statement in this expansion. The molecule that donates every methyl group in the human body is adenine with a sulfur attached. The volume's two subjects are not two subjects. They are one molecule, and the cell spends it several hundred thousand times a second.

PART ONE HUNDRED AND THIRTY-SIX · ONE FREE THIOL

Part One Hundred and Thirty-Six of the evidence volume, sections 1303 to 1315

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The most abundant protein in human blood carries thirty-five cysteines. Thirty-four of them are paired into seventeen disulfide bonds that hold the molecule's shape. One is left over. That single unpaired sulfur atom, at position thirty-four of albumin, is the largest reservoir of free thiol in the circulation, and its state is not fixed. It is reduced in some albumin molecules and oxidized in others, and the ratio between the two forms changes with illness, with age, and with kidney function. That ratio is a published oxidative-stress biomarker. It can be measured in a ninety-six-well plate with a blue dye, and it correlates with the reference method at nought point nine seven. Roughly ninety percent of the homocysteine in a person's blood is attached to that one atom. And the albumin test that appears on every metabolic panel in the world reports the total and says nothing whatever about which state it is in.

1307. The Protein ↩

human serum albumin	
abundance	the most abundant protein in plasma, by a wide margin
cysteines	thirty-five
disulfide bonds	seventeen
cysteines left over	one — at position thirty-four
what it does	carries fatty acids, hormones, drugs, metals; maintains oncotic pressure

Seventeen bonds hold the shape. The thirty-fifth cysteine has no partner, and that is the interesting one.

1308. The Two Forms ↩

Albumin circulates as two chemically distinct species, and they have names.

mercaptalbumin	the free thiol form. Cysteine 34 is reduced
non-mercaptalbumin	the oxidized form. Cysteine 34 is bonded — to cysteine, to homocysteine, to glutathione, or oxidized further
what the ratio is used as	a biomarker of oxidative stress

how it is measured, conventionally	HPLC, or mass spectrometry
how it can be measured cheaply	a colorimetric assay using a blue dye whose absorbance falls when it meets a thiol
agreement with the reference method	correlation of nought point nine seven
the format	a ninety-six well plate, in a standard laboratory

This is not a proposed measurement. It is a validated one, published, cheap, and in a plate format. It is simply not ordered.

1309. What Is Tied to That One Atom ↩

in a person's plasma, total homocysteine is distributed as	
mixed disulfide with albumin — attached at cysteine 34	about ninety percent
homocystine, the symmetrical disulfide	about nine percent
reduced homocysteine, free	about one percent

Elevated homocysteine is an established independent risk marker for vascular and neurological disease. It is measured as a total.

the difficulty the field states openly	
lowering total homocysteine does not improve outcomes	the trials have been done
the free form is toxic only at doses far above what patients have	

the difficulty the field states openly	
so why do small rises track with disease?	unresolved

A 2023 review proposes an answer this volume finds worth recording: that the albumin-bound form is not inert storage but a participant, exchanging its sulfur back and forth in thiol-disulfide reactions and releasing the reactive form where it does harm.

If that is right, then the quantity that matters is not how much homocysteine is present but how much of it is bonded to albumin and how readily that bond exchanges. Neither is measured.

1310. The Second Plasma Protein This Volume Has Already Examined ↩

Part One Hundred and Twenty-Eight sets it out in full. It belongs in this Part as the second instance of the same pattern.

apolipoprotein E allele	cysteines	can it form a disulfide-linked dimer
ε2	two	yes
ε3	one	yes
ε4	none	no

in an ε3 carrier	
fraction present as homodimer	about twelve percent
fraction as heterodimer with apolipoprotein A-II	about two percent
where the dimers have been found	plasma, cerebrospinal fluid, frontal cortex, hippocampus

Two plasma proteins. Two unpaired cysteines. In both cases the clinically ordered test reports a quantity or a genotype, and in both cases the biology is which bond has formed.

1311. The Pattern, Stated Once ↩

protein	what the clinic measures	what determines the biology
albumin	grams per deciliter, total	the redox state of one sulfur atom
apolipoprotein E	which two letters at codons 112 and 158	whether a disulfide has formed
homocysteine	the total	how much is exchangeable off albumin

Three of the commonest measurements in medicine, and all three report an amount or a letter where the physiology is a bond.

1312. Why the Blood Is the Right Place to Look ↩

Part One Hundred and Twenty-One of this volume establishes that the interior of a cell is held reducing and the exterior is not.

	inside the cell	in plasma
the environment	reducing, held by glutathione	oxidizing
what free thiols do there	stay free	form bonds
so a protein secreted into blood		has its cysteines put to a chemical question immediately

Plasma proteins are the population where the sulfur question is asked of every molecule, every minute. That is why the two clearest examples in this whole volume — albumin and apolipoprotein E — are both plasma proteins.

1313. What the Notation Loses Here ↩

what is present in the tube	what the report says
albumin with cysteine 34 free	albumin 4.2 g/dL
albumin with cysteine 34 bonded to homocysteine	albumin 4.2 g/dL
albumin with cysteine 34 oxidized past recovery	albumin 4.2 g/dL
homocysteine, free and reactive	tHcy 14 µmol/L
homocysteine, parked on albumin	tHcy 14 µmol/L
apoE3 monomer	ε3/ε3
apoE3 dimer	ε3/ε3

1314. What This Part Refuses ↩

the claim	the status
albumin has thirty-five cysteines, seventeen disulfides, and one free thiol at position 34	established
albumin circulates as mercaptalbumin and non-mercaptalbumin and the ratio is used as an oxidative stress biomarker	as published
a colorimetric plate assay reproduces the reference method with a correlation of 0.97	as published, 2022
roughly ninety percent of plasma homocysteine is a mixed disulfide with albumin	as published
lowering total homocysteine has not improved outcomes in trials	established, and stated by the field
ApoE2, E3 and E4 carry two, one and zero cysteines and dimerize accordingly	established, and cited in Part 128
that the albumin thiol ratio predicts any clinical outcome	refused as a claim. It is a validated biomarker of oxidative stress; whether it predicts outcomes is what section 1312 proposes to test

the claim	the status
that homocysteine's harm is caused by albumin exchange	refused. It is a published hypothesis, recorded as one
that anyone should order or act on these measurements clinically	refused absolutely. Nothing in this Part is clinical guidance
that the standard albumin assay is wrong	refused. It measures total albumin accurately. What this Part records is that total albumin and albumin thiol state are two different quantities and only one is ever requested

1315. What This Part Claims ↩

1	**The most abundant plasma protein carries exactly one unpaired sulfur atom**
2	That atom exists in a reduced and an oxidized population, and the ratio moves with illness
3	The ratio is a published biomarker measurable in a plate for a few cents
4	About ninety percent of circulating homocysteine is bonded to that one atom
5	Total homocysteine has failed as a treatment target while remaining a risk marker, and the field says the reason is unresolved
6	Apolipoprotein E shows the same pattern in a second plasma protein
7	Plasma is oxidizing, so it is where the sulfur question is put to every secreted protein
8	No routine report in medicine contains a field for bond state

1316. The Experiment This Part Generates ↩

Experiment Fifty-Six, for Part Twenty-Eight, section 65. This volume regards it as the most immediately actionable experiment it contains.

The question. Does the albumin thiol ratio carry information that total albumin does not?

Why it can be done now, and cheaply. Large biobanks hold banked plasma with decades of linked outcomes. The assay is a plate assay validated against HPLC. No new patient needs to be recruited and no new sample needs to be drawn.

Method.

step	
1	In banked plasma from a cohort with long follow-up, measure the mercaptalbumin fraction
2	Record, from the same samples, total albumin, total homocysteine, and where available the apolipoprotein E genotype
3	Test whether the thiol fraction predicts outcomes beyond total albumin and beyond homocysteine
4	Test specifically whether it stratifies people carrying the same apolipoprotein E genotype

Step four is the one this volume is asking for. Part One Hundred and Twenty-Eight ends with the observation that two people with identical ε3/ε3 results may differ in every property that matters. Here is a cheap measurement, on the same tube of blood, that might tell them apart.

Falsification condition, written before the answer. If the thiol fraction adds nothing to total albumin, then bond state carries no clinical information in this setting and this Part's argument is confined to chemistry. That is a real way to lose and the data to reach it already exist in freezers.

1317. A Caution This Part Puts in Its Own Voice ↩

Banked plasma has been frozen and thawed. Thiols oxidize. Any study of this kind must establish first that the measurement survives storage, and must include fresh samples as a control.

This volume states the objection rather than wait for a reviewer to state it. If the biomarker does not survive the freezer, the experiment needs prospective collection and becomes slower and more expensive — but not impossible, and still cheap by the standards of the field.

1318. And Where This Sits in the Argument ↩

the volume's general claim	its instance here
the record is written in letters and amounts	albumin in grams, apolipoprotein E in two letters, homocysteine as a total
the biology is a bond	one free thiol, and whether it is engaged
the measurement usually does not exist	here it does, and costs almost nothing
which makes this the easiest place to test the whole thesis	

1319. The Sixth Category, Closed ↩

Plasma proteins is the sixth of the gene card's functional categories.

Of every argument in this volume, this is the one that could be settled soonest and for the least money. A freezer of plasma, a blue dye, a plate reader, and the question of whether one sulfur atom on the commonest protein in the blood knows something the number on the report does not.

PART ONE HUNDRED AND THIRTY-SEVEN · PREDICTED

Part One Hundred and Thirty-Seven of the evidence volume, sections 1316 to 1328

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The last of the eight categories is the one that gives the whole set away. Seven of them describe what a protein does — it is involved in cancer, in disease, it is essential, it is a drug target, it is metabolic, it is in plasma. The eighth describes what a computer thinks about it. Predicted intracellular proteins is not an observation. It is an inference, drawn from a string of letters, by software, about where a molecule will be found. The prediction is usually right. That is not the issue. The issue is that a category built entirely out of letters has been placed alongside

seven categories built out of measurements, in the same list, in the same typeface, with no mark to distinguish them — and the whole argument of this volume is that letters and measurements are different kinds of thing.

1320. What the Category Actually Is ↩

the seven others	the eighth
cancer-related	predicted
disease-related	
essential	
FDA-approved drug target	
human disease-related	
metabolic	
plasma protein	

how the seven were established	experiments, trials, screens, clinical observation
how the eighth was established	a classifier reading an amino acid sequence
what the classifier looks for	signal peptides, transmembrane segments, targeting motifs, amino acid composition
what it never sees	the protein

1321. Why the Prediction Mostly Works ↩

This Part does not attack the method, and it says so early.

signal peptides	genuinely encoded at the amino terminus, genuinely predictive
transmembrane helices	genuinely detectable from hydrophobicity
nuclear localization signals	short, basic, and often real
accuracy on well-behaved proteins	high, and validated against imaging

Localization prediction is one of the successes of computational biology. Nothing in this Part disputes that.

1322. And Where It Cannot See ↩

The prediction is a statement about a sequence. Location, for many proteins, is not a property of the sequence.

what moves a protein between compartments	is it in the sequence
phosphorylation exposing or masking a signal	no
a disulfide forming and changing the fold	no
oxidation of a single cysteine	no
binding a partner that carries it somewhere	no
the redox state of the compartment it starts in	no
the cell being under stress at the time	no

1323. The Compartment This Volume Has Been Describing All Along ↩

Part One Hundred and Twenty-One of this volume records the finding that gives this Part its point.

	inside	outside
redox state	reducing, held by glutathione	oxidizing
what free cysteines do	stay free	form bonds
why	an inheritance from an anoxic world	

"Intracellular" is not a coordinate. It is a chemical condition. To say a protein is intracellular is to say that its cysteines are being held

reduced. That is the content of the word, and a classifier reading letters is not measuring it.

1324. The Protein That Proves It ↩

Apolipoprotein E, from Part One Hundred and Twenty-Eight, is the clean case.

where it is made	inside the cell, where cysteine 112 and cysteine 158 stay free
where it goes	plasma and cerebrospinal fluid, where they do not
what happens on the way out	about one molecule in eight forms a disulfide-linked dimer
what the sequence predicts	secreted — correctly
what the sequence cannot predict	which of those molecules dimerized, and therefore what each one does

The prediction gets the address right and the molecule wrong.

1325. And the One From the Part Before ↩

albumin	
predicted	secreted. Correct
what happens on arrival	cysteine 34 is put to the oxidizing question and answers in two ways
what fraction answers which way	variable, person to person, illness to illness
what the prediction says about that	nothing, and it was never asked to

1326. The General Form of the Objection ↩

Every one of the eight categories that reaches a conclusion from a sequence inherits this limit, and they do not all announce it.

the inference	what it reads	what it cannot read
predicted localization	amino acid sequence	the redox state on arrival
variant pathogenicity prediction	the letter change	whether the bond that letter permits ever forms
quadruplex prediction	the base string	whether a G is a G — Part One Hundred and Twenty-Nine
off-target prediction in gene editing	a reference genome	the patient's own genome, and its modifications
structure prediction	the sequence	the modifications, the partners, the compartment

Each of these is useful. Each of them is a computation over the four letters or the twenty. And the volume's whole claim is that the alphabet was fixed before the chemistry was understood, and that everything computed on it inherits the omission.

1327. What Would Improve the Prediction ↩

This Part offers something constructive rather than only an objection.

add to the input	what it would capture
the number and spacing of cysteines	disulfide capacity, and dimerization potential
whether those cysteines are conserved across species	whether the bond is load-bearing
predicted persulfidation and thiolation sites	the reactive sulfur chemistry of Part Eighteen
the compartment's known redox potential	whether the bond can form there at all

A localization predictor that counted unpaired cysteines and asked whether the destination is oxidizing would be making a chemical statement rather than a textual one. As far as this volume can establish, none does.

1328. What the Notation Loses Here ↩

what is present	what the record says
a protein in the reducing interior, cysteines free	predicted intracellular
the same protein secreted, cysteines bonded, a different molecule	predicted intracellular
a protein whose localization changes on oxidative stress	predicted intracellular
a protein that is in two compartments at once, in different states	predicted intracellular

1329. What This Part Refuses ↩

the claim	the status
localization prediction is a sequence-based inference	established, by definition of the method
signal peptides, transmembrane segments and targeting motifs are genuinely sequence-encoded	established
the intracellular compartment is held reducing and the extracellular is not	established
apolipoprotein E and albumin both change chemically on secretion	established, and cited in Parts 128 and 136
that localization predictors are unreliable	refused. They are reliable at what they do, and section 1317 says so before the objection is raised
that any specific predictor has a specific error rate on cysteine-containing proteins	not asserted. This Part has not benchmarked one, and section 1327 proposes doing so rather than claiming the result
that adding cysteine features would improve accuracy	refused as a claim. It is a proposal, and it is testable
that this objection is original to this volume	refused. The limits of sequence-based prediction are widely discussed. What this Part adds is the specific chemical content of the word "intracellular"

1330. What This Part Claims ↩

1	**Seven of the eight functional categories record measurements; the eighth records a computation**
2	They are printed in the same list with nothing to distinguish them
3	Localization prediction reads a sequence and is usually right about the address
4	"Intracellular" names a redox condition, not a coordinate
5	A protein's cysteines are in one state inside and another outside, and the prediction is silent on which
6	Every sequence-based inference in genomics inherits the same limit
7	A predictor that counted unpaired cysteines and weighed the destination's redox potential would be making a chemical claim, and none appears to

1331. The Experiment This Part Generates ↩

Experiment Fifty-Seven, for Part Twenty-Eight, section 65.

The question. Do localization predictors fail more often on proteins with unpaired cysteines?

Method.

step	
1	Assemble a benchmark set of human proteins with experimentally determined localization from imaging
2	For each, count total cysteines and estimate how many are unpaired, from structure where available
3	Run the standard localization predictors across the whole set
4	Compare error rate in the high-unpaired-cysteine group against the matched low group

Prediction, written before the answer. Error rate will be higher where unpaired cysteines are present, and highest for proteins that appear in more than one compartment.

result	what it means
errors concentrate on unpaired-cysteine proteins	a named, fixable blind spot, and a feature worth adding to the next generation of predictors
no difference	sequence carries the localization information adequately even for these proteins, and this Part's proposal is withdrawn

Cost. Public benchmark sets, public predictors, public structures. A laptop and a fortnight.

1332. The Eighth Category, and the End of the Expansion ↩

Seven Parts have now walked the gene card's functional categories along this volume's two axes.

category	the inosine finding	the sulfur finding
cancer	the editor hides tumor duplexes from the innate sensors	one desulfurase feeds every cluster and every thiolated tRNA
disease	one gene, two diseases, separated by dose not letter	one failed atom transfer, one seizing newborn
essential	the editor is essential for disguise	the desulfurase sits beneath respiration and repair
drug targets	three trials now recruit the patient's own editor	the thiopurines, the platinum antagonist, the oldest antibiotic
metabolic	the parent purine and its two branches	and the methyl donor is a purine with a sulfur on it
plasma	—	one free thiol on the commonest protein in blood
predicted	prediction cannot tell a G from an I	prediction cannot tell a free thiol from a bonded one

And the sentence the whole expansion exists to reach. Eight categories were placed in one list by people who had good reasons for each of them, and in every single one the same two atoms are doing work that the record has no field for. That is not eight findings. It is one finding, found eight times, which is what it looks like when something is true.

PART ONE HUNDRED AND THIRTY-EIGHT · THE PROTEIN THAT IS NOT IN THE GENE LIST

Part One Hundred and Thirty-Eight of the evidence volume, sections 1329 to 1342

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Immediately upstream of the apolipoprotein E gene sits another gene, and it encodes the pore through which mitochondria import almost everything they are made of. In 2024 a laboratory at the University of Pennsylvania reported that transcription of the first gene runs past its own stop signal, through the intergenic space, and into the second — and that the resulting message is spliced together, from exon nine of the pore into exon two of the apolipoprotein, and translated. The product is a real protein that goes to the mitochondrion. It raises the cell's energy capacity and lowers its oxidative stress. And it does so only when the apolipoprotein half is the cysteine-carrying form. That protein appears in no gene list. It has no gene card and no functional categories. It cannot, because it is not a gene. It is what happens between two of them.

1333. The Neighbor ↩

location	chromosome 19q13.32, immediately adjacent to APOE
the gene	TOMM40
what it encodes	the translocase of the outer mitochondrial membrane, channel forty
what that protein is	the general import pore. Almost every protein a mitochondrion contains was made in the cytosol and came in through it
its relationship to APOE	linkage disequilibrium. The two are inherited together

The strongest common genetic risk factor for late-onset Alzheimer's disease sits beside the gene for the hole that mitochondria import their contents through, and the two travel together through every pedigree ever studied.

1334. The Readthrough ↩

A gene is supposed to stop. The signal that stops it is a six-letter sequence in the RNA that tells the machinery to cut and add a tail.

the canonical stop signal	AAUAAA
what TOMM40 has instead	AAUAUA — one letter different, and non-canonical
the consequence reported	transcription runs past it, through the intergenic region, and into APOE
what the Pennsylvania group observed	frequent and robust nascent RNA extending continuously downstream of TOMM40

And the readthrough transcript is then spliced.

TOMM40 exon 9 ---- splice ----> APOE exon 2\n(the 5' splice site of intron 9) (the 3' splice site of intron 1)\n= T9A2

where it was found	human neurons, and other cells and tissues
at what level	low, and the authors say so
is it translated	yes

One letter in a stop signal, and two genes become one message.

1335. What the Chimera Does ↩

the product	
its structure	apolipoprotein E tethered to near-full-length TOM40
where it goes	to the mitochondrion
what it does there	raises mitochondrial bioenergetic capacity, and lowers oxidative stress

And the comparison the authors drew is the one this volume has been waiting for.

construct	effect on energy capacity and oxidative stress
T9A2 carrying APOE3	the largest benefit
T9A2 carrying APOE4	significantly less
APOE3 alone	less than the chimera
APOE4 alone	the benefit is absent

This volume records the status honestly and at the front. This is a preprint. It has not been peer reviewed. The authors say so on every page and so does this Part.

1336. Which Allele Is Fused Decides It ↩

Part One Hundred and Twenty-Eight of this volume establishes the count.

allele	residue 112	residue 158	sulfur atoms
ε2	cysteine	cysteine	two
ε3	cysteine	arginine	one
ε4	arginine	arginine	none

The chimera that protects the mitochondrion from oxidative stress works when its apolipoprotein half carries a cysteine and fails when it does not. Part One Hundred and Twenty-Eight argued that the difference between the alleles is a bond that can or cannot form. Here is an independent laboratory, working on a different question, arriving at a protein whose function tracks the same count.

And the setting makes it worse for the risk allele. The Pennsylvania group notes what neurons do: they do not normally make apolipoprotein E at all, but they switch it on when stressed or injured, and under oxidative stress they produce and secrete it to dispose of peroxidized lipids generated by mitochondrial reactive oxygen species — because neurons cannot detoxify those lipids themselves.

A neuron under oxidative stress reaches for a protein whose protective form requires a sulfur atom, and one person in seven is carrying the version that has none.

1337. What Comes Through That Pore ↩

Now the connection that makes this a sulfur Part and not only an apolipoprotein Part.

mitochondrial proteins encoded by mitochondrial DNA	thirteen
mitochondrial proteins encoded in the nucleus	more than a thousand
how the second group gets in	through the outer membrane translocase — the pore this gene encodes

Among the proteins that must cross it are the ones this volume has already named as foundational.

what is imported	where this volume met it
the cysteine desulfurase, NFS1	Parts One Hundred and Thirty-One and One Hundred and Thirty-Three
the scaffold and chaperones of iron-sulfur cluster assembly	the same
frataxin	the iron donor of that machinery
aconitase, and the respiratory complexes' subunits	every iron-sulfur protein in the organelle

The gene that sits beside the apolipoprotein encodes the door that the entire sulfur machinery walks through. That is not an interpretation. It is the architecture of the organelle.

1338. The Homopolymer ↩

Inside that gene, in intron six, is a run of thymines of variable length.

the marker	rs10524523, commonly called "523"
what varies	how many T's there are
the reported association	in some studies, poly-T length modulates risk and onset age of late-onset Alzheimer's disease, particularly among ε3 carriers
the linkage	ε4 alleles are reported as nearly exclusively linked to one length class

And a humanized mouse carrying the entire human region — both genes, every intron, the intergenic sequence, and the flanking regulatory DNA — was built to test whether the length does anything.

what that model showed	
the poly-T genotype affected messenger RNA levels of both genes	TOMM40 and APOE
in which tissues	brain, liver and spleen
the authors' summary	the regulatory effect of the poly-T genotype was observed for all studied organs

A run of identical letters, in an intron, in a mouse carrying the human sequence, changes how much of both proteins gets made in every organ examined.

1339. The Categories Do Not Agree With Each Other ↩

This Part now records something it found by putting two sources side by side, and it is not a small thing.

source	short	long	very long
one published account	twenty T's or fewer	twenty-one to thirty	thirty-one or more
another published account	about fifteen to sixteen	about seventeen to eighteen	about nineteen to twenty

The same three category names. The same marker. Boundaries that do not overlap at all. A length called "very long" in one paper is called "short" in the other.

This volume does not claim either is wrong. It records that a variable reported to modify the onset age of Alzheimer's disease is binned differently by different groups, and that a reader comparing two studies has no guarantee the categories mean the same thing.

1340. What a Sequencer Does With a Run of Twenty Identical Letters ↩

And beneath the disagreement about bins lies a measurement problem the field acknowledges openly.

what the marker is	a homopolymer — a run of one letter repeated
what sequencing chemistries find hardest	counting how many letters are in a run of identical ones
why	the signal for a run of nineteen and a run of twenty differs by one increment, and the platforms are known to insert and delete within homopolymers
the standard remedy	sizing the fragment directly, by electrophoresis, rather than reading the letters

The polymorphism proposed to modify the onset of Alzheimer's disease is a length, not a sequence — and length is the one thing sequencing does worst. This volume has spent a thousand pages arguing that the letters lose the chemistry. Here the letters cannot even count themselves.

1341. An Honest Negative ↩

A volume that prints only supporting findings is an advocacy document. This one is not, and this section exists to prove it.

A study of cognitively intact elderly subjects compared the poly-T variants against cerebrospinal fluid markers.

what was measured	result
amyloid beta 1-42, by APOE ε4 status	significantly reduced in ε4 carriers — the expected finding
amyloid beta 1-42, across TOMM40 poly-T variants	no differences detected
amyloid beta 1-40, and tau	unaffected by either

On the amyloid axis, the apolipoprotein allele shows its effect and the homopolymer does not. That is a real negative result, from a real cohort, and this Part prints it in full rather than leave it for a reviewer to find.

And it is compatible with everything above. If the chimera's effect is on mitochondrial energy and oxidative stress, then amyloid is the wrong place to look for it. Section 1354 proposes looking in the right place.

1342. And Where the Association Is Strongest ↩

the largest analysis in the uploaded set	
sample	2,673 affected and 16,246 unaffected, across four studies
validation	a landmark consortium cohort — 3,662 cases and 1,541 controls
the finding	carriers of ε4 who also carry minor alleles at a TOMM40 marker and an APOC1 marker show a large excess of risk
the figure quoted for minor-allele homozygotes	a 4.37-fold excess, at $p = 1.34 \times 10^{-3}$
the authors' conclusion	compelling evidence for definitive roles of the APOE-TOMM40-APOC1 variants

The risk is not carried by one letter. It is carried by a neighborhood — and the neighborhood contains the mitochondrial import pore.

1343. A Second Cysteine, at the Same Disease ↩

One more finding from the uploaded material, on the sulfur axis, and it stands alone.

the enzyme	mitochondrial aldehyde dehydrogenase, ALDH2
what it does	clears reactive aldehydes, including those produced when lipids are oxidized
its catalytic residue	cysteine 302, in the active site — the nucleophile the whole reaction runs through
the common variant	ALDH22, carried by a large fraction of East Asian populations
the meta-analytic association with Alzheimer's disease	odds ratio 1.38, ninety-five percent interval 1.02 to 1.85, p = 0.0348
the heterogeneity	I-squared of 81.1 percent — high, and this Part says so

The enzyme that removes the products of lipid peroxidation works through a cysteine. Its common human variant raises Alzheimer's risk. And the protein whose protective form requires a cysteine — apolipoprotein E — exists in neurons precisely to dispose of peroxidized lipids. Two sulfur atoms, one at each end of the same cleanup.

And a footnote worth the space. A relative of that enzyme, ALDH16A1, lost the catalytic cysteine somewhere in mammalian evolution and is now non-catalytic. What it does instead is bind HPRT1 — the purine salvage enzyme of Part One Hundred and Thirty-Two — and its variant is associated with gout and serum uric acid. A protein that lost a sulfur atom took up a job in purine metabolism.

1344. What the Notation Loses Here ↩

what is present in the cell	what the record says
APOE transcribed from its own start site	APOE
the same protein made as a mitochondrial chimera with TOM40	no entry. It is not a gene
a poly-T run of nineteen	a length, if it was sized; a guess, if it was sequenced
a poly-T run of twenty	often the same call
ALDH2 with cysteine 302 reduced and working	ALDH2
ALDH2 with that cysteine modified by the very aldehyde it was clearing	ALDH2

The chimera is the sharpest case this volume has found. It is not that the notation records it badly. The notation has no place to record it at all, because the annotation is a list of genes and this is a protein made from two of them.

1345. What This Part Refuses ↩

the claim	the status
TOMM40 is adjacent to APOE and in linkage disequilibrium with it	established
TOM40 is the general import pore of the outer mitochondrial membrane	established
nuclear-encoded mitochondrial proteins, including the iron-sulfur assembly machinery, are imported through that complex	established cell biology
a TOMM40-APOE readthrough chimera is spliced from TOMM40 exon 9 to APOE exon 2, translated, and targeted to mitochondria	reported in a 2024 preprint, and flagged as a preprint in section 1331
the chimera's protection tracks with the APOE3 form rather than APOE4	as reported in that preprint. Not peer reviewed. Not independently replicated
the poly-T genotype affects TOMM40 and APOE messenger RNA in brain, liver and spleen of a humanized mouse	as published
poly-T variants showed no effect on cerebrospinal amyloid beta in cognitively intact elderly subjects	as published — and printed here as a negative
a large excess of risk is reported for ε4 carriers also carrying minor alleles at TOMM40 and APOC1 markers	as published
cysteine 302 is the catalytic residue of ALDH2	established
ALDH22 is associated with Alzheimer's risk at odds ratio 1.38 with high heterogeneity	as published, and the heterogeneity is stated
that the chimera explains APOE4 pathogenesis	refused. The preprint calls it a candidate pathway and so does this Part
that TOMM40 poly-T length is an established risk modifier	refused. The literature is divided, section 1337 prints a negative, and section 1335 shows the categories are not even standardized
that sequencing platforms have any particular error rate at this locus	not asserted. Section 1336 states a known general limitation and section 1342 proposes measuring it here
that anything in this Part bears on any individual's	refused absolutely

the claim	the status
risk or care	

1346. The Experiment This Part Generates, and What This Part Claims ↩

Experiment Fifty-Eight, for Part Twenty-Eight, section 65. It has two arms, and the first one is nearly free.

Arm A — how badly is the homopolymer being counted?

step	
1	Take DNA samples already sized at the poly-T locus by capillary electrophoresis, the direct physical method
2	Genotype the same samples by short-read sequencing and by long-read sequencing
3	Compare the length calls, blind

Prediction, written before the answer. Sequencing will disagree with direct sizing often enough to move samples between bins — and the bins are already inconsistent between laboratories, per section 1335.

result	what it means
calls disagree across methods	part of the published disagreement about this marker is measurement, not biology, and a standard is needed
calls agree	the marker is being measured reliably and section 1336's concern is withdrawn

Arm B — look where the effect should be

Section 1350 records that the poly-T showed nothing on amyloid. If the chimera pathway is real, the effect is on mitochondrial function and oxidative stress, not on amyloid.

step	
1	In cells or tissue of known APOE and poly-T genotype, quantify the chimeric transcript directly
2	Measure mitochondrial respiratory capacity and an oxidative stress marker in the same material

step	
3	Measure the albumin thiol fraction and the apolipoprotein E dimer fraction from Parts One Hundred and Thirty-Six and One Hundred and Twenty-Eight in the same subjects

Step three is the request this volume most wants made. Three cheap measurements of bond state, on one set of subjects, against a genotype everybody already has.

The claims

1	The mitochondrial import pore gene sits beside APOE and is inherited with it
2	The entire nuclear-encoded sulfur machinery of the mitochondrion enters through that pore
3	TOMM40 carries a non-canonical stop signal and reads through into APOE
4	A spliced, translated chimera of the two has been reported in human neurons
5	It goes to the mitochondrion, raises energy capacity and lowers oxidative stress
6	And it does so with the cysteine-carrying apolipoprotein and not with the cysteine-free one
7	Neurons make apolipoprotein E only when stressed, to clear peroxidized lipids they cannot otherwise handle
8	The poly-T length in that gene regulates both genes' expression in every organ examined in a humanized mouse
9	The three length categories are defined inconsistently between published sources
10	And length is the measurement sequencing performs worst
11	A separate cysteine, the catalytic residue of the enzyme that clears oxidized lipid products, carries its own association with the same disease
12	None of this appears on any gene card, because the chimera is not a gene

What would refute it

the claim	what would kill it
the chimera	failure of an independent laboratory to detect T9A2, or peer review overturning the preprint
its allele dependence	replication showing equal benefit from the APOE4 chimera
the poly-T regulation	failure to reproduce the humanized mouse expression result
the measurement objection	Experiment Fifty-Eight Arm A finding sequencing and sizing in agreement

the claim	what would kill it
the ALDH2 association	the heterogeneity being resolved against it in a larger meta-analysis

And the sentence this Part exists to reach. For thirty years the strongest genetic risk factor in Alzheimer's disease has been reported as two letters at two positions. This Part adds a gene beside it that imports the cell's sulfur machinery, a length nobody counts the same way twice, a protein made from both genes at once that no annotation contains, and a second cysteine in a second enzyme at the same disease. The letters were never the finding. They were the only part of it anyone had a column for.

PART ONE HUNDRED AND THIRTY-NINE · TWO CODES IN ONE CELL

Part One Hundred and Thirty-Nine of the evidence volume, sections 1343 to 1356

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The genetic code is called universal. It is not universal inside a single human being. Every cell in the body translates about twenty thousand proteins with one dictionary and thirteen with another, at the same time, in the same cytoplasm, separated only by a membrane. In the second dictionary the codon that means stop means tryptophan, the codon that means isoleucine means methionine, and two codons that mean arginine mean stop. The public sequence archives handle this by keeping numbered translation tables — roughly thirty-three of them — and every piece of software that turns a sequence into a protein must be told which number to use. That number is a setting. And beneath the setting lies the thing no table can express: in the mitochondrion the wobble seat is decorated with a modification built out of taurine, which is a sulfur compound, and when that modification is missing the same sequence translates one codon and fails at another.

1347. Two Dictionaries, One Cytoplasm ↩

	the nuclear-cytoplasmic system	the mitochondrial system
proteins translated	about twenty thousand	thirteen
where	the cytosol	inside the organelle
ribosome	the 80S	a separate ribosome, of bacterial descent
transfer RNAs	its own full set	its own set of twenty-two
the code used	the standard table	a different table

These two systems are running simultaneously, a few micrometers apart, in every cell of the reader's body. The word "universal" was applied to the genetic code before anyone had sequenced a mitochondrion.

1348. The Four Deviations ↩

codon	standard code	vertebrate mitochondrial code
UGA	stop	tryptophan
AUA	isoleucine	methionine
AGA	arginine	stop
AGG	arginine	stop

what that means in practice	
a mitochondrial gene read with the standard code	terminates early at every UGA
a nuclear gene read with the mitochondrial code	terminates early at every AGA and AGG
and the letters are identical in both cases	

1349. There Is No Single Genetic Code ↩

The archives do not maintain a code. They maintain a numbered list of them.

how many translation tables the public archive carries	roughly thirty-three
table one	the standard code
table two	the vertebrate mitochondrial code
others include	yeast mitochondrial, invertebrate mitochondrial, moldand protozoan mitochondrial, ciliate nuclear, and several more

Examples of what the other tables do:

organism group	the deviation
ciliates	UAA and UAG mean glutamine, not stop
some yeasts	CUG means serine, not leucine
mycoplasmas	UGA means tryptophan
yeast mitochondria	the whole CUN family means threonine, not leucine

Every one of these was discovered by someone finding a protein that did not match its gene. The code was called universal for two decades on the strength of the organisms that had been looked at.

1350. Twenty-Two Transfer RNAs for Sixty Codons ↩

And now the deviation that matters most to this volume.

	cytoplasm	mitochondrion
sense codons to be read	sixty-one	sixty
transfer RNA species available	dozens	twenty-two

Twenty-two cannot be enough by ordinary pairing. The mitochondrion closes the gap by leaning entirely on the wobble position: in each four-codon family box, a single transfer RNA with an unmodified uridine at position thirty-four reads all four codons.

The mitochondrial code is not a relaxed version of the standard code. It is a code that survives on an expanded license at seat thirty-four. Parts One Hundred and Twenty-Four, One Hundred and Thirty and

One Hundred and Thirty-Nine of this volume are all about that seat. Here it is carrying the whole organelle.

1351. And the Seat That Pays for It Is Made of Sulfur ↩

Where the mitochondrion must distinguish rather than merge — the two-codon boxes — position thirty-four is modified. The modification is not one this volume had to go looking for.

the modification	5-taurinomethyluridine, written τm⁵U
what taurine is	2-aminoethanesulfonic acid
where taurine comes from	cysteine
so the sulfur count in this modification	one, in the sulfonic acid group

And in three of the mitochondrial transfer RNAs — those for lysine, glutamate and glutamine — the modification carries a second sulfur.

the modification	5-taurinomethyl-2-thiouridine, τm⁵s²U
the second sulfur	at carbon two of the ring, in the pairing face
the same position	as the s²U of Part One Hundred and Thirty

The organelle that runs on wobble decorates its wobble seat with a sulfur compound made from cysteine, and on its most critical transfer RNAs it adds a second sulfur atom into the base itself.

1352. The Enzyme That Installs the Second Sulfur ↩

the gene	TRMU
its full name	transfer RNA 5-methylaminomethyl-2-thiouridylate methyltransferase
what it does	puts the sulfur at carbon two of the mitochondrial wobble base
what happens without it	infantile liver failure, at around six months of age
the treatment	liver transplant

A published case follows one patient: transplanted at eleven months for end-stage liver disease, and transplanted a second time at twenty-four years.

A missing sulfur atom on one position of one transfer RNA inside one organelle destroys an infant's liver. Part One Hundred and Thirty-Three of this volume argues that essentiality is a property of a gene and a chemical condition together. Here is a child who is the proof.

1353. The Molecular Surgery ↩

This section records an experiment performed in 2004 that this volume regards as the cleanest demonstration of its central claim anywhere in the literature.

Background. MELAS — mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes — is caused in about eighty percent of patients by a single change, m.3243A>G, in the mitochondrial transfer RNA for leucine. Patients' tRNA is deficient in the taurine modification at the wobble position.

The problem the investigators saw. A patient's tRNA carries both the point mutation and the missing modification. You cannot tell which one is doing the damage.

What they did. They built, by chemical and enzymatic reconstruction, a mitochondrial transfer RNA lacking the taurine modification but carrying no pathogenic mutation at all.

the constructed molecule	
sequence	normal. Identical to healthy
modification at position 34	absent

The result.

codon	translation by the unmodified tRNA
UUG	severely reduced
UUA	no decrease

Their conclusion, in their words: the UUG codon-specific translational defect of the mutant mitochondrial tRNA is the primary cause of MELAS at the molecular level.

A normal sequence. A missing modification. One codon fails and its partner does not. If this volume had been permitted to design a single experiment to prove that the letters do not carry the chemistry, it would have designed this one — and it was done twenty-two years ago, in a hospital disease, and filed under neurology.

1354. What UGA Means, in Three Places ↩

Part One Hundred and Twenty-Six of this volume records that UGA is read as selenocysteine when the machinery and the mineral are present, and as a stop signal when they are not. Table two adds a third.

where	what UGA means	what decides
cytoplasm, ordinary transcript	stop	default
cytoplasm, with the selenocysteine machinery and selenium present	selenocysteine	a mineral and a structure in the messenger RNA
inside the mitochondrion	tryptophan	which compartment the ribosome is in

Three meanings. One three-letter word. The determinants are a mineral, a structural element, and a membrane — and none of the three is written anywhere in the sequence.

1355. Where the Software Fails ↩

Now the practical question, and the reason this Part exists.

failure	what it produces
the wrong table on mitochondrial sequence	every UGA read as a stop; a real protein-coding gene reported as truncated or as a pseudogene
the wrong table in the other direction	every AGA and AGG read as a stop
variant consequence calls	the same nucleotide change is a nonsense variant under one table and a missense variant under the other
selection statistics	any dN/dS or codon-usage analysis computed on the wrong

failure	what it produces
	table is meaningless
metagenomics	one environmental sample contains organisms using several tables, and the gene caller must guess

And this Part states the limit plainly, in its own voice, rather than at the end: every serious tool has an option for the translation table. The question is not whether the capability exists. It is how often the option is set correctly, and that number is not published.

1356. The Contaminant Nobody Has Solved ↩

what a NUMT is	a fragment of mitochondrial DNA that has inserted itself into the nuclear genome
how many	hundreds, across the human genome, of many ages
what they do to an analysis	reads from a NUMT map to the mitochondrial reference sequence
the consequence	false heteroplasmy — an apparent mixture of mitochondrial genotypes that is an artifact of nuclear DNA

A copy of the second dictionary, filed inside the first one, sequenced together, and mapped back onto the second. This is a known, longstanding and unsolved problem in mitochondrial genetics, and it exists because two codes live in one nucleus's worth of sequencing library.

1357. What the Notation Loses Here ↩

what is present	what the record says
UGA in a nuclear transcript, ending the protein	TGA
UGA in the same nucleus, read as selenocysteine	TGA
UGA in the mitochondrion, read as tryptophan	TGA
a mitochondrial tRNA with	U at position 34

what is present	what the record says
the taurine modification, reading UUG	
the same tRNA without it — UUG fails, UUA does not	U at position 34
a mitochondrial read from the organelle	a base call
the same read from a nuclear NUMT	the same base call

And the row that matters most is the fifth. The molecular surgery of section 1349 produced two molecules with identical sequence, and one of them cannot translate a codon the other translates normally. No archive on earth has a field that distinguishes them.

1358. What This Part Refuses ↩

the claim	the status
the vertebrate mitochondrial code differs from the standard code at UGA, AUA, AGA and AGG	established
the public archive maintains roughly thirty-three numbered translation tables	established
human mitochondria use twenty-two transfer RNAs to read sixty sense codons, by expanded wobble	established
the mitochondrial wobble modification is 5-taurinomethyluridine, and 5-taurinomethyl-2-thiouridine in three tRNAs	established
taurine is a sulfur compound derived from cysteine	established
TRMU installs the two-thio group and its loss causes infantile liver failure treatable by transplant	as published
a reconstructed tRNA lacking only the taurine modification showed	as published, PNAS, 2004

the claim	the status
reduced UUG and unchanged UUA translation	
NUMTs generate false heteroplasmy in mitochondrial variant calling	established, and longstanding
that the wobble modification deficiency is the sole cause of MELAS	refused. The literature is divided. The same transfer RNA is also aminoacylated poorly, and at least one review argues the aminoacylation defect may dominate because twelve of the thirteen mitochondrial proteins depend more on UUA than UUG. This Part prints that objection rather than bury it
that bioinformatic pipelines commonly use the wrong translation table	refused as a claim. Not measured. Section 1355 proposes measuring it
any specific error rate in any specific database	not asserted
that taurine supplementation treats anything	refused. It has been suggested for symptom relief in MELAS and this Part records the suggestion, not an endorsement. Nothing here is clinical advice

1359. The Experiment This Part Generates ↩

Experiment Sixty, for Part Twenty-Eight, section 65. It costs nothing but time and it produces a number nobody has.

The question. Section 1351 lists failure modes and then refuses to claim they occur often. How often do they occur?

Arm A — the table audit

step	
1	Take the thirteen human mitochondrial protein-coding genes, in their correct reading frames
2	Submit them through widely used gene-prediction and open-reading-frame tools at default settings
3	Count how many return a truncated product because the standard table was applied
4	Repeat with the mitochondrial genomes of species using other tables — invertebrate, yeast, protozoan

Arm B — the annotation audit

step	
1	Extract mitochondrial variants from public clinical variant databases
2	For each, recompute the protein consequence under table two
3	Count the disagreements with the deposited consequence
4	Report separately the variants at UGA, AUA, AGA and AGG, where the tables actually differ

Prediction, written before the answer. Arm A will find defaults producing table-one results on mitochondrial input in a meaningful fraction of tools. Arm B will find a small number of deposited consequences that are inconsistent with table two, concentrated at the four deviating codons.

result	what it means
disagreements found	a correctable error class in clinical variant annotation, identified by a computation anyone can run
no disagreements	the field is handling the two codes correctly, and section 1351 becomes a statement of what could go wrong rather than what does

This volume regards the second outcome as entirely possible and would print it. The value of the experiment is that at present nobody knows which it is.

1360. What This Part Claims ↩

1	**A human being runs two genetic codes simultaneously in every cell**
2	They differ at four codons, and one of the four is a stop signal in one and an amino acid in the other
3	There is no single genetic code; there is a numbered list of about thirty-three, and choosing one is a software setting
4	The mitochondrial code survives on twenty-two transfer RNAs only by expanding the license at the wobble seat
5	That seat is decorated with a modification built from taurine, a sulfur compound made from cysteine
6	On three transfer RNAs it carries a second sulfur, installed by an enzyme whose loss causes infantile liver failure
7	A tRNA with a normal sequence and no modification fails at

1	A human being runs two genetic codes simultaneously in every cell
	one codon and succeeds at its partner
8	UGA means stop, selenocysteine, or tryptophan depending on a mineral, a structure, and a membrane
9	Mitochondrial DNA fragments in the nuclear genome manufacture false heteroplasmy
10	No translation table has a column for a modification, and the 2004 surgery shows modifications carry codon-specific meaning

What would refute it

the claim	what would kill it
the four deviations	a redetermination of the vertebrate mitochondrial code
the taurine modification	a re-identification of the modified base
the molecular surgery result	failure to replicate the 2004 reconstruction
the causal reading of MELAS	already contested, and printed as contested in section 1354
the software proposition	Experiment Sixty finding no disagreements in either arm

And the sentence this Part exists to reach. For sixty years the phrase has been "the universal genetic code." It is not universal between two compartments of one cell, it is not universal across the tree of life, the archives have quietly kept thirty-three versions of it, and the version your mitochondria use works only because a sulfur compound sits on the wobble seat. Remove that compound and one codon stops being readable while the codon beside it is unaffected — with the sequence unchanged, the gene unchanged, and every letter in every database exactly where it was.

PART ONE HUNDRED AND FORTY · THE READER, THE DEMAND, AND THE POPULATION

Part One Hundred and Forty of the evidence volume, sections 1357 to 1370

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Three findings entered this volume today that change what can be claimed. The first is that a dedicated protein exists which recognizes inosine as inosine — not as a

stand-in for guanine — binds it, and cuts the RNA two bonds downstream; it descends from a bacterial DNA-repair enzyme, its structure has been solved from bacteria to mouse, and the switch from DNA to RNA was accomplished by remodeling loops around an unchanged catalytic core. The second is that antibody-secreting cells run short of the transfer RNAs their own antibody genes require, and answer by manufacturing more inosine at position thirty-four; the codon usage of antibody genes is skewed toward codons that no Watson-Crick transfer RNA in the human genome can read. The third is that thirty thousand three hundred and nineteen editing quantitative trait loci were mapped across forty-nine human tissues, that they are significantly enriched in the risk signals for autoimmune disease, and that the direction of the effect runs one way: risk variants reduce editing.

1361. Three Things That Were Not in This Volume Yesterday ↩

	what it establishes
a dedicated reader	inosine is recognized as its own chemical identity by a protein evolved for the purpose
demand-driven supply	a cell type that needs more inosine decoding makes more inosine
population-scale genetics	how much a person edits is heritable, variable, and carries disease risk

Each of these is peer-reviewed, each was published by workers with no interest in this volume's argument, and each supplies something the volume previously had to argue for rather than cite.

1362. The Reader ↩

Part One Hundred and Twenty-Nine of this volume argued that inosine is printed as guanine and therefore lost. A reasonable objection was available: perhaps the cell also cannot tell the difference. It can.

the first evidence	a ribonuclease purified from human, sheep and pig tissue that binds inosine-containing RNA about three hundred-fold more tightly than unedited RNA — 1997
the enzyme now characterized	Endonuclease V
its ancestral job, in bacteria	recognizing deaminated adenine in DNA and starting its repair
its job in eukaryotes	a dedicated inosine-specific ribonuclease
what it recognizes	inosine. Not adenosine. Not guanosine
what it does	cleaves the RNA at the second phosphodiester bond three-prime of the inosine

how well established	
discovered	independently, by two groups, published back to back in 2013
confirmed structurally	X-ray crystallography of the human enzyme, and of the mouse enzyme
and across natural human variants	yes
the evolutionary switch explained	a 2019 comparative study: the catalytic core is unchanged; variable loops outside it were remodeled to grip RNA instead of DNA
and it is regulated	the human enzyme relocalizes to cytoplasmic stress granules

A bacterial enzyme that removed inosine from DNA as damage became, in our lineage, an enzyme that finds inosine in RNA and cuts. The core chemistry did not change. The grip did.

1363. What the Reader Does Not Establish ↩

This volume states the limit before anyone else can, and states it as sharply as an opponent would.

what the reader's recognition produces	cleavage. RNA turnover. A quality-control outcome
what it does not produce	a distinct coding meaning
the standard this must be measured against	selenocysteine, which has a genomically encoded recoding element; and pyrrolysine, which has a dedicated synthetase
does inosine have either	no
so does inosine's wobble role constitute genetic code expansion, as that field uses the term	it does not

This volume records that plainly. Inosine is read as guanine in translation, is recognized as itself by a nuclease, and is not a twenty-first coding letter by the standard the synthetic biology literature actually applies. Three separate statements, all true, and the volume's argument requires only the first two.

1364. The Demand ↩

In January 2024, in Science, a group at the Ragon Institute reported something that is not a mechanism but an economy.

the observation	antibody genes share a conserved pattern of codon usage
its striking feature	hyperutilization of codons for which the human genome encodes no Watson-Crick transfer RNA at all
what reads those codons	transfer RNAs carrying inosine at position 34
what antibody-secreting cells do about it	they raise their inosine-34 levels
and depend on it	more than naive B cells do
the authors' further suggestion	inosine-34-dependent codon usage may influence which B cells pass regulatory checkpoints

A human cell facing a translational demand its genome cannot meet by ordinary pairing answers by making more inosine. That is not a decoding footnote. That is supply responding to demand, in the cell type that produces the antibodies keeping the reader alive.

And it has a direction for medicine the authors state themselves: implications for the design and selection of antibodies for vaccines and therapeutics.

1365. The Population ↩

The third finding is the one this volume regards as decisive, and it came out of human population genetics rather than biochemistry.

The standing problem it addresses is well known: genome-wide association studies find variants associated with disease, and for a large fraction of them nobody can say what the variant does.

the study, published in Nature in 2022	
what was mapped	editing levels, treated as a quantitative trait, against genotype
how many loci	thirty thousand three hundred and nineteen
across how many human tissues	forty-nine

1366. Thirty Thousand Editing Quantitative Trait Loci ↩

what they found	
enrichment	the editing loci are significantly enriched in the association signals for autoimmune and immune-mediated disease
what the responsible structures are	the expected inverted-repeat Alu duplexes
and what was unexpected	cis-natural antisense transcripts, highly over-represented

Part Sixty of this volume is about the Alu engine. The first half of that result is the volume's own argument arriving from a Stanford genetics department. The second half is new to the volume: a whole class of duplex — a transcript paired with its own antisense partner — that nobody expected to be carrying disease risk through editing.

1367. The Direction of the Effect ↩

And here is the sentence that matters most.

Inflammatory disease risk variants, in aggregate, were associated with reduced editing of nearby double-stranded RNAs and induced interferon responses.

the direction	one way. Risk means less editing
why that is coherent	it is the same mechanism as the mouse work: too little editing, MDA5 fires, interferon follows
what it means for a person	how much inosine you make is partly inherited, varies between people, and moves your risk of psoriasis, type 1 diabetes, inflammatory bowel disease and rheumatoid arthritis

And the same axis has now been closed from the other end. Loss-of-function variants in the sensor itself are protective against coronary artery disease in a large biobank, with no signal of harm — which is what one expects if the sensor's activation, rather than the editing shortfall as such, is the proximate driver. A 2025 study then showed that losing the editor specifically in smooth muscle drives atherosclerotic plaque calcification and instability through that sensor, corroborated in human carotid plaque.

1368. And the Cell Cycle Stops Without It ↩

One further finding, older and less noticed, belongs in Part One Hundred and Thirty-Three's category rather than this one.

in fission yeast	
what was deleted	the genes for the transfer-RNA-specific adenosine deaminase
what stopped	inosine formation at the wobble position
what happened to the cells	arrest at both the G1/S and the G2/M transitions
the authors' conclusion	wobble inosine is essential to cell cycle progression

Not a redundancy. Not a convenience for reducing transfer RNA gene count. Remove it and the cell cannot divide, and it fails at two separate checkpoints.

And the tumor side of the same enzyme is now reported: the editing complex is amplified or overexpressed in several tumor types including liposarcoma, and tumor growth depends on its editing activity.

1369. The Disease of Inosine in the Wrong Place ↩

Part One Hundred and Thirty-Two of this volume catalogs diseases of too little inosine. This is the opposite failure and it is worse.

the enzyme	ITPA — inosine triphosphate pyrophosphatase
its job	clearing inosine triphosphate out of the nucleotide pool before it can be used
what happens when it fails	inosine is misincorporated into RNA
the measured consequence	translation is hindered in human cells
the clinical consequence	severe, in some cases fatal, developmental disorders

And the scale of the housekeeping is measurable. In organisms genetically unable to clear these nucleotides, hypoxanthine and xanthine levels in DNA and RNA rise by up to six hundred-fold — described by those authors explicitly as an added burden of deamination, not a functional state.

The cell spends continuous effort keeping inosine out of the places it does not belong, and a child who cannot do that does not develop normally. Both the presence and the absence of this one base are, in the right position, lethal.

1370. The Question the Tunneling Literature Leaves Open ↩

Part Four of this volume treats proton tunneling. There is now a specific, chemically motivated, and entirely unanswered question sitting at the junction of that Part and this one.

what has been established, for the guanine-cytosine pair	
the event	a double proton transfer across the two central hydrogen bonds — guanine's N1 proton to cytosine's N3, and cytosine's amino proton to guanine's carbonyl oxygen
the product	a rare enol tautomer of guanine, which mispairs
what was measured	NMR combined with path-integral molecular dynamics confirmed that nuclear quantum effects enhance the rare tautomer beyond classical thermal motion
the magnitude modeled	tunneling contributes on the order of a hundred thousand-fold to the transfer rate

the open question	
inosine's relevant chemistry	it shares guanine's N1-H and C6 carbonyl tautomeric core exactly
has anyone examined an inosine-containing pair this way	no published study has

The quantum treatment has been applied to G:C and has never been applied to I:C. Inosine has the same two atoms in the same two positions doing the same job. This volume flags that as an open question rather than a finding, and section 1369 makes it an experiment.

1371. What the Notation Loses Here ↩

what is present	what the record says
a transcript edited at a site, invisible to the sensor	G
the same transcript unedited in a person carrying a risk variant	A — and no field for how much editing happens
a B cell at rest	the antibody gene sequence
the same cell secreting antibody, with raised inosine-34	the same sequence
inosine in a transfer RNA anticodon, doing its job	a modification, unrecorded
inosine misincorporated into a messenger RNA, hindering translation	also unrecorded, and it kills children

Thirty thousand editing quantitative trait loci exist and not one of them appears on a clinical genetic report. The variant is reported. The quantity it controls is not.

1372. What This Part Refuses ↩

the claim	the status
a ribonuclease binds inosine-containing RNA about 300-fold more tightly than unedited RNA	as published, 1997
eukaryotic Endonuclease V is a dedicated inosine-specific ribonuclease, structurally resolved	as published, two independent 2013 studies and subsequent crystallography
the DNA-to-RNA switch was achieved by loop remodeling around an unchanged catalytic core	as published, 2019
antibody genes hyperutilize codons lacking Watson-Crick tRNAs, and antibody-secreting cells raise I34	as published, Science, 2024
30,319 cis-editing quantitative trait loci were mapped across 49 tissues and are enriched in autoimmune risk signals	as published, Nature, 2022
inflammatory risk variants are associated in aggregate with reduced editing	as published, and the direction is stated in the source
deleting the tRNA adenosine deaminase in fission yeast arrests the cell cycle at G1/S and G2/M	as published, 2007
ITPA loss allows inosine misincorporation into RNA, hinders translation, and is linked to severe developmental disorders	as published, 2022
tunneling enhances the G:C double proton transfer, modeled at roughly a hundred thousand-fold	as published
that a dedicated reader makes inosine a twenty-first letter of the genetic code	refused, in section 1359, at length. The reader's outcome is cleavage, and inosine has neither a recoding element nor a dedicated synthetase
that tunneling has been shown to matter for inosine pairs	refused. It has never been examined. Section 1369 proposes examining it
that editing level is a validated clinical biomarker	refused. It is a mapped quantitative trait with disease enrichment. That is not the same thing and this Part will not blur it
that any of this alters anyone's medical care	refused absolutely

1373. The Experiment This Part Generates ↩

Experiment Sixty-One, for Part Twenty-Eight, section 65. Two arms, both computational, both cheap.

Arm A — the quantum question, applied to the right base

step	
1	Take the identical methods already applied to the guanine-cytosine pair — NMR with path-integral molecular dynamics, and the open-quantum-systems treatment
2	Apply them to the inosine-cytosine pair, which shares the same N1-H and C6 carbonyl
3	Compute the tautomerization rate and the tunneling contribution
4	Repeat for I:U and I:A, the wobble pairs

Prediction, written before the answer. Inosine, lacking guanine's carbon-two amino group, sits in a different electrostatic environment; the tunneling contribution will differ measurably from G:C in at least one of the three pairs.

result	what it means
the contribution differs	the mutagenicity and the wobble permissiveness of inosine have a quantum component nobody has quantified
it is indistinguishable from G:C	inosine is a quantum-mechanical guanine mimic as well as a structural one — which is itself a finding, and strengthens rather than weakens the volume's claim that the two are being conflated

Either outcome is publishable and neither has been reached. This is the rare case where both branches favor the argument, which is why this Part states the prediction and the alternative with equal weight.

Arm B — cross the editing map against the sulfur genes

The 2022 study published thirty thousand editing quantitative trait loci. This volume has spent several Parts naming a specific set of sulfur genes: the cysteine desulfurase, the thiouridylase, the diphthamide pathway, cystathionine beta-synthase, and the mitochondrial aldehyde dehydrogenase.

step	
1	Take the published editing loci
2	Ask whether any colocalize with, or lie in the transcripts of, that sulfur gene set
3	Ask the same of the transfer RNA modification enzymes

Nobody has crossed these two lists. If editing level and sulfur-handling capacity share genetic control, that would connect the volume's two atoms at the level of human population genetics rather than chemistry. If they do not, the volume records the null and the connection stays chemical.

1374. What This Part Claims ↩

1	**A protein exists that recognizes inosine as itself and cuts the RNA carrying it**
2	It descends from a bacterial DNA-repair enzyme by loop remodeling around an unchanged core
3	Its outcome is turnover, not a new coding meaning, and this Part says so in its own voice
4	Antibody genes are written in codons the human genome cannot read without inosine
5	Antibody-secreting cells raise their inosine-34 levels to meet that demand
6	Thirty thousand three hundred and nineteen editing quantitative trait loci exist across forty-nine tissues
7	They are enriched in autoimmune disease risk, and risk means reduced editing
8	A previously unexpected duplex class — cis-natural antisense transcripts — carries part of that risk
9	Removing wobble inosine arrests the cell cycle at two separate checkpoints
10	Failing to keep inosine out of RNA hinders translation and causes fatal developmental disease
11	The quantum treatment given to guanine-cytosine has never been given to inosine-cytosine

What would refute it

the claim	what would kill it
the reader	a demonstration that the eukaryotic enzyme's specificity is an artifact of the assay

the claim	what would kill it
the demand	failure to replicate the raised inosine-34 in antibody-secreting cells
the population result	failure of the editing loci to replicate in an independent cohort
the direction of effect	a larger study finding risk associated with increased editing
the quantum proposition	Experiment Sixty-One Arm A, either way — and both ways are informative

And the observation this Part exists to record. Yesterday this volume argued that the quantity of inosine in a person's transcripts is a real biological variable that no record contains. Today it can cite thirty thousand three hundred and nineteen places in the human genome where that quantity is under genetic control, forty-nine tissues in which it was measured, and a direction of effect that runs toward disease when the quantity falls. The argument stopped needing to be made. It only needs to be cited.

PART ONE HUNDRED AND FORTY-ONE · TWENTY-ONE GENES WITH NO PATHWAY

Part One Hundred and Forty-One of the evidence volume, sections 1371 to 1384

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

This Part began as a broader claim and has been narrowed by its own evidence. The broad version was that sulfur has no map. That is false, and the sections below say so in full. What survives the checking is narrower, and mechanical: twenty-one genes constituting both iron-sulfur cluster assembly systems and two transfer RNA thiolation enzymes have no KEGG PATHWAY assignment of any kind. The same genes are properly curated in Gene Ontology, in Reactome, in WikiPathways, and in KEGG's own BRITE hierarchy. Enrichment tools query PATHWAY. The consequence is not that biology has lost this chemistry. It is that two analysts given the same gene list will reach different conclusions about whether sulfur delivery responded, and the difference will be settled by a menu selection made before either of them looked at the data.

1375. The Partition ↩

Retrieved from the reference database, September 2026, by direct query.

map	title	top-level class	human genes
map00920	Sulfur metabolism	Metabolism → Energy metabolism	10
map04122	Sulfur relay system	Genetic Information Processing	8
map00430	Taurine and hypotaurine metabolism	Amino acid metabolism	17
map00270	Cysteine and methionine metabolism	Amino acid metabolism	54
	union of all four		84

top-level classes involved	three
overlap between the four	negligible — only MPST and TST are shared across three, and CDO1 between two
maps named simply "Sulfur"	none

1376. What the Relay Map Is Filed Under ↩

map04122, Sulfur relay system	
what it contains	NFS1, Urm1, the TusA-family carriers, the molybdenum cofactor proteins
its classification	Genetic Information Processing — Folding, sorting and degradation
what it is not classified as	metabolism
its founding reference	Noma, Sakaguchi and Suzuki, 2009, on sulfur relay to 2-thiouridine at transfer RNA wobble positions

And the database's own description of that map states that ubiquitin-mediated protein modification is thought to have evolved from prokaryotic sulfur-transfer systems. That sentence sits in a metadata field and is read by almost no one.

1377. And the Two Maps Do Not Point at Each Other ↩

the related-pathway field of map04122 lists	it does not list
cysteine and methionine metabolism	
thiamine metabolism	
folate biosynthesis	
ubiquitin-mediated proteolysis	the map named Sulfur metabolism

1378. Twenty-One Genes With No Pathway At All ↩

Each of the following was queried individually against the pathway-link interface. Each returned nothing.

system	genes
mitochondrial iron-sulfur assembly	ISCU · GLRX5 · NFU1 · ISCA1 · ISCA2 · IBA57 · BOLA3 · NUBPL · LYRM4 · FDX2 · HSCB · FDXR
cytosolic iron-sulfur assembly	CIAO1 · CIAO2A · CIAO2B · CIAO3 · MMS19 · NUBP1 · NUBP2
translational thiolation	TRMU · ELP3

And three that are mapped, but nowhere relevant:

gene	its only pathway
FXN, frataxin	porphyrin metabolism
ABCB7, the cluster exporter	ABC transporters
HSPA9	RNA degradation, and two others

TRMU is the enzyme whose loss causes infantile liver failure in Part One Hundred and Thirty-Nine. ELP3 installs the wobble modification of Part One Hundred and Thirty. Neither is in any pathway.

1379. But KEGG Has Not Overlooked It ↩

This section exists because the previous version of this Part overstated the case, and the correction belongs in the volume rather than in a footnote.

Retrieving the ISCU entry directly returns:

BRITE placement	
09182	Protein families: genetic information processing
03029	Mitochondrial biogenesis
within it	Proteins involved in Fe-S cluster biogenesis

so the knowledge is present	yes, and correctly organized
the curatorial judgment made	that Fe-S assembly is a protein family, not a metabolic pathway
is that judgment defensible	yes. It is a chaperoned protein-transfer relay, not a series of small-molecule conversions
does this volume dispute it	no

1380. And Neither Has Anyone Else ↩

resource	mitochondrial Fe-S assembly
KEGG PATHWAY	absent
KEGG BRITE	present — hsa03029
Gene Ontology	present — GO:0016226, with ISCU annotated under several evidence codes
Reactome	present — R-HSA-1362409, with NFS1, ISD11, ISCU, frataxin, GLRX5, ISCA1 and 2, IBA57 all curated
WikiPathways	present — WP2702

1381. So the Claim Is Narrow ↩

Sulfur delivery has not been lost by biology, by the literature, or by the databases in general. It is absent from one resource. That resource is the most common default.

What follows from that is not an accusation. It is an arithmetic consequence, and section 1379 sets it out.

1382. The Organelle That Crosses All Three ↩

function	genes	where they sit
sulfide oxidation, protecting complex four	SQOR, ETHE1, TST, SUOX	map00920
iron-sulfur cluster assembly	NFS1, ISCU, FXN, ISCA1 and 2	04122 in part; the rest unmapped
transfer RNA thiolation	TRMU, CTU1 and 2, URM1	04122 in part; TRMU unmapped
cysteine supply by transsulfuration	CBS, CTH	map00270
taurine, and the mitochondrial wobble modification	CDO1, CSAD	map00430

One compartment. One atom. Four maps, three classes, and a substantial remainder in none of them.

1383. What Enrichment Can and Cannot Report ↩

what the method does	tests whether the genes that changed fall disproportionately into a defined set
what it requires	that the set exist
what it cannot return	the name of a set that was never defined
which collection the standard tools draw from	PATHWAY. Not BRITE

A gene present only in a BRITE hierarchy is, for enrichment purposes, absent.

1384. The Arithmetic, and a Prediction That Failed ↩

A simulated coordinated twenty-gene sulfur response within three hundred differentially expressed genes, against a twenty-thousand-gene background.

term	set size	responders	hypergeometric p
map04122	8	4	3.3×10^{-6}
map00920	10	4	9.7×10^{-6}
map00270	54	5	1.3×10^{-3}
map00430	17	2	2.6×10^{-2}
a unified 105-gene set	105	20	8.8×10^{-17}

The author predicted that fragmentation alone would push all four terms below significance. It does not. The sulfur maps are so small that two to four responders clear threshold comfortably.

what fragmentation actually costs	
statistical strength	about eleven orders of magnitude
interpretability	one clear result replaced by four scattered marginal ones
but the signal itself	survives

The failed prediction is printed here beside the result that survived. Absence, not dilution, is what silences a response — and the twenty-one genes of section 1374 cannot be diluted, weakened or under-powered, because no term contains a single one of them.

1385. What the Notation Loses Here ↩

what is happening	what the analysis reports
a coordinated response confined to one map	that map, significant
the same response spread across four	four marginal terms, none interpretable
the same response carried	nothing. No term exists

what is happening	what the analysis reports
by Fe-S assembly	
the sulfur relay to transfer RNA	Genetic Information Processing

1386. What This Part Refuses ↩

the claim	the status
the four maps, their classes and their gene counts	verifiable by direct query, and reproduced in section 1371
map04122 is classified outside metabolism and does not reference map00920	verifiable
twenty-one named genes return no pathway assignment	verifiable, gene by gene
enrichment tools draw from PATHWAY rather than BRITE	the specification of the tools
that sulfur has no map	refused. This Part's own earlier claim, withdrawn. BRITE, GO, Reactome and WikiPathways all carry it, and sections 1375 and 1376 say so before section 1377 argues anything
that KEGG's curation is erroneous	refused. The BRITE placement is a defensible judgment about what kind of thing Fe-S assembly is
that any published study reached a false conclusion	refused. None is named and none is implied
that fragmentation silences a signal	refused by this Part's own arithmetic in section 1380
that the effect on published work is large	refused as an assumption. Section 1383 measures it

1387. The Experiment This Part Generates ↩

Experiment Sixty-Two, for Part Twenty-Eight, section 65. Public data, no laboratory, and it carries its own positive control.

The question. Section 1377 asserts a discrepancy between tools on identical input. That is directly testable.

step	
1	Select public transcriptomic datasets with an expected sulfur-delivery component — Friedreich ataxia, ISCU myopathy, NFS1 knockdown, cysteine restriction, ferroptosis induction
2	Derive one differential expression list per dataset by a single fixed method
3	Run enrichment against KEGG PATHWAY and record every term returned
4	Run the identical list against GO biological process and against Reactome
5	Report, per dataset, whether an iron-sulfur term appears in the second and third and not in the first

Prediction, written before the answer. Gene Ontology will return GO:0016226 or a descendant in most such datasets. KEGG will return none. The disagreement follows from the annotation, not from the data.

result	what it means
the three resources disagree	a correctable blind spot in a common analytical default
KEGG recovers the signal indirectly	through a downstream Fe-S-dependent pathway such as oxidative phosphorylation — the practical claim fails, though the annotation gap remains real

The second outcome is the one this volume regards as most likely to complicate the result, and it is stated here rather than discovered later.

1388. The Remedy Is a Gene Set ↩

what is required	a list of gene identifiers
who could produce it	anyone, in an afternoon
what it would cost	nothing

Every other Part of this volume ends with an experiment somebody else must run. This one ends with a text file. And it began as a larger claim than the evidence supported, which is recorded in sections 1375 and 1382 rather than quietly removed.

PART ONE HUNDRED AND FORTY-TWO · THE RING THAT DECIDES

Part One Hundred and Forty-Two of the evidence volume, sections 1385 to 1398

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

A peptide of thirty-seven amino acids relaxes the arteries of the head, and when it does so in the wrong place at the wrong time a person has a migraine. Two drugs approved in the last several years block its receptor at sub-nanomolar affinity. What holds the active end of that peptide in the shape the receptor requires is a single disulfide bond between two cysteines, six residues apart, closing a ring. Constrain the geometry of that bond without changing a single amino acid identity and the peptide stops being an agonist and starts being an antagonist. Replace the sulfur with carbon in the sister peptide and the same inversion occurs. The sequence is not what decides whether this molecule switches the receptor on or off. The bond is.

1389. The Peptide and the Ring ↩

calcitonin gene-related peptide	
length	thirty-seven amino acids
the feature that matters here	a disulfide bond between cysteine two and cysteine seven
what that bond makes	a closed ring at the amino-terminal end
what the ring does	holds the segment that activates the receptor
what happens without correct ring geometry	section 1387

1390. What the Ring Is Made Of ↩

Two sulfur atoms, and nothing else. The ring is closed by a single bond between them.

Part One Hundred and Twenty-Eight of this volume records apolipoprotein E, where the presence or absence of a cysteine decides whether a dimer can form. Part One Hundred and Thirty-Six records albumin, where one unpaired thiol carries most of the circulating homocysteine. This is the third instance of the same arrangement, and the cleanest, because here the readout is pharmacological rather than structural.

1391. Change the Topography, Change the Drug ↩

Workers at Creighton University substituted penicillamine — an amino acid that stiffens a disulfide bridge — for one or both of the cysteines, and measured binding and function separately.

analogue	binding	function on coronary artery
native peptide	reference	relaxes
penicillamine at position two	not significantly different from native	still relaxes
all other analogues	reduced affinity	reduced or absent relaxation
any analogue with D-penicillamine at position seven		failed to relax, and blocked relaxation by the native peptide
D-penicillamine at both two and seven		the most potent antagonist of the series

the numbers	
antagonist potency of the doubly substituted analogue	K sub B of six hundred and thirty nanomolar
the classical antagonist, the eight-to-thirty-seven fragment, in the same preparation	K sub B of two hundred and twelve nanomolar

The amino acid sequence is essentially unchanged. What changed is the conformational freedom of the sulfur-sulfur bond. And the molecule crossed from agonist to antagonist.

1392. And the Same Result in the Sister Peptide ↩

Adrenomedullin belongs to the same peptide family and carries the same architecture: a disulfide-bonded ring, here of six residues, between cysteine sixteen and cysteine twenty-one. A group at Leipzig, with Bayer, replaced that disulfide with four chemical mimetics and measured receptor activation.

the bond, replaced by	result
a thioester-family linkage — thioether	full receptor activity, with reduced selectivity against the CGRP receptor
thioacetal	full receptor activity, and wild-type-like selectivity retained
lactam	activity depended on position within the bridge
an all-carbon linkage — the sulfur removed	weak antagonist properties

Two sulfur-containing replacements preserved the agonist. The carbon replacement produced an antagonist. In a peptide of fifty-two residues, with fifty-one of them unchanged.

1393. Where the Literature Disagrees With Itself ↩

This volume prints the contradiction rather than choose between the papers.

In 1989, workers in Montreal blocked the disulfide chemically and reported that the analogue retained high binding affinity, concluding that the bridge between positions two and seven is not essential for binding. The same analogue retained full potency in one bioassay and showed no agonist activity at all in another.

what the two literatures say	
1989	the bridge is not essential for the ligand to bind
1998	the geometry of the bridge decides whether the bound ligand activates
and the 1989 paper's own data	full potency in one tissue, no agonism in another, from the same molecule

Read together the two results are not in conflict, and the resolution is the point of this Part. Binding and activation are different events. The disulfide is dispensable for the first and decisive for the second. A

molecule can arrive, occupy the site, and fail to throw the switch — and what it lacks is a bond, not a residue.

1394. One Gene, Two Hormones ↩

And the peptide's origin belongs in this volume for a different reason.

the gene	CALCA
product one	calcitonin — a hormone of calcium metabolism, made in the thyroid
product two	calcitonin gene-related peptide — a neuropeptide and vasodilator
how two products arise	alternative processing of a single primary transcript
when this was established	1984

1395. And the Same Cell Makes Both ↩

The obvious reading — that one tissue makes one product and another tissue makes the other — is not what was found.

Work from the Rosenfeld laboratory in 1985 showed both mature messenger RNAs and both peptide products co-produced in identical thyroid C-cells, in a ratio of ninety-five to one.

Not two tissues. One cell, making both, in a fixed proportion. The choice between a calcium hormone and a vasodilator is made after transcription, inside a single cell, and nothing in the gene sequence records which choice was made in any given molecule.

1396. One Receptor Protein, Two Pharmacologies ↩

The receiving end repeats the pattern.

the receptor protein	the accessory protein	what the pair is
calcitonin receptor-like receptor	RAMP1	the CGRP receptor
the same protein	RAMP2	the adrenomedullin receptor

One gene product. Two pharmacologies. The determinant is which small partner protein it is standing next to, and no sequence record for the receptor mentions the partner.

1397. What the Gepants Do Not Tell Us ↩

This Part declines the obvious enthusiasm, and says why.

the approved antagonists	
rimegepant	inhibition constant of nought point nought two seven nanomolar
ubrogepant	nought point nought six seven nanomolar
what they are	small molecules, developed over two decades of medicinal chemistry
do they contain sulfur	no
do they bear on this volume's argument	no

They are an achievement and they are not evidence for anything here. This volume takes the peptide chemistry and leaves the medicinal chemistry alone.

1398. What the Notation Loses Here ↩

what is present	what the record says
the native peptide, ring closed, agonist	the thirty-seven residue sequence
the same sequence with a stiffened bridge — an antagonist	essentially the same sequence
adrenomedullin with its	the fifty-two residue sequence

what is present	what the record says
disulfide, agonist	
the same peptide with carbon in place of sulfur — an antagonist	fifty-one of fifty-two residues identical
a transcript encoding calcitonin	CALCA
a transcript encoding CGRP, from the same cell	CALCA
the receptor with RAMP1	CALCRL
the same receptor with RAMP2 — different ligand entirely	CALCRL

1399. What This Part Refuses ↩

the claim	the status
CGRP carries a disulfide bond between cysteines two and seven forming an N-terminal ring	established
D-penicillamine substitution at position seven converts the peptide to an antagonist	as published, 1998
the doubly substituted analogue has a K sub B of 630 nM against a classical antagonist at 212 nM	as published
replacing the adrenomedullin disulfide with carbon yields weak antagonist properties, while thioether and thioacetal retain full agonism	as published, 2019
a 1989 study concluded the bridge is not essential for binding	as published, and printed here in full
calcitonin and CGRP arise from one gene by alternative processing	established, 1984
both are co-produced in identical thyroid C-cells at a ratio of ninety-five to one	as published, 1985
the same receptor protein is a CGRP receptor with	established

the claim	the status
RAMP1 and an adrenomedullin receptor with RAMP2	
that the disulfide is essential for binding	refused. The 1989 data say otherwise and section 1389 states the disagreement rather than resolve it in this volume's favor
that sulfur is unusual in peptide hormones	refused. Disulfide-bonded rings are common — insulin, oxytocin, vasopressin, somatostatin. This Part claims an instance, not a rarity
that migraine is a sulfur disease	refused, and firmly. Nothing here supports that and nothing here implies it
that the approved drugs bear on this volume's thesis	refused, in section 1393, in this volume's own voice
that any of this is clinical guidance	refused absolutely

1400. The Experiment This Part Generates ↩

Experiment Sixty-Three, for Part Twenty-Eight, section 65.

The question. Section 1389 leaves a disagreement standing. The 1989 and 1998 studies used different analogues, different tissues and different assays, and the field has not returned to it with modern methods.

Method.

step	
1	Synthesize a matched series: native peptide; disulfide chemically blocked; the D-penicillamine antagonist; and thioether and all-carbon ring replacements of the kind used in the adrenomedullin work
2	Measure binding against the defined CLR–RAMP1 complex, rather than a tissue preparation
3	Measure activation on the same defined complex, by a single second-messenger readout
4	Repeat against CLR–RAMP2

Prediction, written before the answer. Binding will prove largely insensitive to ring chemistry, as 1989 reported. Activation will track it closely, as 1998 and 2019 report. The two literatures will be reconciled by separating the two events on one receptor rather than by either being wrong.

result	what it means
binding preserved, activation lost	the bond is a switch, not a handle — and the disagreement in the literature was an artifact of comparing different assays
both lost together	the 1989 result does not replicate on a defined receptor, and this Part's reading of it is withdrawn
neither affected	the ring chemistry is not decisive at all, and sections 1387 and 1388 must be reconsidered

1401. What This Part Claims ↩

1	**CGRP's active conformation is held by a disulfide ring between two cysteines**
2	Constraining the geometry of that bond, without changing residue identity, converts agonist to antagonist
3	In the sister peptide adrenomedullin, replacing the sulfur with carbon does the same
4	Sulfur-containing replacements of that bond preserve agonism; the carbon replacement does not
5	The literature disagrees on whether the bond is required for binding, and this Part prints the disagreement
6	Binding and activation are separable, and the bond appears decisive for the second
7	One gene yields both calcitonin and CGRP by alternative processing
8	Both are made in the same cell, at a fixed ratio of ninety-five to one
9	One receptor protein is two different receptors depending on its accessory partner

What would refute it

the claim	what would kill it
the agonist-antagonist inversion	failure to reproduce the penicillamine series on a defined receptor
the carbon replacement result	failure to reproduce the adrenomedullin mimetic series
the separability of binding and activation	Experiment Sixty-Three finding both lost together
the co-production ratio	a re-measurement in primary human C-cells

1402. Why This Part Is Short ↩

This Part adds one instance to an argument the volume has already made three times, and it adds nothing else.

But it adds the instance where the consequence is most legible. In apolipoprotein E the missing sulfur changes a risk statistic. In albumin it changes a redox reservoir. Here it changes whether a molecule turns a receptor on or off — which is the difference between a drug and its opposite, in a peptide whose sequence is unchanged.

PART ONE HUNDRED AND FORTY-THREE · THE RECEPTOR REACHED FROM BOTH SIDES

Where the inosine argument and the sulfur argument arrive at the same protein family, by two different routes

This volume has run two arguments in parallel for a hundred and forty-two Parts. One says that a four-letter notation cannot record what a base is actually doing, and inosine is the case that proves it. The other says that sulfur is load-bearing in the material and unnamed in the notation. They have been treated as two halves of one thesis and they have never met on a single object.

They meet on the ionotropic glutamate receptors. One route runs through the message and changes an amino acid that the gene never encoded. The other runs through the protein's own thiols and changes the current without touching the sequence at all. Both are published, both are mechanistic, and they are the same receptor family.

1403. Twenty-Five Positions, and Only One of Them Matters ↩

Higuchi and colleagues at the Max Planck Institute for Medical Research made mice homozygous for a functional null allele of ADAR2, the adenosine deaminase acting on RNA, and reported the result in Nature in 2000.

ADAR2-null mouse	Higuchi et al., Nature 2000;406:78-81
editing positions substantially reduced	most of twenty-five, across diverse transcripts
phenotype	prone to seizures, died young
how much of that phenotype came from one position	all of it
the test	both alleles of the underedited transcript replaced with alleles encoding the edited version exonically
result of the test	the phenotype reverted to normal
the critical position	the Q/R site of AMPA receptor GluR-B pre-messenger RNA

Twenty-five positions lose their editing. Twenty-four of them are survivable. One is not. The authors' own conclusion is that this transcript is the physiologically most important substrate of the enzyme — and the demonstration is that writing the edited sequence into the gene, so that no editing is needed, rescues an animal that would otherwise die.

1404. The Codon the Brain Does Not Use ↩

The Q/R site sits in the pore-lining region of the GluA2 subunit. The gene specifies glutamine there. The receptor in a living brain carries arginine.

one position, one deamination	
what the gene encodes	C A G - glutamine
what ADAR2 does to it	deaminates the adenosine at position two to inosine
what the transcript then reads	C I G
what the ribosome decodes	C G G - arginine
what changes in the channel	an arginine sits in the pore
what that arginine does	the receptor stops passing calcium

The DNA at that position is identical in every cell of the brain, edited or not. No mutation occurs. No sequence record anywhere distinguishes the two states.

What differs is one amino group, removed by hydrolytic deamination, and the consequence is whether calcium enters the neuron. This is the volume's notation argument operating inside a human brain at a position where getting it wrong causes excitotoxicity.

1405. What the Notation Records and What the Channel Does ↩

what is the same and what is not	
the genomic sequence	identical in edited and unedited neurons
the four-letter transcript record	identical, because inosine is deposited as G
the protein	glutamine in one case, arginine in the other
the channel	calcium-permeable in one case, calcium-impermeable in the other
the animal	alive in one case

Five rows. The first two are the notation. The last three are the material. The notation is constant down its whole column and the material is not.

1406. The Same Receptor Family, Reached Through Sulfur ↩

The NMDA-type ionotropic glutamate receptor carries a redox modulatory site. It is not a structural feature that happens to contain sulfur. It is a functional control point made of thiols.

redox modulation of the NMDA receptor	Choi & Lipton, Cell Mol Life Sci 2000;57:1535-41
reducing agents	enhance NMDA-evoked currents
oxidizing agents	decrease them
what the determinants are	multiple cysteine residues, in different receptor subunits
one residue named	cysteine 399 on the NR2A subunit
what happens at that residue	reacts under physiological conditions with nitric oxide by

redox modulation of the NMDA receptor	Choi & Lipton, Cell Mol Life Sci 2000;57:1535-41
	S-nitrosylation, or with nitroxyl anion
what that means for the current	modulation independent of cyclic GMP

Sulfhydryl chemistry turns this receptor up and down. Not the sequence, not the expression level, not a ligand at the agonist site — the oxidation state of thiols already present in the folded protein.

1407. A Thiol Is Not a Strut ↩

Lipton and colleagues stated the historical position and then withdrew it, in a review in Trends in Neurosciences in 2002. The sentence is worth having in full because it is this volume's argument written by somebody else.

Until recently, they write, cysteine residues were thought to be important for metal coordination, catalysis and protein structure by forming disulfide bonds - but they were not thought to regulate protein function. However, this is not the case.

That is the sulfur claim of this volume, made in a neuroscience review twenty-four years ago, about the receptor family that carries most of the excitatory traffic in the mammalian brain. The volume did not need to argue it. It needed to notice that it had already been argued.

1408. The Switch With Three Competing Inputs ↩

The same review states what a reactive cysteine actually is, and it is not a binary.

one sulfur atom, three competing chemistries	Lipton et al., Trends Neurosci 2002;25:474-80
redox	chemical reduction or oxidation of the thiol
S-nitrosylation	catalyzed transfer of a nitric oxide group to the thiol
metal chelation	coordination of zinc, manganese or copper
the relationship between them	these reactions can compete with one another for the same thiol group on a single cysteine residue
what that constitutes	a molecular switch composed of a latticework of possible

one sulfur atom, three competing chemistries	Lipton et al., Trends Neurosci 2002;25:474-80
	modifications

A single sulfur atom holding three mutually exclusive states, with the occupied state setting the receptor's conductance. That is not a strut and it is not a disulfide clasp. It is a register.

1409. Two Strata, Not One Convergence ↩

An earlier draft of this Part called the two routes coincident and said they were the volume's two arguments meeting. The author rejected that reading, and the rejection is correct. It is recorded here rather than quietly repaired, because the distinction it draws is worth more than the claim it removes.

These are not two instances of one phenomenon. They are operations on different substrates, at different levels, obeying different rules.

adenosine-to-inosine editing at the Q/R site	thiol chemistry at the redox site	
substrate	pre-messenger RNA - a nucleic acid	a cysteine side chain in a folded protein
the operation	hydrolytic deamination, enzyme-catalyzed, site-directed	oxidation, nitrosylation or metal coordination, set by ambient conditions
what carries it out	a gene product performing a program d job	the cell's redox potential, and the availability of nitric oxide and zinc
when it acts	once, before translation	continuously, after translation
reversible on the same molecule	no - an edited transcript stays edited	yes - indefinitely, in both directions
what it changes	the polypeptide that gets built	the behavior of a polypeptide already built
the discipline it belongs to	molecular biology	chemistry and biochemistry

Read the reversibility row and the rest follows. An inosine cannot be turned back into an adenosine in a transcript. A cysteine can be reduced and reoxidised ten thousand times in the life of one receptor.

So the correct frame is not two halves meeting. It is a stack of three strata: the gene specifies, the edit decides what is manufactured, and the thiol state governs how the manufactured object runs. Each stratum has its own timescale, its own reversibility and its own agent. Collapsing them into a convergence would flatten exactly the distinction this volume exists to make.

What makes the glutamate receptors worth a Part is therefore not that the two arguments merge here. It is that this is the one protein family where both strata are visible at once and can be told apart.

1410. What the Notation Loses Here ↩

Everything that decides the outcome.

what the four letters record	
a calcium-permeable AMPA receptor	reads as CAG in the genome and as CGG in the transcript record
a calcium-impermeable one	reads as CAG in the genome and as CGG in the transcript record
an NMDA receptor with reduced thiols	reads identically to one with oxidized thiols, at every level of sequence
an S-nitrosylated cysteine 399	reads as cysteine

1411. What This Part Refuses ↩

that inosine binds AMPA or NMDA receptors as a ligand	It does not. Free inosine acts at adenosine receptors and has intracellular actions on axon growth. The connection established here runs through ADAR2 editing of the receptor's own transcript, not through binding, and stating it the other way would be wrong in the first sentence a pharmacologist read.
that this Part proves an expanded genetic code	It does not. It records one edited codon with a measured physiological consequence, which is what the volume has claimed throughout and no more.
that six numbered cysteine pairs on this receptor are established	See section 1408. They may be correct. This volume has not verified them and therefore does not print them.

that the sulfur route and the editing route are known to interact	They are not known to. They are established separately, on the same receptor family. Coincidence of target is not evidence of coupling, and the experiment in section 1410 exists because the coupling is untested.
that any of this constitutes a therapeutic claim	Nothing here bears on whether any compound helps any patient.

1412. The Six Residue Numbers This Part Will Not Print ↩

A source document brought to this volume assigns three specific cysteine pairs to three kinetic components of the NMDA current, with residue numbers, across two subunits.

Two independent literature searches failed to retrieve a paper making those assignments. The general claim - that multiple cysteines in different subunits are the molecular determinants of redox modulation - is verified and is recorded in section 1402. The specific six numbers are not, and they are the kind of detail a referee checks first.

They are therefore withheld rather than repeated. If a source is produced, they take four lines and this Part gains precision. Printed without one, they would have cost the Part its credibility on a point that was never load-bearing.

1413. What Would Show This Part Is Wrong ↩

the rescue was not editing-specific	If the exonic Q/R substitution in the ADAR2-null mouse rescued through some route other than restoring the edited codon, the central demonstration fails.
redox modulation is an artifact of the preparation	If thiol modulation of NMDA currents does not occur in intact tissue at physiological redox potentials, section 1402 is a slice phenomenon and not a control mechanism.
cysteine 399 is not nitrosylated in vivo	The residue assignment carries the specificity of the sulfur claim. Losing it would leave the general redox effect without a named site.
the two routes turn out to be	If thiol state controls ADAR2 activity, or editing controls the redox site's accessibility, then this is not two arguments

one	meeting - it is one argument that was always single. That would be a larger result than the Part currently claims.

1414. The Experiment This Part Generates ↩

An earlier version of this section asked whether the two routes gate one another, and proposed testing whether thiol state controls ADAR2 activity. That question was malformed and the second limb was unsupported.

A literature search for redox regulation of ADAR2 returns nothing. The reciprocal arm was therefore describing an effect with no published basis, and it is withdrawn rather than left standing as a suggestion.

The question that survives is a cross-level one, and it has to be asked in cross-level terms.

Experiment Sixty-Nine, restated	
question	Does a manufacturing decision set the operating envelope? That is: does the Q/R editing state alter the range over which thiol chemistry can modulate the receptor?
why it is not a gating question	Gating would mean one route switches the other on or off. These are different strata. The legitimate question is whether the higher stratum sets the parameters within which the lower one operates.
design	Express edited or unedited GluA2 exonically, as Higuchi's rescue did, so editing state is fixed and not itself variable. Then sweep the thiol redox state across its physiological range and record the full response curve, not a single point.
prediction if the strata are orthogonal	The redox response curve is identical for edited and unedited receptors. Manufacturing and operation are independent axes and the volume should say so.
prediction if the higher stratum sets the envelope	The curve shifts. The amino acid installed by editing changes how much dynamic range the chemical control has - which is a hierarchy result, not a merger result, and a more interesting one.
what is deliberately not tested	Whether ADAR2 is itself redox-sensitive. No published evidence supports it. If someone establishes it, that becomes a separate experiment with its own justification.
cost	Standard electrophysiology. No new reagent.

1415. What This Part Claims ↩

That the ionotropic glutamate receptors are the first object in this volume reached by both of its arguments, and that each route is established independently in the peer-reviewed literature.

That at the Q/R site, a single hydrolytic deamination changes an amino acid the gene does not encode, and the whole lethal phenotype of losing the enzyme resolves to that one position out of twenty-five.

That on the same receptor family, thiol chemistry sets the conductance without altering any sequence, and that the field itself revised its view of what a cysteine is in order to say so.

It does not claim the two routes are connected. It claims they land on the same protein family, that neither is visible to sequence, and that this is the sharpest available instance of the volume's thesis because the readout is the survival of an animal.

1416. Why This Part Sits Here ↩

It is placed last in the body because it is the only Part in which the two halves of the volume are not being argued in parallel.

Every earlier Part carries one of the two claims. Parts One Hundred and Twenty-Eight, One Hundred and Thirty-Six and One Hundred and Forty-Two carry sulfur in apolipoprotein E, in albumin and in the calcitonin ring. Parts Fifty-Nine through Seventy-One carry inosine and the reading of it. This Part carries both, on one protein family, in one tissue - and it does so with an animal that lives or dies on the outcome.

PART ONE HUNDRED AND FORTY-FOUR · THE BOND WAS OLDER THAN THE CODE

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

Why the atomic level was given its own colors: the chemistry is not a parallel stratum, it is the prior one

Part One Hundred and Forty-Three established that adenosine-to-inosine editing and thiol chemistry are two strata rather than two halves. It stopped one step short. Two strata have an order, and this Part records it.

The chemical level came first. Not first in importance and not first in the exposition - first in time. Everything the molecular level does was built on top of a reaction that already worked, and the clearest proof of that is the machine which is supposed to be the definitional object of molecular biology. The ribosome does not make the peptide bond. It arranges for a bond that forms anyway to form quickly and in a chosen order.

1417. The Reaction Happens Without the Machine ↩

A doctoral dissertation submitted to the University of Rhode Island in 2024, on defining the peptidyl transferase active site, states the chemistry in its opening pages and states it plainly.

The peptide bond reaction occurs, in its author's words, via a spontaneous condensation reaction in which the nucleophilic alpha-amino group of one amino acid attacks the carboxyl group of another, forming a tetrahedral intermediate that collapses to form an amide bond.

peptide bond formation	Killeavy, doctoral dissertation, University of Rhode Island, 2024
the nucleophile	the alpha-amino group of the incoming amino acid
the electrophile	the carbonyl carbon of the one already in the chain
the intermediate	tetrahedral
the product	an amide bond
the name of this reaction in organic chemistry	nucleophilic acyl substitution
does it require a ribosome	no

The word doing the work is spontaneous. This reaction is not created by biology. It is a condensation that proceeds on its own, and it

proceeded on its own before there was a ribosome, a transfer RNA, a codon or a cell.

1418. The Fragment Reaction ↩

The claim is not theoretical. It was demonstrated in 1968 and the demonstration is famous enough to have a name.

Monro and colleagues recapitulated peptidyl transferase activity in a test tube. The dissertation lists what was required.

the fragment reaction	Monro et al., 1968
the large subunit alone	the 50S - no small subunit
the A-site substrate	puromycin, an aminoacyl-tRNA analogue
the P-site substrate	a truncated terminal 5-prime CAACCA fragment of an initiator transfer RNA
ions	mono- and divalent cations
and	methanol
what was NOT required	messenger RNA, the small subunit, a codon, an anticodon, or a genetic code of any kind

A six-nucleotide fragment, a drug analogue, salt and alcohol. That is enough to form a peptide bond. Nothing in that list reads a message, and the reaction runs regardless.

1419. Ten Million Times Faster, and No Catalytic Residue ↩

what the machine adds	
rate enhancement by the ribosome	approximately ten to the seventh, relative to the uncatalyzed reaction
source of that figure	Sievers and colleagues, 2004
the mechanism as currently modeled	an entropic proton shuttling mechanism
what has not been found	a clear catalytic residue, of the kind an acid-base mechanism would require
what the active site is made of	ribosomal RNA, not ribosomal protein

what the machine adds	
what the dissertation calls the underlying reaction	the much simpler primordial reaction of peptide bond formation

Read those rows in order. The uncatalyzed reaction has a rate, so it happens. The ribosome multiplies that rate by ten million. And after decades of searching, no residue has been found that does classical chemistry to it.

The best current model is entropic - the machine holds two substrates in position and excludes water, and the reaction they were already going to undergo proceeds faster. That is a positioning device, not a chemist. The chemistry belongs to the molecules.

1420. What the Enzyme Commission Already Knew ↩

The world's own enzyme nomenclature classified the ribosome long ago, and the classification says exactly what this Part is arguing.

two enzymes, one class	
peptidyl transferase, the catalytic core of the ribosome	EC 2.3.2.12
long-chain-alcohol O-fatty-acyltransferase, the wax ester synthase	EC 2.3.1.75
what EC 2 means	transferase
what EC 2.3 means	acyltransferase - an enzyme acting on acyl groups
where they differ	the third digit. 2.3.2 transfers aminoacyl groups; 2.3.1 transfers acyl groups other than aminoacyl

The machine that reads the genetic code and the enzyme that makes beeswax are the same class of enzyme. They differ at the third digit of the classification, which records what is being transferred, not what kind of reaction it is. The reaction is the same reaction.

The distinction is worth keeping exact, because it is the honest version and the honest version is stronger. These are not the same enzyme and not the same subclass. They are the same class - acyl transfer - and the code sits entirely in the third digit.

1421. Ester to Amide, and Thioester to Ester ↩

Write the two reactions next to each other with the chemistry exposed rather than the biology.

protein synthesis	wax ester synthesis	
what the acyl group starts on	the 2-prime or 3-prime hydroxyl of the terminal adenosine of transfer RNA - an oxygen ester	coenzyme A - a thioester
what attacks it	the alpha-amino group of the next amino acid	the hydroxyl of a long-chain fatty alcohol
what leaves	the transfer RNA	coenzyme A
what is formed	an amide - the peptide bond	an ester - the wax
the reaction class	nucleophilic acyl substitution	nucleophilic acyl substitution

Four rows differ in the identity of the participants. The fifth is identical.

An aminoacyl transfer RNA is an activated ester. That is what it is chemically, before it is anything else. The genetic code decides which ester is presented; it does not decide what happens when the amine arrives.

1422. Why the Acyl Donor Is a Carbon-Sulfur Bond ↩

In the wax ester column above, the acyl donor is acyl-coenzyme A. In the citric acid cycle it is acetyl-coenzyme A. On a histone tail it is acetyl-coenzyme A. On a mitochondrial lysine it is acetyl-coenzyme A.

In every case the acyl group is carried on a thioester - a bond between carbon and sulfur - and it is carried there because a thioester is a better acyl donor than an oxygen ester. The thiol is a poorer electron donor to the carbonyl, so less resonance stabilization is lost when the tetrahedral intermediate forms, and the group leaves more readily.

the acyl-transfer economy runs on sulfur	
Acinetobacter calcoaceticus ADP1	synthesises wax esters through a bifunctional wax ester synthase / acyl-CoA:diacylglycerol acyltransferase
the acyl donor there	acyl-coenzyme A
human skin	AWAT1 and AWAT2 esterify long-chain alcohols using oleoyl-CoA as the acyl donor
human sebum by weight	about twenty-six percent wax esters
what happens to mice without them	sebaceous glands atrophy and the animals lose their hair

This volume's sulfur paper carries the sentence that every acetyl transfer in biology runs through a carbon-sulfur bond. Here is why that sentence is not decoration. Acyl transfer is the reaction; the thioester is the standard way of holding an acyl group ready for it; and protein synthesis is the one branch of the family that runs on an oxygen ester instead - held in place, at cost, by a machine.

1423. Two Strata, and Which One Came First ↩

Part One Hundred and Forty-Three set out two strata and refused to collapse them. It did not order them. The order is the point of the color scheme and it should have been stated there.

	what it is	what it does
the chemical stratum	nucleophilic acyl substitution; thiol oxidation state; hydrolytic deamination	proceeds without biology, on its own timescale, reversibly or not according to the reaction
the molecular stratum	which ester is presented, which codon is read, which adenosine is edited	selects among chemical possibilities; cannot create one
the relation	the second is a control layer over the first	not a parallel track, and not a merger

The peptidyl transferase center makes this legible because it is the place where a molecular-biological machine and a chemical reaction can be separated experimentally. Take the machine away and the reaction still runs, ten million times slower. Take the reaction away and there is nothing for the machine to control.

The atomic level was given its own colors in this volume in order to record that asymmetry. Not two languages describing one thing. One thing that happens, and a later layer that decides when and in what order.

1424. What the Notation Loses Here ↩

the bond does not record its origin	
a peptide bond made by a ribosome	an amide
a peptide bond made in a test tube from a six-nucleotide fragment and methanol	an amide
a peptide bond made with no biology present at all	an amide
what the genetic code contributed	the order of the residues, and nothing about the bond

The four letters record which amino acids and in what sequence. They do not record, and cannot record, the reaction that joined them - because that reaction is the same reaction in all three rows.

1425. What This Part Refuses ↩

that the ribosome is unimportant	A rate enhancement of ten million and the imposition of sequence order are not small. Without the machine there is chemistry but no biology. The claim is about precedence, not about significance.
that peptide bonds form readily in water	They do not. The uncatalyzed reaction is slow and thermodynamically uphill in aqueous solution, which is why activation - as an ester or a thioester - is required in every case. Spontaneous here means proceeds without an enzyme, not proceeds easily.
that the ribosome and wax ester synthase are the same enzyme	They are the same EC class and different EC subclasses. Section 1416 states the difference. Collapsing them would be an error a referee would find immediately.
that this proves the RNA world	The peptidyl transferase center being a ribozyme is evidence cited for it, and this Part records that it is cited. It does not adjudicate it.
that thioesters preceded	The thioester world is a serious hypothesis and it is not

oxygen esters in this specific lineage	settled. What is established is the chemistry: a thioester is the better acyl donor and is the one biology uses everywhere except in translation.

1426. What Would Show This Part Is Wrong ↩

a catalytic residue is found	If a residue in the peptidyl transferase center is shown to perform classical acid-base chemistry on the peptide bond, the ribosome becomes a chemist rather than a positioning device and section 1415 weakens considerably.
the fragment reaction does not reproduce	The 1968 result is the load-bearing demonstration. If it fails under modern conditions, the claim that the reaction runs without the machinery loses its cleanest support.
the uncatalyzed rate is effectively zero	The ten-million-fold figure requires a measurable uncatalyzed rate. If that rate is indistinguishable from zero under cellular conditions, spontaneous is the wrong word and this Part should say catalysis-dependent instead.
the EC classification is an artefact	If EC 2.3 groups these enzymes for historical convenience rather than mechanism, section 1416 is a filing observation and not a chemical one.

1427. The Experiment This Part Generates ↩

Experiment Seventy	
question	Does the peptidyl transferase center accept a thioester acyl donor?
the significance	Every other acyl transfer in biology runs on a thioester. Translation is the exception, running on an oxygen ester. If the center will accept a thioester substrate, the exception is a choice; if it will not, the oxygen ester is a requirement of the site and the exception is structural.
design	Synthesize the fragment-reaction P-site substrate with the acyl group on sulfur rather than on the 2-prime or 3-prime oxygen. Run the fragment reaction as Monro did - 50S subunit, puromycin, cations, methanol - and measure product formation against the oxygen-ester control.
prediction if the site is indifferent	The thioester works, and probably faster, since it is the better acyl donor. Translation's use of an oxygen ester is then a decision made elsewhere, most likely at the synthetase.
prediction if the site is specific	No product. The center requires the 2-prime hydroxyl geometry it evolved around, and the oxygen ester is not a choice but a constraint.
what either result settles	Whether translation opted out of the thioester economy or was never able to join it.

Experiment Seventy	
cost	One modified substrate and a reaction that has been run since 1968.

1428. What This Part Claims ↩

That the peptide bond is formed by nucleophilic acyl substitution, that this reaction proceeds without a ribosome, and that both statements are made in the primary literature rather than inferred here.

That the ribosome contributes a rate enhancement of about ten million and the ordering of residues, by positioning and by exclusion of water, and that no catalytic residue has been identified.

That the enzyme classification places the ribosome's catalytic core and the wax ester synthase in the same class, and that the difference between them is recorded in the third digit.

And therefore that the chemical stratum is prior to the molecular one. The molecular stratum selects among chemical possibilities and cannot create them. That is the asymmetry the atomic-level colors were introduced to record, and this is the Part that states it.

1429. Why This Part Comes After the Receptor ↩

Part One Hundred and Forty-Three found the two strata on one protein family and declined to merge them. It left them side by side.

This Part supplies the missing relation. They are not side by side. One is underneath. And the demonstration is not an argument about origins - it is a test tube from 1968 containing a six-nucleotide fragment, salt and methanol, making a peptide bond with no code present.

1430. The Sentence This Volume Has Been Circling ↩

Acyl transfer is one reaction. Biology runs it on a thioester almost everywhere, and on an oxygen ester in the one place where the product is a protein.

The genetic code does not make peptide bonds. It chooses which esters are presented, and in what order. The bond itself is older than the choosing, and the atom that holds the acyl group ready for it, everywhere except in translation, is sulfur.

PART ONE HUNDRED AND FORTY-FIVE · THE SAME TWO ATOMS, THREE TIMES OVER

1431. The Acid in the Urine Is a Thioester That Got Away ↩

Where the leucine pathway keeps its carbon

Leucine is not taken apart by an enzyme acting on leucine. It is taken apart by a relay in which every intermediate is held on the sulfur of coenzyme A. Isovaleryl-CoA becomes 3-methylcrotonyl-CoA, which becomes 3-methylglutaconyl-CoA, which becomes HMG-CoA, which is cut to acetyl-CoA and acetoacetate.

At no point in that sequence is the carbon skeleton free. It is a thioester the whole way down, passed from hand to hand on a sulfur atom.

The enzyme of type I disease acts on the thioester, not on the acid. AUH encodes 3-methylglutaconyl-CoA hydratase, and its substrate carries the CoA. When AUH fails the thioester is not carried forward, the bond to sulfur is hydrolysed, and the carbon leaves the cell as a free dicarboxylic acid.

So 3-methylglutaconic acid in the urine is not a metabolite. It is a report of a carbon-sulfur bond broken early. The clinical assay reads the failure of a thioester relay, which is why the compound appears at all rather than being consumed.

1432. But Type I Is the Small Door ↩

The instinct is to treat this marker as a leucine disorder and stop there. The largest cohort study says otherwise, and its numbers are the reason this Part exists.

977 patients, 50 genes	Wortmann et al., J Inherit Metab Dis 2013;36:913-921
patients screened for 3-MGA on metabolic suspicion	388, of whom 3 percent of urine samples showed it
patients with genetically proven mitochondrial disease	591, across 50 different genes
of those, how many excreted 3-methylglutaconic acid	11 percent
where it was more frequent	ATPase-related disorders, and mitochondrial DNA depletion or deletion
where it was not	single respiratory chain complex deficiencies
the genes in which it is discriminative rather than incidental	AUH, TAZ, SERAC1, OPA3, DNAJC19, TMEM70

Read the last row. Six genes, and only one of them is in the leucine pathway. The other five are membrane genes - cardiolipin remodeling, phosphatidylglycerol remodeling, inner membrane structure, ATP synthase assembly. The single biochemical route that explains type I explains none of the rest.

And the exclusion row is sharper than the inclusion rows. This acid does not track with single complex deficiencies. A cell can lose Complex I outright and not spill it. What it tracks with is damage to the membrane the complexes sit in, and to the ATPase specifically.

1433. The Second Gene on That List Is an Acyltransferase ↩

TAZ encodes tafazzin, and tafazzin remodels monolysocardiolipin into mature cardiolipin by transferring an acyl chain. It is a transacylase. Barth syndrome is what happens when that transfer fails.

Part One Hundred and Forty-Four argued that acyl transfer is the oldest operation in the cell - that the peptidyl transferase center and the wax ester synthases perform the same chemistry, at the same enzyme class, on different cargo. Tafazzin belongs to that class. So does every step of the leucine relay in section 1431.

Both named ends of the discriminative gene set are acyl-transfer chemistry. AUH hydrates a thioester in a soluble pathway; tafazzin moves an acyl chain inside a membrane. The disease marker they share is not an artifact of the assay. It is the residue of one class of reaction failing in two compartments.

That sentence is a pattern in a gene list. It is not a demonstrated pathway, and the next section says why the difference matters.

1434. What Is Not Known, and Is Printed Rather Than Smoothed Over ↩

Wortmann's paper states plainly that in every form except AUH deficiency, the origin of the 3-methylglutaconic acid is unknown. Nobody has traced the carbon. Mitochondrial dysfunction is assumed to be the common denominator; the actual reaction that produces the acid in a tafazzin patient has not been demonstrated.

This volume will not supply a mechanism it cannot source. The acyl-transfer observation above is offered as a lead for the experiment at the end of this Part, and as nothing more than that.

1435. The Pump Is the Cell's Largest Single Customer ↩

Where the energy actually goes

The sodium-potassium pump is not one consumer among many. In the brain it is very close to the whole bill.

where ATP goes in gray matter	Attwell and Laughlin, J Cereb Blood Flow Metab 2001;21:1133-1145
action potentials	47 percent
postsynaptic effects of glutamate	34 percent
maintaining the resting potential	13 percent
recycling glutamate	3 percent
what the first three have in common	all of it is gradient work - sodium and potassium moved back across the membrane against their gradients, by the pump

Ninety-four percent of the signaling budget is spent restoring two ion gradients. Everything else the neuron does competes for the remainder. This is why a mitochondrial membrane defect presents as a brain disease and not as a liver disease. The organ with the least headroom fails first.

1436. And That Pump Is Held Shut by a Thiol ↩

The pump's activity is not set only by ATP supply. It is set by the redox state of specific cysteines on its own subunits, and the mechanism is one this volume has already met.

what is modified	what the modification does	source
the catalytic alpha subunit	Glutathionylation of regulatory cysteines inhibits the enzyme. In hypoxic rat heart, nitric oxide availability falls, oxidised glutathione accumulates, S-nitrosylation of the alpha subunit drops and S-glutathionylation rises, and hydrolytic activity falls with it. Treating homogenate with GSSG inhibits the enzyme completely.	Yakushev et al., Am J Physiol Heart Circ Physiol 2012;303:H1332-1343
the beta-1 subunit	Cysteine 45 sits in a transmembrane region. Glutathione cannot penetrate the bilayer to reach it, so modification requires the alpha-beta association to loosen first. Once glutathionylated the cysteine is anchored in a hydrophilic environment and the beta subunit can no longer move through the catalytic cycle.	Garcia et al., Biochim Biophys Acta 2015;1848:2430-2436
the resting state	Rabbit kidney enzyme carries both regulatory and basal glutathionylation. Reducing agents deglutathionylate it only partially, and partial deglutathionylation activates it. Some of the modification cannot be removed from the native protein at all.	Dergousova et al., Mol Biol (Mosk) 2018;52:289-293

Look at what the first row describes. Three ligands competing for the same cysteine sulfur - the free thiol, the nitrosyl group, and glutathione. Reduced, nitrosylated, or glutathionylated, and the protein behaves differently in each state.

This volume has printed that triangle before. It is the glutamate receptor redox site of Part One Hundred and Forty-Three: Cys399 of NR2A, and Lipton's statement of the thiol as a three-way competing switch. The sodium pump is the second protein family in this volume shown to run on it.

Nothing in the genome specifies whether a given pump molecule is glutathionylated this minute. That is set by the ambient ratio of reduced to oxidized glutathione and by how much nitric oxide is available. Chemistry, not molecular biology, and reversible in both directions indefinitely. Section 1405 separated the two strata and Part One Hundred and Forty-Four ordered them. Here is the ordering operating in a living neuron: the gene builds the pump, and the redox potential decides how hard it runs.

1437. Why a Failing Pump Becomes a Seizure ↩

The step that joins the first half of this Part to the second comes from a computational neuroscience paper rather than a biochemical one, and it is the reason the two halves are in the same Part at all.

Depannemaecker, Ivanov, Lillo, Spek, Bernard and Jirsa, in the Journal of Computational Neuroscience in 2022, build a single-neuron model in which extracellular potassium is the slow variable. Fast dynamics give spikes; the slow rise in external potassium moves the system across bifurcations. Below a threshold, normal firing. Cross a saddle-node and seizure-like events begin. Let potassium keep rising and the events fuse into sustained ictal activity. Higher still and the neuron enters depolarization block, silent but pathologically so.

Potassium accumulates outside the cell when it is not pumped back in.

So the chain closes, and each link is separately sourced. Membrane defect, less ATP. Less ATP, slower pump. Slower pump, potassium rises outside. Potassium rises, the neuron crosses a bifurcation. The clinical name for that crossing is a seizure.

1438. One Gene Where All Three Meet ↩

TIMM50 is the presequence receptor of the TIM23 translocase, the porter at the inner gate. Its second approved gene alias is MGCA9: 3-methylglutaconic aciduria

type IX. Mutations give epilepsy or epileptic encephalopathy, severe intellectual disability, variable complex V deficiency, and 3-methylglutaconic aciduria.

One gene, and the presentation carries the membrane defect, the acid, the ATPase failure and the seizure together. It is the shortest available demonstration that the three threads of this Part are one thread.

TIMM50, verified	what the source establishes
Reyes et al., EMBO Mol Med 2018;10:e8698	TIMM50 as the TIM23 intermembrane-space presequence receptor, with disease
Shahrour et al., Clin Genet 2016;91:690-696	Arg217Trp, Thr252Met, Gly372Ser
Mir et al., Clin Genet 2020;98:102-103	Epileptic spasms in a TIMM50 patient resolved completely on vigabatrin - the seizures proved treatable even though the import defect is not

1439. The Inosine Family Reaches the Same Clinic by Its Own Road ↩

Arriving at epileptic encephalopathy without passing through the membrane

ITPA encodes inosine triphosphate pyrophosphatase. Its job is to hydrolyse inosine and xanthosine triphosphates back to monophosphates so that they are never incorporated into DNA or RNA.

Biallelic loss gives developmental and epileptic encephalopathy 35: profound delay, microcephaly, refractory epilepsy, then regression, with a recurrent imaging pattern of delayed myelination and restricted diffusion in early-myelinating structures. Forty subjects characterized, eighteen distinct pathogenic variants, in Scala et al., Human Mutation 2022;43:403-419.

The substrates matter more here than the syndrome. Zamzami, reviewing the enzyme in Cells in 2022, states it directly: ITP, XTP and their deoxy forms are products of deamination occurring inside the cell. Adenine loses its amine and becomes hypoxanthine. Guanine loses its amine and becomes xanthine. If the resulting triphosphate is not destroyed, it goes into a nucleic acid.

ITPA is the janitor of the deamination channel this volume is about. The volume has spent hundreds of pages on what deamination writes into RNA and DNA. ITPA is the enzyme that decides how much of it gets written at all, and a child without it does not develop.

1440. The Seam: One Drug That Is All Three at Once ↩

The result the three questions were pointing at

Zamzami's review notes, almost in passing, that the thiopurine drugs have been added to the list of ITPase substrates. Following that sentence produces the finding of this Part.

the thiopurines, taken apart	what each step is
the base	Hypoxanthine carries a double-bonded oxygen at carbon six. 6-mercaptopurine is the same ring with sulfur in that position. The drug is hypoxanthine with the oxygen replaced by its conjugate.
what the cell makes of it	Azathioprine is cleaved to 6-mercaptopurine, and HPRT1 - the salvage enzyme of the inosine pathway - adds the ribose phosphate. The product is 6-thioinosine monophosphate. The active metabolite is inosine monophosphate with sulfur at carbon six.
who cleans it up	ITPA hydrolyses the thio-triphosphates as it hydrolyses ITP itself, and ITPA genotype is a recognized determinant of thiopurine response and toxicity.
who inactivates it	TPMT, thiopurine S-methyltransferase, methylates the sulfur. Low-activity variants leave patients severely exposed. This is a methyl group placed onto a sulfur atom in order to switch a molecule off.

Set that beside three claims this volume has already made. That sulfur and oxygen are conjugates at the same position. That inosine is the purine the code reads without spelling. That methyl groups are a sulfur currency, issued from S-adenosylmethionine.

A thiopurine is all three propositions in one molecule. Oxygen replaced by sulfur at carbon six of a purine; the cell's inosine machinery accepting the substitution without complaint and phosphoribosylating it into an inosine monophosphate; the inosine housekeeping enzyme hydrolysing it; and the cell disposing of it by spending a methyl group onto the sulfur.

This pharmacology has been in the clinic since the nineteen-fifties. What it has not been read as is an experiment the medical profession has already run, several million times, on whether the cell can tell sulfur from oxygen at carbon six. The answer it returns is: not well enough to refuse the substrate.

1441. What the Notation Loses Here ↩

Written as letters, the finding above is invisible. A thiopurine has no letter. Inosine has no letter. The volume's four-symbol alphabet cannot express a purine that is hypoxanthine at every position except one, and differs there by a single atom of the same column of the periodic table.

Written as structures, it is immediate. The two molecules are drawn identically apart from one atom label, and the enzymes treat them accordingly. The notation is what made this hard to see, not the chemistry.

1442. What This Part Refuses ↩

No mechanism is offered for how a cardiolipin or membrane defect produces 3-methylglutaconic acid. Wortmann says the origin is unknown and it remains unknown. The acyl-transfer pattern in section 1433 is a pattern in a gene list.

No claim is made that ITPA, AUH or tafazzin are themselves redox-regulated. That would be the tidy version of this Part. A search returns nothing to support it, and the withdrawal of the ADAR2 thiol arm in section 1410 is the precedent for not writing it.

The step order of the leucine relay, the cleavage of azathioprine to 6-mercaptopurine and its phosphoribosylation by HPRT1, the identity of the TPMT methyl donor, and the ITPA effect on thiopurine toxicity are standard assignments carried from working knowledge rather than retrieved sources. Each is expected to hold. The distinction is printed because this volume prints it.

1443. The Experiment This Part Generates ↩

Section 1440 is qualitative. It becomes evidence only if the discrimination is measured, and that measurement does not appear to have been made for its own sake.

Experiment Seventy - the carbon-six swap, measured	
question	By how much does the inosine machinery distinguish oxygen from sulfur at carbon six of the purine ring?
why it has not been answered	Thiopurine pharmacokinetics is measured for dosing. The comparison that matters here - one enzyme's constants for the oxo and thio substrates side by side, under identical conditions - is a chemistry question asked inside a clinical literature, and it falls between the two.
design	Purified recombinant ITPase. Michaelis-Menten constants for ITP and for 6-thio-ITP in the same buffer, the same magnesium, the same day. Repeat with HPRT1 on hypoxanthine versus 6-mercaptopurine.
prediction if the conjugate claim holds	The constants sit within roughly one order of magnitude. The enzyme is built around ring geometry and the phosphate, and the carbon-six substituent is not the discriminator.
prediction if it does not	A gap of three orders or more, meaning the conjugate relationship is real in chemistry but not in enzymology, and this volume must narrow the claim to positions where the substitution is tolerated rather than asserting it generally.
the value either way	A negative result is publishable and constrains the thesis. Very few experiments in this volume have that property. Experiment Seventy does.
cost	Two purified enzymes, commercially available substrates, a plate reader. An afternoon, not a grant.

PART ONE HUNDRED AND FORTY-SIX · THE WINDOW WAS MADE OF LIPID

1444. Forty-Seven to One ↩

What happens when elemental sulfur is cut thin

Krishnappa, Naganna, Rajan, Rajashekarappa and Gowdru made sulfur two ways and put both on four human cell lines for twenty-four hours. A chemical route gave agglomerated nanoparticles of thirty to forty nanometers; a plant-extract route gave nanosheets of ten to twenty nanometers, with a lattice spacing of 0.32 nanometers indexing to the (206) plane of ordinary orthorhombic sulfur.

Not a compound. Not a drug. The element, cut thin.

cell line	IC50, nanosheets, micrograms per	IC50, nanoparticles	selectivity of the sheets

	milliliter		
A549, human lung carcinoma	9.5	129.3	46.7
A431, human epidermoid carcinoma	18.29	122.4	24.3
HL60, human promyelocytic leukemia	10.49	153.2	42.3
IMR90, normal lung fibroblast	443.8	342.7	—

Against the normal fibroblast the nanosheets are the least toxic thing in the study. Nine and a half micrograms kills half a lung carcinoma population; it takes four hundred and forty-four to do the same to a normal lung fibroblast. A window of forty-seven to one, from an element that has been sitting in acne ointment for a century.

1445. Shape Decides, Not Only Chemistry ↩

The second result in that table is the larger one and it is easy to read past.

The same element at the same purity is roughly thirteen times more cytotoxic as a sheet than as a particle. Composition is identical. Crystal form is identical — both index to orthorhombic sulfur. What differs is geometry.

This volume has argued at several points that the notation loses the shape and keeps only the letters. Here is a case where the shape carries an order of magnitude and the composition carries nothing at all. Two samples that any chemical assay would report as the same substance differ thirteenfold in what they do to a cell.

The selectivity ratio follows the same split. The sheets discriminate between cancer and normal by a factor of forty-seven. The particles manage under three. Whatever produces the window is a property of the sheet, not of sulfur in general.

1446. The Paper Does Not Ask Why ↩

The authors attribute the effect to particle uptake and surface area. That explains potency. It does not explain selectivity, because a normal fibroblast takes up nanosheets too.

The caspase data sharpen the problem rather than solving it. Caspase-3 fluorescence in the lung carcinoma line rises from 12.62 untreated to 50.34 on nanosheets, and the authors assign the activation to the mitochondrial pathway. In the normal fibroblast the same treatment moves caspase-3 from 9.19 to 13.46 — and that is the one value in their table carrying no mark of significance at all. The normal cell is not mildly affected. Within the resolution of the assay it is not affected.

So the question the paper leaves standing is a specific one. What is different about the mitochondrion of a cancer cell such that sulfur finds it and not the other one?

term	occurrences in the full text of the paper
cardiolipin	0
thiol	0
cysteine	0
glutathione	0
Warburg	0
glycolysis or glycolytic	0
reactive oxygen species	22

A forty-seven-fold therapeutic window is reported through the mitochondrial apoptotic pathway, and the words cardiolipin, thiol, cysteine and glutathione do not appear once. This is not a criticism of the authors, who wrote a materials paper and wrote it well. It is an observation about where the explanation would have to come from, and it is not in their literature.

1447. Seyfried's Lipid ↩

The answer arrives from a book that never mentions sulfur

Seyfried's case in Cancer as a Metabolic Disease is that cancer is not primarily a genetic disorder but a mitochondrial metabolic one, with damage to respiration

preceding genomic instability. Chapter Five carries the physical evidence, and the evidence is about a lipid.

Cardiolipin is the signature phospholipid of the inner mitochondrial membrane. Respiratory complex proteins carry hydrophobic grooves shaped to accommodate its acyl chains. Complex I and complex III activities are directly related to cardiolipin content, and respiratory efficiency depends on which molecular species of cardiolipin is present.

He purified mitochondria from five mouse brain tumors and from the normal syngeneic host tissue, and reported that the content and composition of cardiolipin differed markedly between them. His generalization is stated plainly: most tumors , regardless of cell origin, would contain abnormalities in cardiolipin composition or content, and those abnormalities will significantly reduce the efficiency of oxidative phosphorylation.

1448. Immature Means Unremodeled ↩

The specific defect he reports is not simply less cardiolipin. It is the wrong kind — what he calls immature cardiolipin molecular species in tumor mitochondria, found alongside impaired respiratory function.

That word is doing precise work. Newly synthesized cardiolipin carries whatever acyl chains it was assembled with. It becomes mature cardiolipin only when those chains are exchanged for the correct ones, in a second step that happens after synthesis.

Immature cardiolipin is cardiolipin that has not been remodeled. Which means the defect Seyfried places at the center of the metabolic theory of cancer is not a missing molecule. It is an unperformed reaction.

1449. Which Names an Enzyme Already in This Volume ↩

The reaction is an acyl transfer and the enzyme is tafazzin. It takes monolysocardiolipin and moves an acyl chain onto it to give mature cardiolipin.

Section 1433 placed tafazzin in the acyl-transfer class alongside the ribosome's peptidyl transferase center and the wax ester synthases — the class Part One Hundred and Forty-Four argued is the oldest operation in the cell, and the one that runs on a carbon-sulfur thioester almost everywhere it occurs.

So the chain from Seyfried's data to this volume's spine is three links long. Tumor mitochondria carry immature cardiolipin. Cardiolipin is matured by an acyl transfer. Acyl transfer is thioester chemistry. The lipid defect at the center of the metabolic theory of cancer is the failure of a sulfur-dependent reaction.

1450. The Prior Art, Before the Argument Goes Further ↩

This volume has three times presented established work as though it were a finding. The record goes here, before the argument continues, rather than in a footnote afterward.

what is already published	what it establishes
Seneviratne et al., Cell Stem Cell 2019;24:621-636	A CRISPR screen identified tafazzin as necessary for the growth and viability of acute myeloid leukemia cells. Genetic inhibition reduced stemness and drove differentiation both in vitro and in vivo. And: knockdown of TAZ did not impair normal haematopoiesis under basal conditions.
Schild et al., Biochim Biophys Acta 2019;1865:158596	Tafazzin knockout dramatically reduced proliferation of C6 glioma cells — and did so independently of cardiolipin composition. The authors state the mechanism remains unclear.
Zhu et al., Cancer Sci 2020;111:4288-4302	In liver cancer arising from fatty liver disease, VDAC1 correlated with suppression of the mature cardiolipin species and elevation of nascent species, and correlated negatively with tafazzin.

The therapeutic window is therefore not a prediction this volume gets to make. It was demonstrated in 2019: interfere with cardiolipin maturation and leukemia cells fail while normal blood-forming cells carry on. Schild's result is the necessary caution — the dependency is real but it is not cleanly a cardiolipin-composition effect, and anyone who tidies that away is tidying away the evidence.

1451. What Is Still Open ↩

One join appears not to have been made, and it is the reason the two documents belong together.

Nobody has asked whether the selectivity of nano-sulfur is a cardiolipin effect. The nanosheet paper measures a forty-seven-fold window and explains it by uptake. The tafazzin literature has a validated cardiolipin-dependent window pointing the same way. The two have never appeared in the same experiment, and the sulfur paper does not contain the word.

The hypothesis is one sentence. A mitochondrion whose inner membrane already carries immature cardiolipin sits closer to the threshold of permeabilization, so the cell carrying that membrane dies at a dose the normal cell survives. On that reading sulfur is not seeking out cancer. The cancer cell is the one already standing near the edge.

It would account for section 1445 as well. A sheet presents a continuous hydrophobic face; an agglomerate presents contact points. If the mechanism is membrane interaction rather than dissolution, geometry should carry the effect — and geometry is the largest single factor in their data.

1452. What the Notation Loses Here ↩

Written as a formula, the two sulfur preparations are the same entry. S8, orthorhombic, same lattice, same purity. Nothing in any notation this volume has examined distinguishes a sheet from an agglomerate, and the difference between them is thirteenfold in potency and seventeenfold in selectivity.

The same loss runs through the lipid. Mature and immature cardiolipin have the same name, the same abbreviation and the same position in every pathway diagram. What separates them is which acyl chains occupy which positions — and that is precisely what a diagram of the pathway does not draw.

1453. The Experiment This Part Generates ↩

Experiment Seventy-One, the carbon-six swap's successor	
question	Is the selectivity of sulfur nanosheets a function of the cardiolipin state of the target mitochondrion?
why it has not been asked	The two literatures do not overlap. Nano-sulfur cytotoxicity is published in materials chemistry; cardiolipin remodeling in cancer is published in cell biology and haematology. Neither cites the other.
first arm	Use the leukemia system already characterized by Seneviratne. Compare tafazzin-knockdown cells against wild type for sensitivity to biogenic sulfur nanosheets. If cardiolipin immaturity is the substrate of the effect, the knockdown cells should be more sensitive, not less.
second arm, and the one that matters	Reverse it. Use the Barth syndrome fibroblast, which carries immature cardiolipin constitutively and is not malignant. If the hypothesis holds it should be abnormally sensitive to nanosheets despite being a normal cell — which separates cardiolipin state from malignancy entirely.
prediction if it holds	Sensitivity tracks the cardiolipin maturation index and not the diagnosis. The Barth line dies at carcinoma-like doses.
prediction if it fails	Sensitivity tracks proliferation rate or particle uptake and is indifferent to cardiolipin. The volume then keeps the observation and withdraws the mechanism.
the value	The falsifying arm is one plate. A Barth fibroblast that behaves like a normal fibroblast ends the hypothesis in a single experiment.
cost	Two established cell lines, one commercially available nanomaterial, a viability assay, and a cardiolipin species panel by mass spectrometry.

1454. What This Part Refuses ↩

No therapeutic claim. These are four immortalised cell lines in dishes at twenty-four hours. There is no animal work in the sulfur paper, no trial and no patient, and the distance between a nine-microgram IC50 in a dish and a treatment is the distance most compounds never cross.

No position on whether the metabolic theory of cancer is correct against the somatic mutation theory. This Part uses Seyfried's cardiolipin measurements, which stand on their own, and does not require his larger thesis to be true.

And no claim to the tafazzin dependency, which belongs to Seneviratne and colleagues and is recorded at section 1450 for that reason.

PART ONE HUNDRED AND FORTY-SEVEN · THE NUCLEOTIDE DECIDES WHERE THE NITROGEN GOES

1455. A Correction on One Word ↩

Deamination and transamination are one letter apart in usage and a world apart in chemistry

This Part begins with a correction because the distinction it turns on is the one most easily lost.

the two words	what each one does
deamination	Takes the amino group off and releases it as ammonia. What it was attached to becomes a different molecule. Cytosine becomes uracil. Adenine becomes hypoxanthine, which is inosine's base, and which the sequencer writes as G. This is the mutational channel and it is this volume's subject.
transamination	Moves the amino group from one carbon skeleton to another. Nothing is destroyed and nothing is released. Glutamate hands its amine to pyruvate and becomes alpha-ketoglutarate; the pyruvate becomes alanine. This is amino acid metabolism, and on its own it mutates nothing.

Transamination is not a mutational driver and this volume does not claim it is. The count across all sections stands at 188 occurrences of deamination against two of transamination. But the question that arises from confusing them survives the correction, and in a stronger form, because of what sits on the other side of the switch.

1456. Glutamate Dehydrogenase Is a Deaminase ↩

Seyfried's chapter on transamination describes a choice. Glutamate has to become alpha-ketoglutarate, and two routes are available.

glutamate → α-ketoglutarate by deamination, or by transamination

The first route is glutamate dehydrogenase, and the enzymology names the reaction without ambiguity: GDH catalyzes the oxidative deamination of glutamate to alpha-ketoglutarate and ammonia. The amine is removed and released. Seyfried's own words are that this makes ammonia a toxic by-product which must be eliminated.

The second route is the transaminases — glutamate-oxaloacetate giving aspartate, glutamate-pyruvate giving alanine. Here, in his phrasing, oxaloacetate accepts the amino group. Nothing is released. The nitrogen is passed to a carbon skeleton and kept.

So the switch is not transamination against something unnamed. It is a switch between destroying the amine and moving it — between a deamination and a transfer. Which is this volume's subject arriving from the metabolic side rather than the nucleic acid side.

1457. Seyfried Proposes It; the Enzymology Has Measured It

Seyfried is careful to mark his mechanism as a suggestion. His sentence reads that he considers the transamination reactions would predominate since the GTP, and also the ATP, formed through substrate-level phosphorylation could inhibit the glutamate dehydrogenase reaction. In his book that is a hypothesis.

In the enzyme literature it is a measurement.

the claim	what was found	source
GTP inhibits the housekeeping human GDH1	powerfully, with a half-maximal inhibitory concentration of 0.20 millimolar	Plaitakis and Zaganas, J Neurosci Res 2001;66:899-908
ADP and L-leucine activate the same enzyme	and act synergistically at low concentrations of each	Plaitakis and Zaganas 2001
the enzyme is an energy sensor by design	activated under low cellular energy states, which is what GTP inhibition and ADP activation amount to together	Spanaki et al., Neurochem Int 2012;61:470-481

The mechanism Seyfried offers as a consideration is the operating condition of the enzyme, characterized independently by people studying brain metabolism who were not thinking about tumors at all.

1458. The Duplicate That Escaped the Purine ↩

One sentence in that literature settles the matter more firmly than any inhibition curve, and it is worth quoting because of what it assumes rather than what it argues.

Spanaki and colleagues write that hGDH2 has dissociated its function from this energy switch, being able to metabolize glutamate even when the Krebs cycle generates GTP levels sufficient to inactivate the housekeeping hGDH1.

Read the subordinate clause. It states as routine that the Krebs cycle generates enough GTP to switch off glutamate dehydrogenase. Not under stress, not in tumors — as the normal condition the second isoenzyme had to escape.

And GDH2 is a recent gene duplication, present in apes and humans and dated to less than twenty-three million years ago. What the duplicate gained was release from GTP control.

Evolution's most recent edit to this enzyme was to take one copy out of the reach of a purine nucleotide. That is a strong statement about how much the purine was constraining it.

1459. So the Branch Point Is Upstream ↩

If GTP is what sets the switch, then whatever sets GTP is upstream of the switch, and the purine pathway does not have two independent sources.

Inosine monophosphate is the branch point at which the pathway decides between adenine and guanine — IMP to AMP on one arm, IMP through XMP to GMP on the other. Part Seventy and section 1440 hold this volume's case that IMP is the parent of both rather than a waypoint between them.

IMP → GTP ⊣ glutamate dehydrogenase → the amine is moved, not destroyed

The nitrogen policy of the mitochondrion is therefore set by the output of the purine branch point. Not by analogy and not by resemblance. The molecule that inhibits the deaminase is manufactured at the branch point this volume has spent a hundred Parts arguing about.

1460. And It Closes Into a Circuit ↩

What makes this a Part rather than a cross-reference is that the arrow returns.

the loop	
1	Succinyl-CoA synthetase performs substrate-level phosphorylation and produces GTP. Seyfried is explicit that this proceeds in the absence of oxygen, which is why it matters inside a tumor
2	That GTP inhibits glutamate dehydrogenase at 0.20 millimolar.
3	Glutamate can no longer be deaminated, so the amine goes to transamination instead — onto oxaloacetate giving aspartate, or onto pyruvate giving alanine.
4	Aspartate is the nitrogen donor that carries IMP toward AMP through adenylosuccinate, and that reaction consumes GTP as well as aspartate.
5	The amine spared destruction at step three is built into a purine at step four, and the GTP that spared it is spent doing so.
6	Spending the GTP relieves the inhibition at step two. The deaminase comes back on.

Every arrow in that circle is either a purine nucleotide or an amino group. The cell runs a control loop in which the purine decides the fate of the nitrogen, and the nitrogen is then spent making the purine. IMP sits at the center because IMP is where the purine is decided.

1461. The Thioester Pays for the Switch ↩

Step one is where the loop is driven from, and it is worth naming what does the driving.

Succinyl-CoA is a thioester. The carbon is held on a sulfur atom, and the energy released when that bond is broken is what phosphorylates the nucleoside diphosphate. Substrate-level phosphorylation at this step is a sulfur bond being spent.

Part One Hundred and Forty-Four argued that acyl transfer on a thioester is the oldest operation in the cell and that the chemical stratum precedes the molecular one. Here that stratum is setting the

nitrogen policy of a cancer cell: a carbon-sulfur bond breaks, a purine is phosphorylated, and a deaminase goes quiet.

Seyfried names GTP as the inhibitor and stops there, correctly for his purpose — in his frame GTP is an energy currency and its provenance is not the point. In this volume's frame GTP is a purine with a history, and the history runs back through the branch point to inosine monophosphate and one step further to the thioester that paid for the phosphate.

1462. What the Notation Loses Here ↩

Every diagram of this chemistry writes GTP as an energy symbol — a charge level, interchangeable with ATP, drawn as an arrow with a squiggle. Nothing in that notation records that GTP is a guanine nucleotide with a specific parent, or that its concentration relative to ATP is set at a branch point two steps upstream.

Written as energy, the inhibition of glutamate dehydrogenase looks like a thermostat. Written as chemistry, it is one purine regulating the disposal of nitrogen that will be used to make another purine. The notation is what makes the first reading the obvious one.

1463. What This Part Refuses ↩

The stoichiometry at step four — that adenylosuccinate synthetase consumes GTP and aspartate to carry IMP toward AMP, and that guanine synthesis from XMP consumes ATP and glutamine — is standard biochemistry carried from working knowledge rather than retrieved for this Part. It is load-bearing for the loop and the loop is only as good as it is.

No claim is made that the circuit has been demonstrated as a circuit. Each arrow is separately established. Nobody has measured the loop closing, and a chain of true steps is not the same object as a working feedback control.

And no claim that this explains mutation in tumors . Deamination of a nucleotide base and deamination of glutamate are the same reaction type on different

substrates, catalyzed by different enzymes. That they share chemistry is real. That one drives the other is not shown, and is not asserted.

1464. The Experiment This Part Generates ↩

Experiment Seventy-Two	
question	Does moving flux through the IMP branch point change the ratio of deamination to transamination in a tumor mitochondrion?
the feasibility now	Every element has a reagent. IMPDH inhibitors push IMP away from guanine and toward adenine, altering the GTP to ATP ratio without touching the dehydrogenase or the transaminases directly.
design	Isolated tumor mitochondria respiring on glutamine. Measure ammonia release, which reports deamination, against aspartate and alanine production, which report transamination. Then shift the purine balance — inhibit IMPDH to lower GTP, or supply GTP directly — and measure the ratio again.
prediction if the circuit is real	Lowering GTP releases the dehydrogenase: ammonia output rises and aspartate output falls. Raising GTP reverses it. The ratio tracks the purine nucleotide rather than the glutamine supply.
prediction if it is not	The ratio tracks oxaloacetate and pyruvate concentration — the acceptors — and is indifferent to GTP. The mechanism is then mass action at the acceptor end, and the inhibition, though real for the isolated enzyme, is not what governs the cell.
the control that matters	Repeat in a cell expressing GDH2, the ape and human duplicate that escaped GTP control. If the circuit is real that cell should not respond to the purine shift at all. It is the cleanest available negative control because evolution built it rather than the experimenter.
cost	Isolated mitochondria, a commercial IMPDH inhibitor, an ammonia assay and an amino acid panel. No new reagent.

PART ONE HUNDRED AND FORTY-EIGHT · THE PROTEIN THAT CUTS ITSELF OUT

1465. The Cysteine Attacks the Peptide Bond ↩

An omission, named by the author, and it is the largest one in the volume

A precursor protein is made in one piece. Inside it sits a segment called an intein, flanked by the two pieces that will become the finished protein, called exteins. The

intein removes itself and joins the two exteins with a normal peptide bond, and when it is done nothing remains to show it was ever there.

The first step is the one that matters here. The side chain of the intein's first residue — a cysteine, or a serine or threonine — attacks the peptide bond immediately upstream of it. The acyl group moves off the backbone nitrogen and onto the side chain atom.

N-acyl → S-acyl the N-to-S shift

When that residue is a cysteine, what has just been made is a thioester. The protein has converted a piece of its own backbone into the activated carbon-sulfur bond that Part One Hundred and Forty-Four calls the oldest operation in the cell — and it has done so without leaving its own sequence.

1466. What the Shift Actually Does ↩

The full sequence is four steps and every one of them is an acyl transfer.

the four steps of class 1 protein splicing	
1 · N-to-S shift	The cysteine side chain of the intein's first residue attacks the peptide bond of the last residue of the N-extein. A linear thioester intermediate forms.
2 · transesterification	The side chain of the first residue of the C-extein attacks that thioester. The N-terminal end of the intein is freed, and a branched intermediate exists in which the two exteins are joined — but not yet by a peptide bond.
3 · asparagine cyclization	The last residue of the intein is always asparagine. The amide nitrogen of its side chain cleaves the bond between intein and C-extein, and the intein departs carrying a terminal cyclic imide.
4 · S-to-N shift	The free amino group of the C-extein attacks the thioester holding the two exteins together. The acyl group moves back from sulfur to nitrogen, and a peptide bond appears.

Read the first and last steps together. The acyl group leaves nitrogen for sulfur, travels, and returns to nitrogen. Sulfur is not a component of the product and does not appear in the finished protein. It is the vehicle, and it is the whole reason the reaction can happen at all.

1467. No Cofactor, No Energy, No Enzyme ↩

The property that makes this remarkable is what is absent. Protein splicing requires no exogenous cofactor and no external energy source — not ATP, not GTP. There is no separate enzyme. The intein is not a catalyst acting on a substrate; it is the substrate, acting on itself, once, and then it is gone.

Schwarzer, Ludwig, Thiel and Mootz describe inteins precisely as single-turnover catalysts that splice themselves out of a precursor polypeptide chain, and confirm that for most inteins the first step is formation of a thioester through an N-S acyl shift at the upstream splice junction.

A peptide bond is broken and a peptide bond is made, with no energy spent and no machinery involved. The only requirement is a sulfur atom placed where it can reach the carbonyl.

1468. And No Base Either ↩

There is a further result in that paper which belongs in this volume more than it belongs where it was published.

The expectation would be that a general base has to deprotonate the cysteine thiol before it can attack — that is how most thiol chemistry in enzymes is described. Schwarzer and colleagues replaced the catalytic Cys1 with homocysteine, which is cysteine with one extra carbon in the side chain. Splicing was strongly inhibited. But thioester formation was not impaired.

Their conclusion is stated plainly: the results argue against the requirement of a base to deprotonate the catalytic thiol group prior to the N-S acyl shift, because such a base would be misaligned for optimal proton abstraction.

The thioester forms because the geometry puts the sulfur next to the carbonyl. Not because an enzyme activates it, and not because a residue removes the proton. Proximity is the mechanism.

1469. The Same Result as the Peptidyl Transferase Center ↩

Part One Hundred and Forty-Four reported that the ribosome's peptidyl transferase center has no catalytic residue, that its rate enhancement is entropic, and that the peptide bond forms by proximity and orientation rather than by chemistry supplied from outside. That finding was drawn from the ribosome literature and it sat, in this volume, as a single case.

It is not a single case. The intein is an independent system, unrelated by sequence or structure, performing the reverse operation — breaking a peptide bond rather than making one — and arriving at the same answer. No catalytic residue. No general base. No energy input. Geometry.

two systems, one answer		
what makes the bond	peptidyl transferase center, in the ribosome	intein, inside a protein
catalytic residue	none identified	none required; homocysteine still forms the thioester
energy source	the aminoacyl ester already carries it	the peptide bond already carries it
mechanism of rate enhancement	proximity and orientation, entropic	proximity of the side chain to the carbonyl
what the acyl group sits on	an oxygen ester, in the one place the product is a protein	a sulfur ester, everywhere the first residue is cysteine

Two unrelated systems, one making the peptide bond and one unmaking it, both dispensing with catalysis in the usual sense. This is a stronger statement of Part One Hundred and Forty-Four's claim than Part One Hundred and Forty-Four was able to make, and it arrived from outside the volume.

1470. Chemists Rediscovered It and Called It Something Else ↩

Native chemical ligation is the standard method for joining two synthetic peptides into a protein in a test tube. A peptide bearing a C-terminal thioester meets a peptide bearing an N-terminal cysteine; transthioesterification occurs; an S-to-N acyl shift delivers a native peptide bond at the junction.

That is steps two and four of section 1466, performed deliberately by chemists on the bench. The method by which synthetic proteins are assembled in laboratories is the mechanism inteins have been using since before there were laboratories, and the sulfur is doing the same job in both.

This volume has argued repeatedly that sulfur's role is obscured because the notation does not record it. Here is a case where it was obscured differently — the same reaction has two literatures and two names, one in molecular biology and one in synthetic chemistry, and the shared chemistry sits in the middle unremarked.

1471. Why This Was Not in the Volume ↩

Before going on, the omission should be recorded rather than quietly repaired.

Across all sections prior to this Part the volume contained zero occurrences of intein, extein, protein splicing, acyl shift or native chemical ligation. A volume whose central claim is that thioester acyl transfer is the oldest and most general operation in the cell had omitted the one system in which a protein performs that transfer on itself, unaided, and then removes the evidence.

The reason is worth naming because it is the same failure as the notation problem. The volume searched for sulfur where sulfur appears in the product — in cysteine residues, in iron-sulfur clusters, in thioester cofactors that persist. The intein's sulfur appears in no product. It is present only in the intermediate, and the finished protein carries no trace of it. A search organized around what is left behind will not find a mechanism whose whole character is that it leaves nothing behind.

The author identified this gap. It is recorded here as his, and the correction stands in his name.

1472. The Second Sulfur in the Same Envelope ↩

Ras is held to the membrane by a cysteine

The same set of documents carries a second sulfur mechanism that this volume also lacked, and it belongs to the most studied oncogene in medicine.

Ras proteins end in a CAAX motif — cysteine, two aliphatic residues, and a variable terminal residue. A prenyl group, either farnesyl or geranylgeranyl, is attached covalently to that cysteine. Xu and colleagues state the operation directly: the modification occurs by covalent addition of isoprenoids to cysteine residues at or near the carboxyl terminus of proteins possessing a CaaX motif, such as the Ras small GTPase family, and the attachment of the hydrophobic prenyl group anchors the protein to intracellular membranes and triggers downstream signaling.

Ras is a signaling switch that only functions at the membrane, and the thing that puts it there is a lipid tied to a sulfur atom. Remove the cysteine and the protein is made, folded and functional in every respect except that it is in the wrong place, and therefore does nothing.

1473. And the Drug Target Is a Cysteine That Should Not Be There ↩

KRAS was considered undruggable for thirty years. Mathieu and colleagues summarize that history without sentiment: KRAS has been the subject of extensive drug-targeting efforts aimed at the protein itself, its post-translational modifications, its membrane localization, its protein interactions and its downstream pathways, and most of those strategies failed.

What broke the problem was a mutation. Glycine at position twelve becomes cysteine in the G12C variant, found in a third of lung and roughly half of colorectal and pancreatic cases carrying KRAS mutations. Sotorasib and adagrasib are covalent binders that target that mutated cysteine twelve and occupy the switch II pocket.

The drug does not bind the oncogene. It binds a sulfur atom the oncogene acquired by accident. Thirty years of failure against a

protein ended when the protein mutated in a way that gave chemistry something to hold on to, and what it gave was a thiol.

Section 1440 took apart the thiopurines as hypoxanthine with sulfur substituted at carbon six. This is the same pattern in the other direction: not a drug built around sulfur, but a target that became druggable by acquiring one.

1474. Ras Runs on Both Switches ↩

Part One Hundred and Forty-Seven established that GTP is a switch — that it inhibits glutamate dehydrogenase at 0.20 millimolar and thereby decides whether an amine is destroyed or moved. Small GTPases are the other place the same nucleotide does the same job.

A small GTPase is active bound to GTP and inactive bound to GDP. Exchange factors load GTP and switch it on; activating proteins accelerate hydrolysis and switch it off. The molecule is a binary device and the bit is set by a guanine nucleotide.

three questions about one protein	what decides it	what the decider is made of
whether Ras is on	GTP bound or GDP bound	a purine nucleotide, made at the IMP branch point
whether Ras is anywhere useful	prenyl group on the CAAX cysteine	a sulfur atom
whether Ras can be drugged	cysteine at position twelve, present only when mutated	a sulfur atom

Three independent properties of the most consequential oncogene in human medicine, and every one of them is settled by either a purine nucleotide or a sulfur atom. Those are the volume's two subjects, and they are not being applied to Ras from outside. They are what Ras is built to run on.

1475. What the Notation Loses Here ↩

An intein leaves no mark. The mature protein's sequence contains no record that a segment was removed, and a sequence read from the finished product cannot be distinguished from a sequence that was never interrupted. Everything this volume has said about the record losing the chemistry applies here in its strongest form: the chemistry removes itself deliberately.

The prenyl group is lost the same way. It is not encoded, it does not appear in the translated sequence, and a gene record of KRAS says nothing about whether the protein it specifies is at a membrane or floating uselessly in the cytosol.

And the G12C mutation is the one thing in this Part the notation records perfectly — a single letter change, glycine to cysteine, visible in any sequencing read. It is also the only one of the three that produced a drug. That is not a coincidence to pass over. The pharmaceutical industry solved the part of the problem the notation could see.

1476. What This Part Refuses ↩

No claim that inteins are ancestral to the ribosome, or that one mechanism descends from the other. They are unrelated systems reaching the same chemical solution, and convergence on a solution is evidence about the solution, not about lineage. Section 1405's ruling on strata applies: these are two instances of one chemistry, not two stages of one history.

No claim about why inteins exist. Their biological function is disputed — selfish element, regulatory device, or accident retained — and this Part takes no position, because the mechanism is what matters here and the mechanism holds whichever answer is right.

No therapeutic claim regarding KRAS. Sotorasib and adagrasib are approved agents with published trial data, and nothing in this Part adds to or qualifies that evidence.

1477. The Experiment This Part Generates ↩

Experiment Seventy-Three	
question	Does the N-to-S shift require anything beyond proximity? Schwarzer's homocysteine result says no base is needed. If that is right, the shift should occur in a minimal construct carrying no intein fold at all.
design	Synthesize a short peptide with a single cysteine placed at the position an intein's Cys1 occupies, in a sequence context with no intein scaffolding. Look for thioester formation by mass spectrometry under physiological conditions, with no enzyme and no cofactor present.
prediction if proximity is sufficient	A detectable thioester population forms, slowly, with no catalyst. The intein fold accelerates a reaction that would happen anyway — which is the same relationship the ribosome has to the peptide bond.
prediction if it is not	Nothing forms without the fold, and the intein is doing real catalytic work that the homocysteine experiment did not isolate. The volume then narrows section 1468 to what the paper actually showed and stops extrapolating from it.
why the second outcome would be useful	It would establish a boundary on the proximity argument, which this volume has now applied to two systems and should not apply to a third without knowing where it stops.
cost	Solid-phase peptide synthesis and a mass spectrometer. No living material.

PART ONE HUNDRED AND FORTY-NINE · BOTH THEORIES, BOTH ENDS

1478. The Question This Volume Declined to Answer ↩

A refusal, reopened, because it was the wrong refusal

Section 1476 states, among the things Part One Hundred and Forty-Eight will not claim: no position on whether the metabolic theory of cancer is correct against the somatic mutation theory.

That refusal was correct in what it declined and wrong in what it assumed. It assumed the only available move was to choose between the two theories. It is not.

There is a third position, and the volume had already assembled every piece of it without ever setting them beside one another. Sulfur is present at the cause and at the treatment of both theories. Not as a theme and not as an analogy — as the specific chemistry, named, in all four places.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

The author identified this. The sections that follow are the volume's own material, rearranged into the table it should have contained.

1479. Where the Money Is Bet ↩

Not which account is right — which account is funded

The author's observation is about capital, not about truth, and this Part is built on his framing rather than on a scientific adjudication. The two accounts below are the two that receive the government grants and the corporate research budgets. Whether either is correct is a separate question that this Part does not open.

the two places research capital goes	what buying into it funds
the somatic mutation account	Cancer originates in damage to the nuclear genome, and the way to act on it is to sequence, catalog and target the mutations. This is the account that built the cancer genome atlases, the oncogene pipelines and the targeted-therapy industry.
the metabolic account	Cancer originates in damage to respiration, with genomic instability following rather than leading. This is the account behind metabolic therapy, the ketogenic and glutamine-restriction programs, and the mitochondrial drug efforts.

One anchor is checkable and worth printing for scale. The Cancer Genome Atlas alone carried over three hundred million dollars in total funding across more than two dozen institutions, and that is a single program inside the first account rather than the account's whole budget.

The relevant fact for this Part is not which side is winning the argument. It is that essentially all of the money is placed on one or the other, and that a finding present in both is therefore a finding that does not depend on the wager being settled.

1480. Cell One — Sulfur at the Genetic Cause ↩

The largest single source of endogenous mutation in the human genome is deamination at a methylated CpG, and the volume has the numbers.

the CpG hotspot, from Part One Hundred and Three	
share of mutations behind human inherited disease at CpG sites	about one third
C-to-T at methylated CpG, against other transitions	ten to fifty times the rate
observed CpG mutation frequency against chance expectation	about fifteen-fold
why the damage is not repaired	a methylated cytosine deaminates to thymine rather than uracil, and thymine is invisible to the base excision repair that removes uracil

Now ask where the methyl comes from. It is donated by S-adenosylmethionine, and S-adenosylmethionine is a sulfonium — a positively charged sulfur with three bonds, which is why it can give a methyl away at all. An ordinary thioether will not donate a methyl. A sulfonium will, and does, in more than two hundred distinct human enzymes.

So the chemistry that creates the hotspot is sulfur chemistry. A sulfonium places a methyl on cytosine; the methylated cytosine deaminates to a base the repair system cannot recognize as wrong; and that single fact accounts for roughly a third of the mutations behind human genetic disease. The methyl that regulates the gene is the same chemical event that hides the damage — and a sulfur atom delivers it.

1481. Cell Two — Sulfur at the Genetic Solution ↩

The treatments that act on the genetic account are sulfur compounds, and two of them are in this volume already.

what is given to patients	what it is made of
the thiopurines	Azathioprine, mercaptopurine and thioguanine have been standard leukemia therapy since the nineteen-fifties. Section 1440 takes them apart: 6-mercaptopurine is hypoxanthine with sulfur in place of oxygen at carbon six, HPRT1 phosphoribosylates it to 6-thioinosine monophosphate, and TPMT disposes of it by placing a methyl on the sulfur.
the KRAS covalent inhibitors	Section 1473: thirty years of failure against KRAS ended when the G12C mutation supplied a cysteine at position twelve. Sotorasib and adagrasib bind that sulfur atom covalently. The drug does not bind the oncogene; it binds a thiol the oncogene acquired.

One of these is the oldest targeted therapy in oncology and the other is among the newest. Seventy years apart, and both of them work by putting a sulfur atom where the chemistry can use it.

1482. Cell Three — Sulfur at the Metabolic Cause ↩

Part One Hundred and Forty-Six established the first half and Part One Hundred and Forty-Seven the second.

the two metabolic defects, and what they are made of	
the lipid	Seyfried reports immature cardiolipin species in tumor mitochondria, with impaired respiration alongside. Immature cardiolipin is cardiolipin that has not been remodeled, and remodeling is an acyl transfer performed by tafazzin — a transacylase of the class that runs on a carbon-sulfur thioester. Section 1449.
the switch	Succinyl-CoA is a thioester, and breaking that carbon-sulfur bond is what phosphorylates GDP to GTP without oxygen. That GTP inhibits glutamate dehydrogenase at 0.20 millimolar, which decides whether the cell destroys an amine or moves it. Section 1461.

The defect at the center of the metabolic theory is a failed acyl transfer, and the switch that sets the tumor mitochondrion's nitrogen policy is paid for by a thioester. Both are sulfur bonds doing work that nobody describes as sulfur chemistry.

1483. Cell Four — Sulfur at the Metabolic Solution ↩

what acts on the metabolic account	what it is
nano-sulfur	Biogenic sulfur nanosheets kill lung carcinoma at 9.5 micrograms per milliliter and normal lung fibroblast at 443.8 — a window of forty-seven to one, through the mitochondrial apoptotic pathway. Elemental sulfur, cut thin. Section 1444.
the tafazzin dependency	Interfering with cardiolipin maturation kills leukemia cells while leaving normal haematopoiesis intact under basal conditions. Seneviratne and colleagues, 2019, recorded at section 1450 as prior art.

Neither of these is a mature therapy and this volume does not present them as one. They are the two places where acting on the metabolic account has produced a selective effect, and both of them are sulfur — one as the agent, one as the target.

1484. The Table, Whole ↩

Four cells, and sulfur is named in every one

	the cause, in sulfur	the treatment, in sulfur
THE SOMATIC MUTATION THEORY	A sulfonium donates the methyl that makes 5-methylcytosine. The methylated cytosine deaminates to thymine, which repair cannot see. One third of inherited-disease mutations.	Thiopurines — hypoxanthine with sulfur at carbon six. KRAS G12C inhibitors — covalent binding to an acquired cysteine.
THE METABOLIC THEORY	Cardiolipin maturation fails; the enzyme is a thioester-class acyltransferase. Succinyl-CoA, a thioester, makes the GTP that sets the deamination switch.	Sulfur nanosheets at a forty-seven-fold window. Tafazzin dependency with a normal-tissue margin.

The two theories have been argued against each other for a hundred years. Sulfur is in all four cells of the argument. That is not an argument for either side, and this Part does not offer it as one. It is an observation about what the two sides are made of.

1485. One Reading of Why, Marked as a Reading ↩

Why sulfur should appear in all four cells is a separate question from the fact that it does, and the fact does not depend on the answer. What follows is this volume's own interpretation and is marked as interpretation rather than finding.

Section 1405 distinguished two strata — the chemical, where bonds are made and broken, and the molecular, where sequences are read and written — and Part One Hundred and Forty-Four ordered them. On that reading the two funded accounts are each betting on a different stratum, and sulfur appears in both because sulfur operates at the boundary between them. The sulfonium that methylates a cytosine is chemistry acting on a nucleic acid. The thioester that phosphorylates GDP is chemistry paying for a molecular switch.

That reading may be wrong, and section 1484 survives if it is. The table is a set of four sourced observations. This section is one attempt to say why they line up, offered as such, and a reader who rejects it loses nothing in the cells above.

It does suggest why neither literature names the atom. A researcher funded to find mutations has no reason to describe S-adenosylmethionine as a sulfonium, and one funded to find metabolic defects has no reason to describe succinyl-CoA as a sulfur bond. Each names the part its own program is paying for, and the atom that is in both gets named by neither.

1486. The Position That Does Not Require the Bet to Settle ↩

Here is what follows from section 1484, stated without reference to which account is correct.

A research program built on the somatic account is hostage to that account being right. A program built on the metabolic account is hostage to that one. A program directed at the chemistry that appears in the cause and the treatment of both is hostage to neither.

That is a claim about risk rather than about biology. The two funded accounts have been arguing since Boveri and Warburg and the argument has not resolved in a century. Any work that has to wait for it to resolve waits indefinitely. Work aimed at what the two have in common does not wait, and is not made wrong by either outcome.

The author's framing puts it more directly than this volume would have: the money is on two horses, and the same atom is in both animals.

What does not follow is that sulfur causes cancer, or that sulfur is the explanation of it. Presence in four cells is presence. This volume has been explicit elsewhere that an element appearing throughout a process is not a demonstration that the element governs the process, and sulfur is abundant enough in biochemistry that some of its appearance here is what abundance produces. Section 1489 is written to test exactly that.

1487. What the Notation Loses Here ↩

Every cell in the table of section 1484 is written, in its own literature, without the sulfur. The methyl donor is drawn as a methyl group with an arrow. Succinyl-CoA is drawn as an energy intermediate. Tafazzin is written as an acyltransferase. The thiopurines are written as antimetabolites. In four separate fields, the working notation records what the molecule does and drops what it is made of.

That is the same loss the volume documents for inosine written as G, for the modified nucleosides written as their parents, and at section 1475 for the intein that removes itself and leaves no record. The pattern is consistent enough to be worth naming as a rule: notations retain the identity of what persists and discard the identity of what carries.

1488. What This Part Refuses ↩

No adjudication between the two accounts. This Part is constructed so that it does not need one, and if it were used to argue for either side it would be being used wrongly. The author has been explicit that he asserts neither account is correct; what he asserts is that these are the two that are funded.

The characterization of the funding landscape at section 1479 is the author's observation. The Cancer Genome Atlas figure is checkable and is checked. The broader claim that these two accounts receive essentially all of the research capital is his, is not accompanied here by a budget analysis, and is printed as his rather than as a retrieved statistic.

No claim that the four cells are equally strong. Cell one rests on measurements this volume has checked. Cell two rests on approved drugs with trial data. Cell three rests on published biochemistry and one book's lipid measurements. Cell four rests on cell-line work at twenty-four hours and one CRISPR screen. A table with four filled cells is not four equal claims and should not be read as one.

And no therapeutic recommendation of any kind. Nothing in this Part should be read as advice about treatment.

1489. The Experiment This Part Generates ↩

Experiment Seventy-Four	
question	Is the appearance of sulfur in all four cells more than sulfur's background abundance in biochemistry would predict?
why it has to be asked	Section 1486 concedes that sulfur is common and that some of its appearance is what commonness produces. Until that is quantified, the table at 1484 is a pattern that has not been tested against chance.
design	Take the set of genes and enzymes implicated in each of the two theories — the cancer gene census on one side, the mitochondrial and metabolic gene sets on the other. Compute the frequency of sulfur-dependent cofactors, thioester intermediates, catalytic cysteines and iron-sulfur clusters in each set. Compare against a size-matched and expression-matched background drawn from the rest of the proteome.
prediction if the pattern is real	Sulfur-dependent chemistry is enriched in both sets relative to background, and enriched to a similar degree in each — which would say the two theories draw on the same chemistry rather than on different chemistries that happen to share an element.
prediction if it is not	The frequency matches background. Sulfur is in all four cells because sulfur is everywhere, the table at 1484 is a selection effect, and this Part reduces to a list of four true facts with nothing joining them.
why the null result matters	It is the falsification this volume most needs and has least often written. The permutation test at Part One Hundred and Forty-One was specified in advance and returned null; this one should be specified the same way, before the count is run.
cost	Public gene sets, public annotation, one afternoon of computation. There is no reason this has not been done.

PART ONE HUNDRED AND FIFTY · THE PARTICLE THAT FATHERED THE TRANSPOSON

1490. One Gene, Two Colors ↩

Where the largest inosine reservoir in the human genome came from, and what the parent molecule recognizes with

Part Sixty established that Alu is not merely where editing happens but the machine that manufactures the substrate: inverted Alu pairs fold back on each other and make the double-stranded RNA that ADAR requires. That Part took Alu as given.

This Part asks where Alu came from, and the answer places sulfur at the origin of the orange.

The Alu element is a retrotransposed, duplicated derivative of 7SL RNA — the RNA component of the signal recognition particle. Section 552 recorded this in passing, in the course of a different argument. It is recorded here as a spine.

the lineage	
the ancestor	7SL RNA, transcribed by RNA polymerase III from RN7SL1 on chromosome 14, about 300 nucleotides, the RNA core of the signal recognition particle
the descendant	the Alu element, about 300 base pairs, two similar monomers joined by an A-rich linker, over one million copies, more than ten percent of human DNA
what the descendant does in this volume	carries the overwhelming majority of adenosine-to-inosine editing in the human transcriptome
what the ancestor does in the cell	recognizes the signal peptide of a nascent protein and arrests translation until the ribosome reaches the membrane

The same locus therefore stands upstream of both of this volume's two dominant colors. The orange — inosine — descends from it by retrotransposition. The yellow — sulfur — is what it recognizes with. That is the claim of this Part and the rest of it is the evidence.

1491. What the Particle Recognizes With ↩

The methionine-rich domain, and the experiment that isolated it

The signal recognition particle must bind the signal peptide of every secreted and membrane protein the cell makes. Those peptides share no sequence. They share only a stretch of hydrophobic residues of variable length and composition. The recognition problem is therefore the opposite of the usual one: the binding site must be specific for a class and indifferent to sequence.

The subunit that does it is SRP54, and the part of SRP54 that does it is called the M domain, for methionine.

Lütcke, High, Römisch, Ashford and Dobberstein showed by photo-crosslinking that a signal sequence contacts only the methionine-rich domain of SRP54; that free SRP54 binds signal sequences without the

rest of the particle; that the M domain alone suffices; and that an essentially intact M domain is required. EMBO J 1992;11:1543-1551.

Four findings, and together they isolate the recognition surface to one domain named for one amino acid. That amino acid carries a sulfur atom in its side chain.

1492. The Count, Performed Here ↩

Methionine density in human SRP54, by domain, computed from the sequence

The name of the domain is a claim about composition, and a claim about composition can be checked. The human SRP54 sequence was taken from UniProt P61011, 504 residues, and the methionine residues counted by position.

region of human SRP54	residues	methionines	share
whole protein	504	33	6.55%
N domain, residues 1-100	100	4	4.00%
G domain, the GTPase, residues 101-300	200	5	2.50%
M domain, residues 301-504	204	24	11.76%
the last hundred residues	100	15	15.00%

The methionine density of the recognition domain is roughly five times that of the GTPase domain in the same protein, and rises to fifteen percent across the final hundred residues. Against a human proteome average near two percent, the binding site for every signal peptide in the cell is a sulfur-lined surface by a wide margin.

The structural account matches. Keenan, Freymann, Walter and Stroud solved the signal-sequence-binding subunit and describe a deep groove bounded by a flexible loop and lined with conserved hydrophobic side chains — a flexible hydrophobic environment whose plasticity is what lets one site accept peptides of different lengths and sequences. Cell 1998;94:181-191.

1493. And the Bacterial Exception, Which Sharpens It ↩

The same count run on a thermophile

The Keenan structure is of Ffh, the SRP54 homolog of Thermus aquaticus. Its authors name conserved hydrophobic residues rather than methionines, and the reason is visible in the sequence.

protein	residues	methionine, whole protein	methionine, C-terminal M domain	methionines in the last hundred residues
human SRP54, UniProt P61011	504	6.55%	11.76%	15
Thermus aquaticus Ffh, UniProt O07347	430	2.79%	4.02%	5

The thermophile solves the same recognition problem with a groove that is barely enriched in methionine at all. So the methionine bristle is not a universal requirement of signal recognition. It is the solution this lineage adopted — and it is the solution present in the organism whose genome the Alu element went on to colonise.

This is the correct form of the claim and the volume states it in that form. Hydrophobic plasticity is the requirement. Sulfur is how eukaryotes supply it.

1494. A Thiol Reagent Switches It Off ↩

The sulfur is not decorative, and there is an experiment that says so

In the same 1992 paper, alkylation of the N and G domains of intact SRP54 with N-ethylmaleimide prevented a signal sequence from binding to the M domain. After the protein was cut with V8 protease, the same treatment no longer prevented it.

N-ethylmaleimide reacts with free thiols. The reagent that interrupts signal recognition is a sulfur reagent, and the interruption is allosteric — it acts at a distance, through a domain contact, on a binding site named for a sulfur-bearing residue.

Part One Hundred and Forty-Eight argued that a cysteine side chain performing an N-to-S acyl shift is the pivot of protein splicing. Here a

cysteine side chain being capped is the off switch for protein targeting. Two different operations, one atom, both load-bearing.

1495. The Other Half of the Particle Is Called the Alu Domain ↩

The name is not an analogy

The SRP RNA has two ends and they do different jobs. The large domain carries SRP54 and the signal peptide. The small domain — the 5-prime and 3-prime extremities folded together — is called the Alu domain, and it binds the SRP9/14 heterodimer. That module is what contacts the ribosome and pauses elongation while the complex finds the membrane.

Bousset, Mary, Brooks, Scherrer, Strub and Cusack solved a chimeric Alu domain at 3.2 angstroms and showed that highly conserved non-canonical base pairs allow unusually tight side-by-side packing of the 5-prime and 3-prime stems within the SRP9/14 binding surface, in a closed conformation competent to elicit elongation arrest. RNA 2014;20:1955-1962.

Note what the structure turns on: non-canonical base pairs. Not Watson-Crick. The closed conformation that makes elongation arrest possible is held shut by pairings the four-letter notation has no symbol for, in the domain that gave the transposon its name.

1496. The Protein Still Grips Its Own Descendants ↩

And the grip weakens with evolutionary distance, which is the part that matters

The SRP9/14 heterodimer does not only bind the Alu domain of its own RNA. It binds free Alu-derived transcripts across the genome.

Bovia, Wolff, Ryser and Strub, Nucleic Acids Res 1997;25:318-326	
what binds	human and mouse SRP9/14 bind with high affinity to a range of Alu-like RNAs of different evolutionary ages, including the neuron-specific BC200 RNA

Bovia, Wolff, Ryser and Strub, Nucleic Acids Res 1997;25:318-326	
the ordering	the relative dissociation constants are inversely proportional to the evolutionary distance between the Alu RNA species and 7SL RNA
the inference the authors draw	the conservation of high-affinity interactions strongly indicates that these Alu-like ribonucleoproteins exist in vivo and have cellular functions
the species difference	human SRP9/14 binds better than the mouse protein to distantly related Alu RNAs, including recently transposed elements
what the authors propose	the anthropoid-specific excess of SRP9/14 may have a role in controlling Alu amplification rather than compensating a defect in SRP assembly

Affinity that falls off with evolutionary distance is a molecular clock read by binding energy. The parent protein still recognizes its own transposed children, and recognizes the recent ones best. The particle and the parasite have never separated.

1497. And the Children Are Where the Inosine Is ↩

The scale of it, from two independent studies a decade apart

Athanasiadis, Rich and Maas identified intramolecular pairs of Alu elements as the major target for editing in the human transcriptome, and concluded that modification of repetitive elements is a predominant activity for RNA editing. PLoS Biol 2004;2:e391.

Bazak, Haviv, Barak, Jacob-Hirsch, Deng, Zhang, Isaacs, Rechavi, Li, Eisenberg and Levanon went further with ultradeep sequencing and reported that virtually all adenosines within Alu repeats that form double-stranded RNA undergo A-to-I editing, most at low levels, and estimated over one hundred million human Alu editing sites located in the majority of human genes. Genome Res 2014;24:365-376.

7SL RNA → retrotransposition → Alu → inverted pairs → double-stranded RNA → ADAR → inosine

One hundred million sites. Every one of them a molecular character the genetic alphabet writes as G. The largest single reservoir of unlettered characters in the human genome is a copying error made from the gene for the sulfur-recognition machine.

1498. The Two Colors Meet at One Locus ↩

Stated once, plainly, with the shares this volume actually measured

The color census of this volume returned yellow at 27.8 percent of all colored marks and orange at 17.9 percent — 45.6 percent of the book between them. Those two colors are sulfur and inosine.

color	what it carries	share of the volume	what it is doing at this locus
yellow	sulfur	5,620 marks, 27.8%	the M domain of SRP54: the recognition surface, methionine-lined, eleven to fifteen percent sulfur-bearing residues
orange	inosine	3,624 marks, 17.9%	the Alu element: a duplicated copy of the same particle's RNA, and the site of over a hundred million editing events

The volume did not choose this locus to make the point. The point is that the two most heavily painted colors in fifteen hundred pages converge on a single ribonucleoprotein and its retrotransposed shadow — one of them the recognition chemistry, the other the mutational channel.

1499. What the Notation Loses Here ↩

Written in the alphabet, an Alu element is three hundred letters of A, T, G and C, and a hundred million of its adenosines that have become inosine are written as G. The record of the retrotransposition survives; the record of the editing does not.

Written in the alphabet, the M domain is a string of single letters in which M is one character among twenty. Nothing in that notation records that the M is the only one of the twenty carrying a sulfur atom in a thioether, or that its density in this domain is five times its density two hundred residues away in the same chain.

Two erasures, one at each end of the same lineage. The chemistry that does the recognizing is invisible in the protein notation; the chemistry that does the editing is invisible in the nucleic acid notation. The

color system restores both and the restoration is the same restoration.

1500. The Prior Art, Before the Argument Goes Further ↩

Every link in the preceding chain is published, and the volume claims none of them.

the claim	where it comes from	status
Alu derives from 7SL RNA	standard, textbook, long established	prior art
the M domain of SRP54 is methionine-rich and binds signal sequences	Lütcke et al. 1992; Keenan et al. 1998	prior art
the SRP RNA's small domain is the Alu domain and binds SRP9/14	long established; structure at 3.2 angstroms by Bousset et al. 2014	prior art
SRP9/14 binds Alu-like RNAs with affinity ordered by evolutionary distance	Bovia et al. 1997	prior art
Alu is the dominant site of A-to-I editing in humans	Athanasiadis et al. 2004; Bazak et al. 2014	prior art
the methionine densities and the human-versus-Thermus comparison at 1492 and 1493	computed for this Part from UniProt P61011 and O07347	this volume
the observation that the two dominant colors of this volume converge on one locus	this Part	this volume

What is new here is the assembly and the arithmetic, not the biology. The biology has been sitting in four separate literatures that do not cite one another, which is the condition this volume was built to address.

1501. What Nobody Appears To Have Asked ↩

And it is a small question with a cheap answer

SRP9/14 binds the Alu domain through a closed conformation stabilized by specific non-canonical base pairs. ADAR converts adenosine to inosine in Alu RNA at

enormous density. Inosine does not pair like adenosine — it pairs like guanosine in a Watson-Crick geometry and it changes duplex stability wherever it lands.

So: does editing change the grip? Nobody appears to have measured whether A-to-I editing of an Alu transcript alters its affinity for SRP9/14, in either direction.

The question matters because of what Bovia and colleagues proposed. If the anthropoid excess of SRP9/14 has a role in controlling Alu amplification, and if editing changes the affinity, then the editor is a regulator of retrotransposition through an RNA-binding protein rather than through the RNA's coding content. That is a mechanism, it is stated here as a hypothesis, and it has not been shown.

1502. The Experiment This Part Generates ↩

Experiment Seventy-Five	
question	Does adenosine-to-inosine editing of an Alu transcript change its affinity for the SRP9/14 heterodimer?
the feasibility now	Both halves are off-the-shelf. Recombinant human SRP9/14 has been purified and used in binding assays since the 1990s. Synthetic RNA with inosine at defined positions is a catalog item.
design	Transcribe or synthesize a defined Alu RNA in three forms: unedited; edited at the positions most frequently edited in vivo; and edited at an equal number of positions chosen at random. Measure dissociation constants against recombinant SRP9/14 by filter binding or gel shift, the same assay Bovia and colleagues used to establish the evolutionary-distance ordering.
prediction if editing regulates the grip	The edited RNA's dissociation constant differs measurably from the unedited, and the in-vivo-positioned edits differ from the randomly placed ones by more than the number of substitutions alone would predict. Position carries information.
prediction if it does not	All three bind indistinguishably. SRP9/14 reads backbone and shape rather than base identity at the edited positions, the hypothesis fails cleanly, and the negative result is worth publishing because it constrains every model in which editing regulates Alu mobility through protein binding.
the second arm, if the first is positive	Repeat in cells. Compare SRP9/14 occupancy on Alu transcripts in ADAR1-competent and ADAR1-depleted cells by crosslinking and immunoprecipitation. The reagents exist; the comparison has not been made.
cost	One recombinant heterodimer, three RNA preparations, one binding assay. No new instrument and no new reagent.

1503. What This Part Refuses ↩

No claim that the signal recognition particle was built out of sulfur for the reasons this volume cares about. The methionine bristle is a hydrophobicity solution; the Thermus comparison at section 1493 is recorded precisely because it shows the same problem solved with less sulfur, and any account that suppresses that comparison is suppressing evidence.

No claim that the 7SL ancestry of Alu means the editing is purposeful. Retrotransposition is a copying accident and inverted-repeat formation is a consequence of copy number, not of design. That the parent molecule uses sulfur to recognize peptides and the descendant sequence is where inosine accumulates are two facts about one lineage; this Part does not assert a causal arrow between them.

And no claim to the convergence being predictive. The two colors meet at this locus, and the volume records it because it is striking and because it is checkable. One locus is an observation, not a law.

PART ONE HUNDRED AND FIFTY-ONE · THE BAR CODE HAS TWO CHANNELS

1504. The Plate, and What It Encodes Twice ↩

A hand-colored drawing made years before the software, and the thing it encodes that nobody asked it to

Among the plates in this archive is a hand-lettered rendering of DNA replication and transcription to messenger RNA. The bases are colored by hand: adenine red, thymine yellow, guanine green, cytosine blue, uracil purple. Below the drawing the five bases are set out as structures, and inside those structures the atoms are colored too — nitrogen green, oxygen orange, hydrogen red.

That is the color system of this volume, on paper, at both strata at once, drawn before any software existed to apply it. But the plate carries something the color system alone does not.

Between the two strands the artist drew the hydrogen bonds as tick marks. Two marks where adenine faces thymine. Three marks where guanine faces cytosine. So every rung of the ladder carries a color and a count, and the eye takes in both without being instructed.

Which makes the plate a bar code with two independent channels rather than one. Identity is carried in hue. Bond order is carried in stroke count. Neither channel requires the other and neither is written in the genetic alphabet.

1505. The Full Set, In Color ↩

Eight characters, seven colors, and the bond count each one brings

The plate's legend carries five characters because five is what the alphabet has. The volume's palette carries eight, on seven colors, because indigo does double duty. Set out in full, with the color printed rather than named:

the character, in its own color	the element the color also carries	bond channel	status in the alphabet
ADENINE · A	hydrogen	two, to thymine or to uracil	in the alphabet
THYMINE · T	sulfur	two, to adenine	in the alphabet · DNA only
GUANINE · G	nitrogen	three, to cytosine	in the alphabet
CYTOSINE · C	carbon	three, to guanine	in the alphabet
URACIL · U	phosphorus	two, to adenine	in the alphabet · RNA only
INOSINE · I	oxygen	two, to cytosine	MISSING · written as G
XANTHINE · X	selenium	two, to cytosine, with a repulsive contact where guanine's third bond was	MISSING · written as damage or read through
OROTATE · O	selenium	not a pairing partner; the gateway through which every pyrimidine is built	MISSING · has no place in the notation at all

Five rows are in the alphabet and three are not. Every one of the three that is not brings two hydrogen bonds where the letter it gets written as brings three. The missing characters are not only absent from the

color channel — they are systematically weaker in the bond channel, which is the channel nobody records.

1506. The Rungs, and What Each One Says Twice ↩

The same set read as pairs rather than as characters

the rung	color channel	bond channel	the meaning
ADENINE · THYMINE	red faces yellow	two	the weak rung; this is where the ladder opens
ADENINE · URACIL	red faces purple	two	the same count in RNA, a different color on the second position
GUANINE · CYTOSINE	green faces blue	three	the strong rung; three donors and acceptors in register
INOSINE · CYTOSINE	orange faces blue	two	guanine's partner, guanine's letter, adenine's bond count
XANTHINE · CYTOSINE	indigo faces blue	two, impaired	what a guanine becomes when it is deaminated

Read the fourth row against the third. Inosine holds the same partner that guanine holds and is written down as guanine — with two hydrogen bonds where guanine has three. In the color channel the substitution shows as orange where green was expected. In the bond channel it shows as a missing stroke. Two independent tells for one event.

The plate would therefore catch an inosine twice. The four-letter alphabet catches it zero times.

1507. The Lone Guanine ↩

The first of the two observations this Part was built around

A ladder drawn as rungs invites a question the letters never raise: what about the rungs that are not there? Wherever a duplex is open — a replication fork, a transcription bubble, a displaced strand, a hairpin loop, a single-stranded overhang — bases sit without partners.

And the observation is this. Where a guanine and a cytosine are not hydrogen bonded to each other, it is the lone guanine that becomes the target of the inosine read, or the inosine misread.

Two distinct things converge on that one unpartnered position, and the volume separates them before joining them.

the two problems at a lone guanine	
the reading problem	A sequencer writes G for guanine and G for inosine alike. At any position reported as G, the record cannot say which molecule was there. The ambiguity is not confined to unpaired positions — but an unpaired position is where there is no partner base to corroborate the call.
the chemical problem	An unpaired base is a chemically exposed base. Deamination of guanine produces xanthine, and the rate of that reaction depends on whether the base is held in a duplex.

The first is an artefact of notation. The second is a fact about chemistry, and it has been measured twice by different groups using different methods.

1508. Pairing Is Protection, and the Protection Has Been Quantified ↩

Two measurements, eight years apart, in agreement

Frederico, Kunkel and Shaw built a genetic assay sensitive enough to detect a single deamination event against a background of one in two hundred thousand, and used it to measure the rate at which cytosine deaminates in DNA.

Frederico, Kunkel and Shaw, Biochemistry 1990;29:2532-2537	rate constant	what it comes to
cytosine in single-stranded DNA, 37 degrees, pH 7.4	1 x 10^-10 per second	half-life about 200 years
cytosine in double-stranded DNA, same conditions	about 7 x 10^-13 per second	half-life on the order of 30,000 years
the ratio		deamination is approximately 140-fold slower inside the double helix

A hundred and forty fold. The difference between a base that is held and a base that is not is the difference between two centuries and

three hundred centuries. The hydrogen bonds the plate draws as tick marks are not bookkeeping. They are the shield.

Caulfield, Wishnok and Tannenbaum approached the same question from the nitrosative side, delivering nitric oxide to deoxynucleosides and to single- and double-stranded oligonucleotides and measuring the deamination products by mass spectrometry.

Caulfield, Wishnok and Tannenbaum, J Biol Chem 1998;273:12689-12695	
single-stranded oligomers versus free deoxynucleosides	five times more reactive toward the nitrosating agent
double-stranded oligomers versus single-stranded	ten-fold less reactive
the authors' conclusion	Watson-Crick base pairing protects DNA from deamination
G-quartet structures	also protective, attributed by the authors to hydrogen bonding

Two laboratories, two chemistries, one conclusion: the bond count is the protection. Which means the second channel of the bar code is not decorative. It is reporting the vulnerability of the position it marks.

1509. And the Lone Guanine Makes the Second Missing Letter ↩

The part of the same paper that decides this section

The Caulfield study did not only compare structures. It compared the two halves of the pair.

Within a G:C base pair, nitrosative deamination converts guanine to xanthine and cytosine to uracil. The authors measured both products in the same experiment.

Xanthine was formed at twice the rate of uracil.

So at an exposed G:C position the guanine is the preferential casualty — twice as often as its partner — and the molecule it becomes is xanthine.

guanine → deamination → xanthine → written by the sequencer as nothing it has a letter for

Which is the second of the three missing characters. Section 1496 recorded that indigo carries xanthine four hundred and fifty-four times in this volume. This section records where xanthine comes from: a guanine that was not holding a cytosine when the chemistry arrived.

1510. Three Characters Collapsed Onto One Letter ↩

And the structural requirements point in opposite directions, which is the interesting part

what is physically present at the position	how it got there and what it looks like in the bar code	what the record says
a real guanine	inherited; three hydrogen bonds to cytosine; green in the plate	written G
an inosine	made from adenine by ADAR, which requires a double-stranded substrate; two hydrogen bonds to cytosine; orange in the plate	written G
a xanthine	made from guanine by deamination, which is ten-fold faster when the base is unpaired; indigo in the plate	written as a damaged or ambiguous base, or read through

Note the asymmetry, because it is the finding of this section and it is not obvious.

Inosine is manufactured where the strand is paired. Xanthine is manufactured where the strand is not. Opposite structural requirements, opposite halves of the bar code's second channel — and both of them end up, in the record, at a position that reads as guanine or as nothing at all.

A notation that had a symbol for each would place them in different places on the map. A notation with four letters places them nowhere, and the position that reads G is doing the work of at least three distinct molecular histories.

1511. The Other End of the Bar Code: Where A and T Let Go ↩

The second observation, and it runs the opposite way from the first

Section 1507 asked what happens at the strong rung when it comes apart. This section asks the prior question: which rung comes apart first.

The answer is in the bond channel and nowhere else. Adenine and thymine are held by two hydrogen bonds. Guanine and cytosine are held by three. A duplex does not open everywhere at once. It opens where the strokes are fewest.

The thermodynamics have been measured exhaustively. SantaLucia reconciled seven laboratories' nearest-neighbor parameters into a single set derived from 108 oligonucleotide duplexes, and the consequence for this argument is the one every molecular biologist uses daily: a sequence rich in adenine and thymine melts at a lower temperature than one rich in guanine and cytosine, and does so predictably. PNAS 1998;95:1460-1465.

Which is why the cell puts its opening points where it does. The bacterial origin of replication carries a run of adenine-thymine-rich repeats — the DNA unwinding element — and that is the segment at which the two strands are first prised apart. Eukaryotic origins and the melting regions of promoters carry the same signature. The TATA box is named for its composition.

So the question is answered, and answered in the plate's own second channel: yes. Where adenine and thymine are not bonded is where the double strand becomes two single strands. The weak rung is the door.

1512. And the Door Opens Onto the Exposed State ↩

Joining this section to section 1508, which is where it becomes an argument rather than an observation

Put the two halves together and the bar code makes a prediction about damage that the alphabet cannot make.

the chain, stated in five steps	
1	A duplex opens preferentially where the bond count is two — that is, at adenine-thymine-rich stretches.
2	Opening produces single-stranded regions: replication bubbles, transcription bubbles, displaced strands, loops.
3	In single-stranded DNA, deamination runs roughly 140-fold faster than in the duplex, by direct measurement.
4	Any guanine that happens to sit inside that opened region is now unpaired, and unpaired guanine deaminates to xanthine at twice the rate its cytosine partner deaminates to uracil.
5	So the weak rung decides where the window opens, and the strong rung's guanine is what gets damaged through it.

The adenine-thymine content sets the location. The guanine pays the price. Neither statement can be made in a notation that records identity and drops bond order, and both fall out immediately from a drawing that counts strokes.

1513. And Where Thymine Becomes Uracil ↩

The second half of the question, and the color changes at exactly the same place

The opened region is also where transcription happens, and transcription substitutes one character for another. DNA has thymine. RNA has uracil. At every position in the message where the template said adenine, the product says uracil where the coding strand said thymine.

In the plate, that substitution is visible as a color change and nothing else: the messenger strand is drawn purple where the strand above it is yellow. Same position, same partner, same bond count — two, in both cases, to adenine.

the two characters	color	what the molecule is	where it is used
thymine	yellow	5-methyluracil	DNA
uracil	purple	uracil	RNA
the difference	yellow to purple	one methyl group at carbon five	and nothing else

Thymine is uracil with a methyl on it. That is the whole of the difference between the DNA character and the RNA character — one carbon and three hydrogens at position five — and the volume's color system assigns those two molecules different colors because the notation assigns them different letters. Which raises the question the next section answers: why does the methyl exist at all?

1514. The Methyl Marks DNA as DNA, and a Thiolate Puts It There ↩

Why the archive is methylated and the message is not

The methyl is not decoration and it is not arbitrary. It is a tag, and what it tags against is the damage described at section 1508.

When cytosine deaminates it becomes uracil. In RNA that is a mutation the cell largely tolerates, because the message is transient. In DNA it is a permanent corruption of the archive, and the cell defends against it with uracil-DNA glycosylase, an enzyme whose job is to find uracil in DNA and cut it out.

But that defense only works if uracil has no legitimate business being in DNA. Which is exactly what the methyl guarantees. Thymine is the methylated version of uracil, and the methyl is the cell's way of saying: this pyrimidine belongs here. Any unmethylated uracil found in the archive is, by definition, damage.

So the yellow-to-purple color change at section 1513 is not cosmetic. It is the difference between a character that is permitted in the archive and a character whose presence in the archive triggers excision.

And what installs the methyl

Thymidylate synthase makes the DNA character from the RNA one — deoxyuridine monophosphate to deoxythymidine monophosphate — and the first step of its mechanism is not the methyl transfer.

Kholodar and Kohen state it plainly: the enzymatic reaction is initiated by a nucleophilic activation of the substrate via formation of

a covalent bond to an active site cysteine. J Am Chem Soc 2016;138:8056-8059.

A cysteine thiolate attacks the pyrimidine ring and holds it while the methyl is delivered. The same chemistry recurs in the transfer-RNA version of the reaction: Hamdane and colleagues showed that TrmFO, which methylates uridine 54 to give ribothymidine, forms a covalent complex through a conserved cysteine — Cys-226 as the nucleophile, with a second conserved cysteine acting as the general base. J Biol Chem 2011;286:36268-36280.

the chain from the color change to the atom	
the character that distinguishes DNA from RNA	thymine, which is uracil plus a methyl at carbon five
what the methyl is for	it marks the pyrimidine as legitimate, so that unmethylated uracil in DNA can be recognized as damage and excised
what puts the methyl on, in DNA	thymidylate synthase, whose mechanism begins with a covalent bond from an active-site cysteine
what puts the methyl on, in transfer RNA	TrmFO, whose mechanism runs through a conserved cysteine nucleophile and a second conserved cysteine as base
the element in both cases	sulfur

Follow the plate's yellow from the base to the atom and it does not change color. Thymine is yellow because thymine is the volume's pairing for sulfur — and the methyl that makes thymine thymine is installed by a sulfur nucleophile. The assignment was made for reasons of notation. The chemistry underneath it turns out to agree.

1515. What the Notation Loses Here ↩

The alphabet records identity and drops bond order. There is no letter, no symbol and no field in any sequence format that says how many hydrogen bonds held a position — and bond order is what the papers at section 1508 show to be the determinant of chemical vulnerability, and what section 1511 shows to be the determinant of where the strands come apart.

The plate keeps it, in the crudest possible way, by drawing two strokes or three. A drawing made by hand carries a variable that a hundred-gigabyte sequencing file does not.

This volume has argued that the four-letter alphabet is three characters short. This Part adds a second and separate charge: it is also one channel short. Identity without bond order is half the information, and the missing half is the half that predicts both where the molecule opens and where it is damaged.

1516. The Second Sheet: the Over and the Underworld ↩

Why the popular account of element sixteen reads as it does

Also in the archive is a printed page titled Oxygen and Sulfur: the over and underworlds of group VIA, annotated in the author's hand with the question why humans are sulfur haters. The oxygen words are highlighted orange throughout and the sulfur words yellow, which is to say the page has been marked in this volume's own palette by a reader who did not need to be told which color went where.

The text itself is a fair specimen of the genre. Oxygen is a fifth of the air, the third most abundant element in the universe, just under half the Earth's crust, the shield in the upper atmosphere, and water. Sulfur is brittle, pale yellow, burns to a gas that becomes acid rain, and forms a fiendishly toxic hydride that smells of rotten eggs.

the conjugate pair, in one number	
oxygen, Pauling electronegativity	3.44
sulfur, Pauling electronegativity	2.58
the consequence	hydrogen bonding dominates in water and is nearly absent in hydrogen sulfide, which is why one is an ocean and the other is a gas

Same group, same valence, same number of outer electrons needed. The entire difference in reputation rests on an electronegativity gap of 0.86 — and on which of the two happens to hold the hydrogen bonds. The conjugate pair this volume has argued for a hundred Parts is the subject of that page, written up as a morality tale.

And note where that leaves the argument of this Part. Hydrogen bonding is the second channel of the bar code. It is also the single property that separates the over-world from the under-world on that page. The same variable is doing both jobs.

1517. The Passage Refutes Its Own Headline ↩

And it does so in its own last sentence, which is why the page is worth reproducing rather than arguing with.

After the acid rain and the rotten eggs, the author writes that whole colonies of creatures nevertheless live in the dark on energy metabolized by sulfur-breathing bacteria beside deep ocean volcanic vents bubbling hot hydrogen sulfide.

An entire biosphere, running on the underworld gas, in the final clause of a passage about how poisonous it is. The framing is cultural. The chemistry underneath the framing is an ecosystem.

This volume takes no position on the merits of popular science writing. It records the page because the reputation of element sixteen is part of the reason it went unwritten, and because the correction was already present in the text that maligned it.

1518. Why the Aversion Is Built In ↩

The answer to the annotation, and it is not cultural

Humans do not dislike hydrogen sulfide by convention. The human nose is among the most sensitive detectors of it that exists.

hydrogen sulfide and the human nose	figure	what follows
odor detection threshold	about 0.5 parts per billion	among the lowest thresholds for any compound the human nose registers
OSHA acceptable ceiling in workplace air	20 parts per million	roughly forty thousand times the detection threshold
olfactory fatigue	sets in within two to fifteen minutes above 100 parts per million	the sense that warns of it stops working at the concentrations that kill

So the aversion is real, evolved and exquisitely tuned — and it fails at exactly the wrong end. We detect the gas forty thousand times below the concentration that is regulated, and we stop detecting it above the concentration that is lethal.

Which is a precise account of the sulfur hater. The revulsion is a warning system doing its job at trace levels, mistaken over time for a judgment about the atom. An aversion calibrated to one compound has been generalized to an element that is also insulin, coenzyme A, iron-sulfur clusters, the methyl on every thymine in the archive, and the recognition surface described in Part One Hundred and Fifty.

1519. The Prior Art, Stated Plainly ↩

the claim	where it comes from	status
hydrogen bond counts of the canonical pairs, and of inosine and xanthine with cytosine	textbook, long established	prior art
adenine-thymine-rich DNA melts at lower temperature; nearest-neighbor parameters	SantaLucia 1998, reconciling seven laboratories	prior art

the claim	where it comes from	status
plate, and the placement of all eight characters within it		
the five-step chain at section 1512 joining bond count to location of damage	this Part	this volume
the observation that inosine and xanthine have opposite structural requirements and the same output letter	this Part	this volume

Every measurement here belongs to someone else. What this Part supplies is the frame that makes the measurements answer a question about notation rather than about damage.

1520. The Experiment This Part Generates ↩

Experiment Seventy-Six	
question	Does the bond channel predict where the missing characters are made? Specifically: does xanthine accumulate preferentially at guanines that sit inside adenine-thymine-rich, easily opened regions?
the feasibility now	Xanthine is measurable by mass spectrometry in hydrolysed nucleic acid. Single-strandedness genome-wide is measurable by existing structure-probing chemistry. Adenine-thymine content is free, from the sequence.
the cheap version, and the one to run first	One designed oligonucleotide, two constructs. The same guanine held in a hairpin stem in one and in the loop in the other. Same sequence, same base, one paired and one not. Deaminate both under identical conditions and measure xanthine. That is one afternoon and it tests the load-bearing half.
the genome version	Quantify xanthine and inosine separately at mapped positions, and plot each against measured single-strandedness and against local adenine-thymine content.
prediction if the reading here is right	Xanthine correlates positively with single-strandedness and with local adenine-thymine content; inosine correlates negatively, because ADAR requires a duplex. The two missing characters should anticorrelate across the same coordinate.
prediction if it is not	Both track transcription rate, or exposure, or nothing. The bar code reading is then a mnemonic rather than a prediction, and the volume keeps the mnemonic and drops the claim.
cost	Two synthetic oligonucleotides, one nitrosating source, one mass spectrometry run.

1521. What This Part Refuses ↩

No claim that the tick marks on the plate were drawn with any of this in mind. They were drawn because that is how many hydrogen bonds there are. The reading of them as a second information channel is this volume's reading, made afterward, and is offered as such.

No claim that bond count alone determines duplex stability. It does not. Base stacking contributes at least as much, which is precisely why nearest-neighbor parameters are tabulated by dinucleotide step rather than by base composition, and why some adenine-thymine steps are more stable than some containing guanine and cytosine. Bond count is a first-order proxy and this Part uses it as one.

No claim that strand separation at a replication fork is driven by adenine-thymine content. Once initiated, helicases open the duplex processively and do not consult the sequence. The composition bias is at initiation — at origins, at promoters, at the points where opening begins — and that is the claim section 1511 makes and the limit of it.

No claim that inosine is preferentially generated at unpaired guanines. It is not, and the chemistry says the opposite: ADAR requires double-stranded RNA. What the lone guanine is, is the position at which the record cannot distinguish the possibilities, and the position at which xanthine is preferentially made. Those are two different statements and section 1507 keeps them apart deliberately.

No claim that the deamination rates measured in DNA oligonucleotides transfer unchanged to RNA in a living cell. The direction of the effect is robust across two methods; the magnitude in vivo is not established by either paper and is not asserted here.

And no claim about the popular reception of sulfur beyond what the two figures at section 1518 support. That people find the smell of hydrogen sulfide repellent at half a part per billion is documented. That this is why element sixteen was under-studied is an inference, and is marked as one.

1522. What Was Announced ↩

Stated without adjectives, so that the rest can be argued about

On 8 September 2026 Google DeepMind released the AlphaGenome Atlas: a precomputed dataset of approximately one petabyte containing predicted molecular effects for roughly nine billion single-nucleotide variants — described as every possible single-letter change in the human genome — each carrying an AlphaGenome Variant Impact score, the AVI, which combines outputs of the AlphaGenome model and AlphaMissense into a single number per variant.

It is roughly thirty times the size of the AlphaFold Database. It is free for non-commercial use through a web portal and an API. It was covered as a landmark within hours.

This paper does not dispute that the artifact exists, that it is large, or that it was hard to build. It disputes what it is a map of, what its zero point is, what its output can carry, and whether any of that survives the word complete.

1523. What Was Already on the Record, and When ↩

This critique is not a reaction to a September release. It is a May prediction, confirmed.

Before the argument proceeds, its date of origin has to be fixed, because the date is part of the evidence.

On 21 May 2026 — one hundred and ten days before the Atlas was published — two documents were placed on the record under the Berger Triplex 3-6-9 framework, formally closed 21 April 2026, preprint DOI 10.64898/2026.04.22.720138.

document	date	the finding
AlphaGenome: A Magnificent Monument to the Wrong Direction	May 2026	the critique: one axis of three, the RNA world assumed away, benchmark victory over equally incomplete competitors
AlphaGenome and the Berger Triplex (PP-2026-AG-01)	May 2026	the constructive mapping: AlphaGenome's output domains against the three axes, and five API-testable predictions
AlphaFold 3 and the Berger Triplex Integration	May 2026	the structural companion: where AF3's training distribution ends

What the May critique said, in its own words

On the architecture: the model accepts one megabase of DNA — “one strand, one axis” — and is asked to predict gene expression, which is an RNA operation. “Scaling a fundamentally incomplete input is not a breakthrough. It is an amplified error.”

On the benchmarks: matching or exceeding external models in twenty-five of twenty-six variant-effect evaluations was described not as validation but as “winning a race in the wrong direction” — measured “against other models that also use only DNA input,” making the winner “the fastest horse in the wrong race.”

On scale: “Bigger is not better. Bigger is more wrong, faster.”

And on the coordinate system: “It lives, entirely, in the Flatlander's world — a world where the Z-axis is not missing but simply inconceivable, because the inhabitants have never looked up.” The term Flatlander, as used throughout this paper, is from that May document.

And the arithmetic of the nucleotide was already published

The May framework documents list, among the framework's existing components:

The 63+1 nucleotide system — seven bases × three sugars × three phosphates = 63, plus one quaternion stop.

That factorization — that the unit of variation is a product of three moieties and not a choice among four letters — was on the record with a DOI in May 2026. So was the placement of sulfur in the third moiety: in the framework's quaternion backbone, DNA = 1, RNA = i, ANA = j, and the phosphorothioate backbone = k = ij, with non-commutativity encoding Rp/Sp stereochemical chirality.

Section four of this paper therefore does not introduce the base-sugar-phosphate accounting. It restates a published result, using a deliberately narrower list of species, and arrives at a smaller number than the one already in print. Priority belongs to the May document and is recorded here for that reason.

What September added

The May critique argued that the direction was wrong. It could not yet point to the multiplication table.

The Atlas supplied it. Nine billion is three times the genome, in public, as a product specification — which converts an argument about direction into an arithmetic anyone can check. That is the only thing this paper adds to the May position, and it is a matter of evidence rather than of insight.

A note on what this paper does and does not assert

Two classes of claim appear in this document and they are kept apart deliberately.

class of claim	the coverage	its standing in this paper
the public record	the Atlas's construction rule, the T2T abstracts, the deamination and phosphorothioate measurements, the PCSK9 outcome data, the scale arithmetic	each carries a citation or a computation the reader can redo
the Berger Triplex framework	the three-axis architecture, ANA as the Z-axis selector, the quaternion encoding, the 63+1 system	a stated theoretical position with a preprint DOI and a date; cited here as prior statement of the argument, not as established consensus

The critique in sections three through thirteen stands on the first class alone. It does not require the second to be correct. That is deliberate: an argument that needs a framework to be accepted first can be declined by declining the framework.

1524. The Arithmetic That Defines the Scope ↩

Not numerology — the construction rule, restated

Nine billion is approximately three times three point one billion. The three is the number of alternative letters available at a position when the alphabet has four characters.

This is not a discovered coincidence and no significance is being read into it. It is the dataset's stated construction rule written back as multiplication: every position, every substitution, four letters, three alternatives each.

From which one thing follows immediately and inescapably: the Atlas is complete with respect to substitutions inside the alphabet and structurally silent about everything outside it. You cannot enumerate a character that has no symbol.

So one petabyte of exhaustive coverage is, read exactly, the largest formal wager ever placed on the sufficiency of A, T, G and C.

What the alphabet does not have a symbol for

the character	the definition	the record
inosine	made from adenosine by ADAR at more than one hundred million sites in the human transcriptome	written by every sequencer as G
xanthine	made from guanine by deamination, preferentially at unpaired positions	written as damage, or read through
orotate	the gateway through which every pyrimidine in the body is built	has no place in the notation at all
5-methylcytosine	the principal epigenetic mark in mammals	identical to cytosine in the notation; not a variant at all

None of these appears in the nine billion. Not because they were overlooked, but because the enumeration is closed over an alphabet that has no cell for them. The Atlas is exhaustive within its notation, and the notation is the thing in question.

1525. A Nucleotide Has Three Parts. They Varied One. ↩

The term in the announcement names the unit. The data varies one third of it. The factorization below is prior Berger work of May 2026 — see section two.

A nucleotide is not a letter. It is three chemical moieties joined together: a nitrogenous base, a five-carbon sugar, and a phosphate group.

The Atlas enumerates single-nucleotide variants. What it actually varies is the base. The sugar is held constant by construction. The phosphate is held constant by construction.

moiety of the named unit	the Atlas treatment	the dataset contents
the base	varied — three alternatives per	this is the entire nine billion

moiety of the named unit	the Atlas treatment	the dataset contents
	position	
the sugar	held constant	no entries, no scores, no coordinates
the phosphate	held constant	no entries, no scores, no coordinates

One of the three parts of the thing the product is named after is allowed to vary. The other two are frozen and unmentioned. This is not a quibble about wording — it is a statement about what fraction of the chemistry was enumerated, and the fraction is one third of the moieties and none of the interesting ones.

The sugar is the difference between the archive and the message

Deoxyribose carries hydrogen at the 2-prime position. Ribose carries a hydroxyl. One oxygen atom. That single atom is the whole distinction between DNA and RNA — between the copy that is meant to persist and the copy that is meant to be destroyed.

And the sugar is modified in the living cell. 2-prime-O-methylation is abundant in ribosomal RNA, transfer RNA, small nuclear RNA and the messenger RNA cap, where it alters stability, folding and which proteins will bind. It is a different nucleotide, at the same position, with the same base.

In the Atlas's accounting it is not a variant at all, because the letter did not change.

And the phosphate carries sulfur

The backbone is not inert either, and what happens to it is this volume's subject arriving in the third moiety.

Phosphorothioation replaces a nonbridging oxygen in the sugar-phosphate backbone of DNA with sulfur. It is catalyzed by the DndABCDE proteins and read by DndFGH as a restriction-modification system. Tong, Chen, Wang and colleagues surveyed 1,349 bacterial systems occurring sporadically across diverse phylogenetic groups, and showed that a solitary phosphorothioate modification contributes to the overall cellular redox state, whose loss perturbs the redox balance and forces the cell to reconfigure its metabolism against oxidative stress. PNAS 2018;115:E2988-E2996.

Chen and colleagues showed further that phosphorothioation and adenine methylation converge on shared consensus sequences, with 1,100 to 1,300 modified motifs per genome, and that one modification can substitute for the other in conferring restriction resistance. PNAS 2017;114:4501-4506.

So the oxygen-for-sulfur exchange — the conjugate pair at the center of this volume — operates in the phosphate, is enzymatically written and read, changes the redox state of the cell, and is epigenetically interchangeable with a base modification.

It is also the chemistry of an entire approved drug class. Every antisense oligonucleotide in clinical use rests on a phosphorothioate backbone, because replacing that oxygen with sulfur is what keeps the molecule alive in a human being long enough to work. Sulfur in the phosphate is not exotic. It is on pharmacy shelves.

None of it is a single-nucleotide variant, because the letter did not change.

The arithmetic, on a conservative accounting

Count the chemically distinct states a nucleotide can occupy at one position, using only well-documented species. Bases: the four canonical letters plus 5-methylcytosine, 5-hydroxymethylcytosine, inosine and xanthine — eight. Sugars: 2-prime-deoxyribose, ribose, 2-prime-O-methylribose — three. Phosphates: phosphodiester and phosphorothioate — two.

the accounting	the route	figure
states per position	8 bases x 3 sugars x 2 phosphates	48
alternatives per position		47
alternatives the Atlas enumerates	base substitutions only	3
share of the accounting covered		6.4%
the full space, across 3,054,815,472 positions		143,576,327,184
the Atlas		9,300,000,000
understatement		15.4-fold

Hold the base at the four canonical letters and vary only the two moieties the Atlas freezes, and the space is still twenty-three alternatives per position — 70,260,755,856 across the genome, against nine billion. A 7.6-fold understatement from the sugar and the phosphate alone, with the alphabet entirely conceded.

The framework's own published figure is larger: seven bases × three sugars × three phosphates = 63 + 1, on the record in May 2026. The 48-state count above is a deliberately conservative recomputation restricted to species with individual citations, and it lands below the published number rather than above it. This is an accounting of a chemical state space, not a claim that every combination occurs at every position in human DNA. It is offered to show the shape of what enumeration means when the unit is a nucleotide rather than a letter. Even on the most conservative reading, every possible variant turns out to be six percent of them.

The vocabulary is where the deletion happened first

The term is universal. Every working geneticist reads single-nucleotide variant as base substitution without hesitation, and has done so for thirty years.

That is not a defense of the term. It is the measure of how deep the substitution runs. A notation can be unanimous and wrong at the same time, and unanimity is the subject of this paper, not its refutation.

The sugar and the phosphate were deleted from the vocabulary before they were deleted from the data. Having no word for a thing is how a field arrives at having no column for it, and then at having no coordinate for it, and then at calling the result exhaustive.

No one needs to have intended any of that. A notation does it by itself, to everyone who uses it, including the people who build instruments on top of it.

1526. The Zero Point Is a Construct ↩

Every one of the nine billion entries is a difference from something. This is what that something is.

A variant is not a property of a person. It is a difference between a person's sequence and a reference sequence. The Atlas is built on GRCh38 coordinates, so every AVI score is a distance from GRCh38.

GRCh38 is a mosaic assembled from multiple anonymous donors, with one donor contributing the majority of it. It corresponds to no living human being. It was never screened for health. Nobody checked.

The disease load that must be in there

MacArthur and colleagues applied stringent filters to 2,951 putative loss-of-function variants across 185 human genomes and concluded that a typical human genome carries approximately one hundred genuine loss-of-function variants with approximately twenty genes completely inactivated, and across that set identified twenty-six known and twenty-one predicted severe disease-causing variants. Science 2012;335:823-828.

The reference donors were humans. Humans carry that load. Therefore the zero point of the Atlas carries some number of inactivated genes and some number of disease alleles, and no audited count of them has ever been published. The absence of that count is itself a finding.

Ninety-six thousand positions where the reference is the rare allele

More than ninety-six thousand loci in the reference assembly carry a reference allele whose population frequency is below one percent — Rare Reference Alleles — and at many of those the reference allele can itself be a loss-of-function or gain-of-function variant.

At those positions the sign is inverted. The healthy majority allele receives the impact score and the rare allele is the baseline. The Atlas does not flag them, because to flag them it would have to know which of its own coordinates were wrong, and the only way to know that is to already possess the thing it is standing on.

And the call flips with the build

Alleles classified as pathogenic against one reference build are common non-pathogenic alleles against another. Same DNA, same patient, different answer, depending on which construct is subtracted from.

1527. The Complete Genome That Could Not Live ↩

What CHM13 actually is

The first gapless human genome, T2T-CHM13, was published in Science in March 2022 under the title The complete sequence of a human genome. The indefinite article is the authors' own and it is doing real work.

From that abstract: the reference had covered only the euchromatic fraction since 2000, leaving heterochromatin unfinished; the completed assembly is 3.055 billion base pairs; it is gapless for all chromosomes except Y; it corrects errors in the prior references; and it introduces nearly two hundred million base pairs of new sequence containing 1,956 gene predictions, ninety-nine of them predicted to be protein-coding.

The source material

CHM13 is a complete hydatidiform mole cell line. A complete mole arises when an egg loses its nucleus and a single sperm fertilises the empty shell and duplicates itself. The result is androgenetic and homozygous at every locus in the genome.

Every recessive deleterious allele that one sperm happened to carry is therefore present in the complete human genome in double dose. In a person those alleles would be masked — one damaged copy, one intact copy, a healthy carrier. In CHM13 there is no second copy. There is only the one, twice.

And a complete mole is non-viable by definition. It never becomes a person.

So the first complete sequence of a human genome is the genome of something that could not live, homozygous for whatever that sperm was carrying, with no Y chromosome at all. Version 2.0 patched the Y in from a different individual entirely, making the canonical complete human genome a chimera of two sources, one of them a failed conceptus.

Why that line was chosen

Because a mole is homozygous throughout, which removes the need to separate two haplotypes and makes assembly vastly easier. The choice optimized for tractability. This paper does not fault the choice. It faults the word placed on the result.

1528. More Than Half the Y Was Missing ↩

And this is in the consortium's own abstract, not a critic's paraphrase

“More than half of the Y chromosome is missing from the GRCh38 reference sequence.” Rhie, Nurk, Makova, Phillippy and colleagues, Nature 2023;621:344-354.

The rest of that abstract, itemised:

the report	
the complete Y	62,460,029 base pairs, assembled from HG002 — a different individual from CHM13
errors	corrects multiple errors in GRCh38-Y
sequence added	over thirty million base pairs added to the reference
gene families resolved	the complete ampliconic structures of TSPY, DAZ and RBMY
genes that were absent	forty-one additional protein-coding genes, mostly TSPY family
heterochromatin	Yq12 resolved as alternating human satellite 1 and 3 blocks
the chimera, in their words	“We have combined T2T-Y with a previous assembly of the CHM13 genome”

DAZ stands for Deleted in Azoospermia. The gene family whose deletion is a leading genetic cause of male infertility was sitting in the half of the Y that the reference did not contain. Forty-one protein-coding genes — not mis-annotated, absent — from the coordinate system the world has been calling the human genome since 2013.

What that does to nine billion

You cannot enumerate every possible variant at an address that does not exist. Across more than half of the Y there were no addresses, so there are no variants, no AVI scores, and no marker telling a user that the silence is absence rather than safety.

Every possible single-letter change in the human genome is, on the Y, every possible change in the fraction of it that had been written down.

1529. Twenty Years of the Word Complete ↩

The interval, counted

the interval	
“the human genome is complete” declared	14 April 2003
the Y chromosome actually finished	23 August 2023
elapsed	7,436 days · twenty years and five months
for comparison, McClintock	presented transposition 1951, Nobel 1983 — thirty-two years

Neither delay was caused by the science being impossible. Both were caused by nobody looking hard at what was already in front of them — and in the Y's case, by the word complete circulating for two decades over a chromosome that was more than half unwritten.

1530. What a Scalar Is, and What It Cannot Carry ↩

The central technical objection, and the one this paper rests on

The AVI is one number. A single real value per variant.

A protein fold is 3N spatial coordinates. An enzyme opening and closing is a trajectory in time. A proton tunneling through a barrier in the inner mitochondrial membrane is a wavefunction with an amplitude and a phase. Each of those objects lives in many dimensions and the dimensions are where the chemistry is.

Collapsing any of them onto a single real number is not compression. It is a projection — and projections are not invertible. The structure cannot be recovered from the score. Not with difficulty; at all. The information is destroyed at the moment the number is written.

Which is precisely where the AlphaFold comparison fails

The Atlas is explicitly framed as running the AlphaFold Database playbook. The two outputs are not the same kind of object.

the product	the return	the downstream remainder
AlphaFold	outputs a structure — atomic coordinates	a chemist can place a hydrogen bond in it, measure a groove, count a methionine, dock a

the product	the return	the downstream remainder
		molecule
AlphaGenome Atlas	outputs a scalar — a rank	a chemist can do nothing with it except sort

Structure keeps chemistry available downstream. A ranking number closes it. One of these is an instrument and the other is a sort order.

And the score has no units

The AVI carries no physical dimension, no error bar visible at the point of use, and no falsification path for any individual variant. A number without units and without a mechanism is a ranking, not a measurement — and a ranking cannot be wrong about any particular case, which is another way of saying it cannot be tested on one.

1531. There Is No Chemistry in the Model ↩

An inventory of what is absent, and why it matters at the bedside

AlphaGenome maps sequence to predicted regulatory output, learned by association across a training corpus of assay readouts. The following do not appear anywhere in its inputs:

the omission	the meaning
the atom	no element identity, no electronegativity, no orbital
the bond	no hydrogen bond count, no bond order, no stacking energy
the metabolite	no methyl donor supply, no folate status, no S-adenosylmethionine pool
the energy state	no redox potential, no oxygen tension, no GTP or ATP level
the cell	no enzyme expression state, no ADAR level, no cardiolipin composition

The AVI is a property of a position, invariant across cell states. The same variant in a hypoxic tumor cell and in a well-perfused cell of the same tissue receives the identical score — and the actual consequence differs, because the chemistry differs. The model has no channel through which that difference could enter.

A correction the author of this paper enforced during its drafting

An earlier draft of this argument asserted that the model had “absorbed some physics implicitly” from its training data, on the grounds that chromatin accessibility

and contact maps are three-dimensional quantities. That assertion was withdrawn. Accessibility and contact maps are assay readouts the model was trained to predict. They are measured outputs, not derived physics. The claim was unearned credit and is struck.

1532. The One Cell Where the Two Frames Collide ↩

It does not merely omit the missing characters. It contains an entry that will be read as one.

Take any of the more than one hundred million adenosines in Alu elements that undergo adenosine-to-inosine editing. In the Atlas each such position carries three entries, one of which is A to G, with an AVI score attached.

In the living cell, an adenosine that becomes inosine is read as G.

So the Atlas already contains a scored entry that looks exactly like editing — and scores it as an inherited genomic substitution, when the real event is a reversible, enzyme-driven, metabolically conditioned RNA modification that leaves the DNA untouched.

The same structure applies to the second missing character. At an unpaired guanine the deamination product is xanthine, which mispairs with thymine and surfaces after replication as a G to A transition. The Atlas's G to A entry at that position is the downstream shadow of a lesion the Atlas has no way to represent.

a real substitution, an edited base, and a chemical lesion → one letter, one score

Three distinct molecular histories collapse onto one cell of the table. A notation with symbols for each would place them in three different rows. A notation with four letters places them in one.

1533. Enumeration Has Never Produced a Medicine ↩

The counterexamples, taken first and in full, because the strong form of the claim survives them

A weak form of the criticism — that no genomics-derived drug has cured anything — is false and should not be made. The counterexamples are real and this paper states them plainly.

PCSK9, the one case where the pipeline closed end to end

French families with catastrophic inherited cholesterol led to a gene. Then Cohen, Boerwinkle, Mosley and Hobbs went looking for people in whom that gene was broken, in the Atherosclerosis Risk in Communities cohort, over a fifteen-year interval. N Engl J Med 2006;354:1264-1272.

cohort	carriers	lipid effect	clinical outcome
3,363 Black participants	2.6% carried nonsense mutations in PCSK9	28% lower LDL cholesterol	88% reduction in coronary heart disease · hazard ratio 0.11
9,524 white participants	3.2% carried a PCSK9 sequence variant	15% lower LDL cholesterol	47% reduction in coronary heart disease · hazard ratio 0.50

A monoclonal antibody raised against that genetically validated target is evolocumab. Genetics to target to drug to hard clinical outcome. That one closed.

And the others

the medicine	the origin
Casgevy	CRISPR editing of BCL11A for sickle cell disease, approved 2023. One administration, durable. A cure, for a major disease, in the strict sense.
Trikafta	turned cystic fibrosis from a disease that killed children into one that is managed, for roughly ninety percent of patients.
imatinib	from the Philadelphia chromosome, seen down a microscope in 1960.
insulin and the antibody drugs	out of physiology, not out of sequence.

Now the part that matters

Not one of them came from enumeration.

PCSK9 came from two families and a question — Hobbs and Cohen found people who were unusual and asked why. Phenotype first, mechanism second, drug third. CFTR was positionally cloned in 1989, before the Human Genome Project existed. The Philadelphia chromosome was a cytogenetic observation. Every one began with someone finding a mechanism in a patient.

Genome-wide association studies have produced hundreds of thousands of associations across twenty years. The count of approved drugs traceable to genome-

wide discovery alone — not to a family, not to a phenotype, not to a mechanism already in hand — rounds to nothing. The strongest defense the field offers is that targets with human genetic support are roughly twice as likely to survive clinical trials.

That is an argument for genetics as a filter on hypotheses that already exist, not as a generator of new ones. It is a sieve, and it has been sold as a mine.

The form of the claim that cannot be answered

Every genomic medicine that works was built on a mechanism found in a patient. The enumeration program has produced a ranking. A ranking is not a mechanism, and nobody has ever cured anything with a sort order.

Which is the scalar objection of section nine, arriving at the bedside: one dimension going in, one dimension coming out, and nothing in between that a chemist could put a bond into.

1534. Written to Scale ↩

The magnitudes, computed, so that a reader can see them rather than nod at them

Every figure in this section was calculated for this paper from the sourced quantities above. A reader can reproduce all of them with a pocket calculator.

Read it aloud

the object read	size	time
one genome, at one base per second, without stopping	3,054,815,472 bases	96.8 years
the Atlas, at one variant per second, without stopping	9,300,000,000 variants	295 years
the Atlas, at one variant per second, eight hours a day, 250 days a year		1,292 years

A human lifetime is not long enough to say one genome aloud once. To be finishing the Atlas now at a normal working pace, a reader would have had to begin before the Magna Carta.

Print it

the paper column	
one petabyte at two kilobytes to a page	500,000,000,000 sheets
stacked at 0.1 mm per sheet	50,000 kilometers
the Earth's equator, for comparison	40,075 kilometers
so the printed Atlas wraps the planet	one and a quarter times

A column of paper visible from orbit, and not one sheet of it legible to a person — nine billion English letters, uncolored, unbarcoded, with no visual channel by which a human being could apprehend any of it.

The thing that was missing, to scale

the rounding error	
difference between the two figures in common use, 3.1 billion and 3.055 billion	45,184,528 base pairs
chromosome 21, for comparison	46,709,983 base pairs
so the discrepancy is	ninety-seven percent of an entire chromosome
and chromosome 21 is	the chromosome where one extra copy is Down syndrome

The difference between the two numbers in casual circulation is the size of the chromosome where the difference between two copies and three changes a person's whole life.

And the ratio that closes the argument

The PCSK9 finding — a handful of families, a gene, a broken copy — fits on one page. Two thousand bytes. It produced a drug class that lowers LDL by sixty percent and prevents heart attacks.

The Atlas is one petabyte. It has produced a ranking.

$$\textit{one page} \;:\; \textit{one petabyte} \;=\; 1 \;:\; 500{,}000{,}000{,}000$$

Five hundred billion to one, and the page won.

For calibration: the Grand Canyon at its deepest is 1,857 meters and a grain of sand is half a millimeter — a ratio of 3.7 million to one. The ratio above exceeds that comparison by a factor of roughly one hundred and thirty-five thousand.

1535. What This Paper Grants ↩

Stated at full strength, because a scope critique is only as good as the concessions it survives

the concession	its full strength
it is benchmarked	AlphaGenome's predictions are evaluated against held-out experimental data. That is not voodoo and this paper does not call it that. The honest charge is different: benchmark performance on curated tasks establishes nothing mechanistic.
it is useful as a lookup	A clinician facing a variant of unknown significance gets an instant prior. That has real value and nothing in this paper requires it to have none.
it was hard to build	A petabyte of precomputed inference across the whole genome is a serious engineering achievement and is treated here as one.
the limits were published	The T2T authors wrote “a human genome.” They wrote “more than half of the Y chromosome is missing.” Those sentences exist and this paper quotes them rather than paraphrasing. What follows from that is a question about transmission, not about candour.

The scope critique stands without needing the tool to be bad. That is the strongest position available and it is the one this paper takes.

1536. Why the Headline Outran the Science ↩

The failure is not in the laboratory and it is not in the reader

The limits are stated in the primary literature. The indefinite article is in the title of the 2022 Science paper. The missing half of the Y is in the first sentence of the 2023 Nature abstract. The limits were published. The limits did not travel.

What fails is the transmission layer. The indefinite article is dropped between the paper and the press release. The product is built on the reading rather than on the paper. By the time a number reaches a clinician the caveat has been sanded off three times.

So the public is not gullible. The caveat and the product travel at different speeds, and only one of them arrives.

Which is what makes the coverage click-bait rather than reporting

the claim and the qualification	
the headline	a predictive map of every possible DNA letter change in the human genome
the truth	a predictive ranking of every substitution within a four-letter alphabet, relative to a composite reference that matches no living person, silent across more than half of one chromosome, with no chemistry in the model and no units on the output
the difference	not a nuance. The second sentence is the first sentence with its four load-bearing qualifications restored.

1537. What Would Make It Worth the Fanfare ↩

Falsifiable asks, in order of cost

the answer required	
1	Publish the audited count of pathogenic and rare reference alleles inside the reference, and mark those coordinates in the Atlas. This is a database join and it has never been done.
2	Ship a mask layer marking every coordinate where the reference is absent, unresolved or known-erroneous, so that silence is distinguishable from safety — beginning with the Y.
3	Give the AVI a unit, or an error bar visible at the point of use, or a documented path by which a single variant's score can be shown to be wrong.
4	Score against a pangenome rather than a single composite, so that a variant is a difference from a population and not from a construct.
5	Expose an intermediate representation that retains structure — not the final scalar — so that chemistry remains available downstream, the way AlphaFold's coordinates are.
6	State in the release, not in the supplement, which characters the notation cannot represent, and how many positions are affected.

None of these requires new science. All are bookkeeping and disclosure, and every one of them would make the artifact more useful rather than less.

1538. The Experiment This Paper Generates ↩

Experiment Seventy-Seven	
question	Has the model learned the editing signal without knowing what editing is? Does the AVI at heavily edited Alu adenosines behave systematically differently from the AVI at matched, non-edited adenosines?
the feasibility this week	The Atlas API is open for non-commercial use. REDIportal holds the editing coordinates. Both are free.
design	Sample adenosines with high measured editing frequency in Alu elements. Match them to adenosines of equal sequence context and equal local repeat content with no detectable editing. Compare the distribution of the A-to-G AVI scores between the two sets.
prediction if the model has absorbed the signal	The A-to-G scores at heavily edited sites cluster separately. The model has learned a chemical process it has no representation of, by proxy, through its downstream regulatory consequences.
prediction if it has not	The distributions are indistinguishable, and the Atlas is blind to the largest single source of molecular characters in the human transcriptome while scoring the cell that most resembles it.
the value either way	One outcome shows the model knows something it cannot say. The other shows it does not know it at all. Both are publishable and neither requires a laboratory.
cost	A weekend, two open APIs, and no reagents.

1539. What This Paper Refuses ↩

No claim that the AlphaGenome model does not predict. It does, measurably, against held-out data, and this paper does not contest a single benchmark.

No speculation about intent, anywhere in this paper — not because the question is impolite but because it is unfalsifiable and it hands a reviewer an exit. A notation that deletes chemistry does so whether or not anyone wanted it to. The arithmetic in sections two, three and twelve cannot be answered. A claim about what people knew can always be answered, and the answer will be no.

No claim that a reference genome should not exist, or that a single coordinate system was a mistake in 2001. It was necessary. The objection is to the word complete surviving twenty years past the point where it was accurate, and to a product being built on the word rather than on the paper.

No claim that the Atlas will never produce anything. It is four days old. What is claimed is narrower and harder to escape: that exhaustive enumeration inside a

representation cannot repair the representation, and that nothing in a petabyte of rankings changes what the alphabet has no symbol for.

And no claim that the three missing characters named in sections three and four are the complete list. They are the three this author has spent twenty-nine years on. There may be more. That possibility is an argument for the position of this paper, not against it.

1540. The Argument in One Page ↩

the point	the form that cannot be answered
it was predicted in May, not noticed in September	the critique, the Flatlander framing, and the base × sugar × phosphate factorization were published 21 May 2026 with a DOI, one hundred and ten days before the Atlas existed.
the enumeration is closed	nine billion is three times the genome because the alphabet has four letters. Inosine, xanthine, orotate and methylcytosine have no cell in the table.
they varied one moiety of three	a nucleotide is base plus sugar plus phosphate. The sugar is the DNA/RNA distinction and carries 2-prime-O-methylation; the phosphate carries sulfur as phosphorothioate and is the backbone of the antisense drug class. Both are frozen. On a conservative accounting the Atlas covers 6.4% of the alternatives.
the zero point is a construct	GRCh38 matches no living person, carries an unaudited disease load, and holds the rare allele at more than ninety-six thousand positions.
the complete genome could not live	CHM13 is a non-viable mole, homozygous throughout, with no Y; the canonical version 2.0 is a chimera of two individuals.
more than half the Y was absent	thirty-one million bases, forty-one protein-coding genes including DAZ, for twenty years and five months under the word complete.
the output is one-dimensional	a scalar is a projection and projections are not invertible. AlphaFold returns a structure; the Atlas returns a rank.
there is no chemistry in the model	no atom, no bond, no metabolite, no redox state. The score is invariant across the cell states that determine the answer.
three histories, one cell	a substitution, an edited base and a chemical lesion all land on the same entry with the same score.
enumeration has never produced a medicine	PCSK9, CFTR, Philadelphia, insulin — every one began with a mechanism found in a patient. The program has produced a sieve, sold as a mine.
and the scale	one page produced a drug class; one petabyte produced a sort order. Five hundred billion to one.

The achievement is real as engineering. The headline is a claim about biology, and biology is where it does not hold.

1542. Note on Method ↩

This paper was drafted in dialogue with an AI system and every quantitative claim in it was checked against a primary source or computed from one during drafting. Two assertions made by the machine were caught by the author and removed: that the model had “absorbed some physics implicitly,” which it had not; and the description

of a forty-five-million-base-pair discrepancy as differing “by a hair,” which softened a concession in the same breath as making it.

Both corrections are recorded here rather than quietly applied, because a paper about a transmission layer that sands off caveats has no business sanding off its own.

The reader is not asked to trust the drafting process. Every number carries a citation or an arithmetic that can be redone in a minute. That is the point, and it is the standard this paper asks of the artifact it is about.

This completes the beginning.

PART ONE HUNDRED AND FIFTY-THREE · THE UNIT IS A NUCLEOTIDE, NOT A LETTER

1543. The Index Entry That Was Never Written ↩

Subject 397 of the Berger 816 index, recovered

The master subject index of this corpus carries 1,063 numbered subjects. A coverage audit run against the 1,546 sections of this volume on 12 September 2026 established that eighty-one of them had been written about and nine hundred and eighty-two had not.

Entry three hundred and ninety-seven reads, in full:

Genetic code should use nucleotides not bases.

It had been indexed and never argued. This Part argues it, and closes fourteen further entries from the same cluster along the way.

The occasion is that the case can now be made entirely from published measurement. Every claim below is somebody else's experiment. The only thing this volume supplies is the arithmetic and the arrangement.

1544. What a Nucleotide Is, Counted Three Ways ↩

Three moieties, and what varies in each

A nucleotide is not a letter and it is not a base. It is three chemical parts bonded together: a nitrogenous base, a five-carbon sugar, and a phosphate group. The word names all three. Conventional notation varies one.

moiety	the variation	the notation
THE BASE	adenine, thymine, guanine, cytosine, uracil — and inosine, xanthine, orotate, and the methylated forms	the only moiety the four-letter alphabet can write
THE SUGAR	deoxyribose, ribose, arabinose, and the 2-prime-O-methyl forms	decides DNA from RNA; one oxygen atom
THE PHOSPHATE	phosphodiester and phosphorothioate	carries sulfur where the notation shows only a backbone line

The claim of this Part is not that the base is unimportant. It is that a system which varies one of three moieties and calls the result a nucleotide variant has named a unit it is not measuring.

1545. Somebody Already Built the Eight-Letter Version ↩

And it crystallized, transcribed, and worked

The objection that an expanded alphabet is speculative was answered in 2019, in Science, by Hoshika, Leal, Kim, Karalkar, Bates, Watkins, SantaLucia, Meyer, DasGupta, Piccirilli, Ellington, Georgiadis and Benner.

They report DNA- and RNA-like systems built from eight nucleotide letters — hachimoji — forming four orthogonal pairs, meeting the structural requirements needed to support Darwinian evolution, including a polyelectrolyte backbone, predictable thermodynamic stability, and stereoregular building blocks that fit a Schrödinger aperiodic crystal. Science 2019;363:884-887.

the demonstration	
letters	eight, in four orthogonal pairs
structural proof	three crystal structures; the synthetic building blocks do not perturb the aperiodic crystal of the double helix
thermodynamics	measured parameters predict duplex stability
information density	hachimoji DNA increases the information density of natural terran DNA
transcription	hachimoji DNA was transcribed to hachimoji RNA
function	the product was a working fluorescent aptamer

Eight letters. Built, crystallized, transcribed, and made to fold into something that works. The sufficiency of four is not a law of chemistry. It is a local historical fact about one lineage, and it has been exceeded in a laboratory.

Note also the phrase the authors reach for: a Schrödinger aperiodic crystal. Subject sixty-six of the index — aperiodic crystal and Penrose design — sits in the unwritten column of the same audit that produced this Part.

1546. The Sugar Has a Third Pucker, and It Was Measured ↩

Arabinose, by NMR, geometrically between the two canonical forms

The second moiety is not binary either. Beyond deoxyribose and ribose there is arabinose — the 2-prime epimer — and its geometry has been solved.

Denisov, Noronha, Wilds, Trempe, Pon, Gehring and Damha determined the NMR solution structures of ANA/RNA and DNA/RNA hairpin duplexes and compared them with the 2-prime-fluoro-ANA/RNA hairpin. Nucleic Acids Res 2001;29:4284-4293.

Denisov and Damha, 2001	the measurement
the RNA strand	C3-prime-endo — north — A-form
the DNA strand	flexible; no single rigid pucker
the ANA strand	a rigid O4-prime-endo — east — pucker: neither A-form nor B-form
minor groove width, all three hybrids	9.0 plus or minus 0.5 angstroms — in the authors' words, intermediate between that of A- and B-form duplexes
the functional consequence they draw	this rationalises the ability of ANA/RNA and 2-prime-F-ANA/RNA hybrids to elicit RNase H activity, which double-stranded RNA cannot

A third sugar pucker, rigid, east, occupying the geometry between the two canonical forms — measured by nuclear magnetic resonance twenty-five years ago. The volume's arabinose geometry is not a proposal awaiting evidence. It is a published solution structure.

And it does work the canonical forms cannot: an ANA/RNA hybrid recruits RNase H, and an RNA/RNA duplex does not. The third sugar is not a variation on a theme. It changes what enzyme will act.

1547. And the Phosphate Carries the Volume's Own Atom ↩

Sulfur in the third moiety, written and read by enzymes

Part One Hundred and Fifty-Two established the phosphate case and it is restated here in one paragraph because the three moieties belong in one table.

Phosphorothioation replaces a nonbridging oxygen in the sugar-phosphate backbone of DNA with sulfur. Tong and colleagues surveyed 1,349 bacterial systems and showed that a solitary phosphorothioate modification contributes to the overall cellular redox state. Chen and colleagues showed that phosphorothioation and adenine methylation converge on shared consensus sequences, 1,100 to 1,300 motifs per genome, and that one can substitute for the other. PNAS 2018;115:E2988-E2996 and PNAS 2017;114:4501-4506.

It is also the backbone chemistry of every antisense oligonucleotide in clinical use — which makes the third moiety the only one of the three with an approved drug class resting on a deliberate change to it.

1548. The 63+1 System, Stated ↩

Subjects 266, 267, 268, 90, 179 and 626 of the index, in one place

Six separate entries in the master index circle the same construction. Set out once:

$$7 \text{ bases} \times 3 \text{ sugars} \times 3 \text{ phosphates} = 63, \text{ plus one stop} = 64$$

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

Seven bases rather than four or five, because the count includes the characters the alphabet has no symbol for. Three sugars, because arabinose is real and measured. Three phosphates, because the backbone is not one thing. Sixty-three distinct nucleotides, and a sixty-fourth position reserved as the terminator.

The arithmetic is arresting for a reason that has nothing to do with the framework: sixty-four is the size of the codon table. A system counted at the level of the nucleotide arrives at the same number that the triplet code arrives at by counting letters three at a time. This volume records the coincidence and does not build on it.

The conservative recount, for comparison

Part One Hundred and Fifty-Two performed an independent count restricted to species with individual citations — eight bases, three sugars, two phosphates — and reached forty-eight states, forty-seven alternatives per position. It is a smaller number than the framework's own and it is offered as the floor rather than the ceiling.

accounting	factorization	states per position	provenance
the framework's published system	7 × 3 × 3	63 + 1	on the record May 2026
the conservative recount	8 × 3 × 2	48 states, 47 alternatives	this volume, September 2026
conventional practice	4 bases, 1 sugar, 1 phosphate	4 states, 3 alternatives	every sequence database in use

Whichever of the two counts is preferred, the operative figure at the bottom of the table is three — and three is what every genome database, every variant caller and every enumeration built on them can represent.

1549. The Six-Letter Case, Which Is Already Running ↩

Subjects 868, 478 and 479: inosine as the sixth character

The expansion does not have to be built. One character is already in the cell, at scale, doing work.

character	molecule	status
A	adenine	in the alphabet
T	thymine	in the alphabet, DNA only
G	guanine	in the alphabet
C	cytosine	in the alphabet
U	uracil	in the alphabet, RNA only
I	inosine	made by ADAR at over one hundred million sites; written by every sequencer as G

Inosine's claim to be counted is not that it is exotic but that it is ancient and central. It sits at the wobble position of transfer RNA, where its capacity to pair with more than one partner is the reason the codon table degenerates the way it does. It is the deamination product of adenosine and the branch point of purine synthesis.

And it is the working mechanism of the most precise gene-editing tool in use. Gaudelli, Komor, Rees, Packer, Badran, Bryson and Liu state it plainly: the deamination of adenine yields inosine, which is treated as guanine by polymerases. Their adenine base editor manufactures inosine on purpose, at roughly fifty percent efficiency in human cells with product purity typically at least 99.9 percent. Nature 2017;551:464-471.

A character with no letter is the operating principle of a technology in clinical trials. The same paper notes that the deamination of cytosine accounts for half of known pathogenic point mutations in humans.

1550. What the Notation Loses Here ↩

Written as a letter, a position records which of four bases is present and nothing else. It does not record which sugar carries that base, which linkage carries that sugar, or whether the base has been modified since it was laid down.

So a position that reads G may be a guanine on deoxyribose with a phosphodiester linkage; or a guanine on ribose; or an inosine that was an adenosine this morning; or a guanine on a phosphorothioate backbone in a bacterium defending itself. Four different molecules, four different chemistries, one letter.

The alphabet is not merely three characters short, as this volume has argued for fifteen hundred pages. It is two moieties short as well — and the two it omits are the one that distinguishes the archive from the message and the one that carries the atom this book is about.

1551. The Prior Art, Stated Plainly ↩

the claim	the origin	status
eight-letter genetic systems are constructible, crystallize, transcribe and function	Hoshika, Benner and colleagues, Science 2019	prior art
ANA adopts a rigid O4-prime-endo pucker; hybrid minor groove intermediate between A- and B-form	Denisov, Damha and colleagues, Nucleic Acids Res 2001	prior art
ANA/RNA and 2-prime-F-ANA/RNA hybrids elicit RNase H; RNA/RNA does not	same paper	prior art
phosphorothioate is an enzymatically written and read DNA modification affecting redox state	Tong 2018; Chen 2017, PNAS	prior art
adenine deamination yields inosine, read as guanine by polymerases; the basis of adenine base editing	Gaudelli, Liu and colleagues, Nature 2017	prior art
nearest-neighbor thermodynamics of duplex stability	SantaLucia, PNAS 1998	prior art
the 63+1 factorization of the nucleotide into base, sugar and phosphate	Berger Triplex framework, on the record May 2026, DOI 10.64898/2026.04.22.720138	this corpus
the coverage audit establishing that this subject was indexed and unwritten	this volume, 12 September 2026	this volume

Every experimental result in this Part belongs to someone else. What was missing was not evidence. It was a table that put the three moieties in one place and counted them.

1552. The Index Entries This Part Closes ↩

Fifteen subjects, moved from unwritten to written

index no.	subject	the place in this volume
397	Genetic code should use nucleotides not bases	the thesis of this Part
266	Designing a 63-nucleotide system with three sugars	section 1548
267	Designing a 64-code genetic system with modified nucleotides	section 1548
268	Designing a 64-codon genetic code system	section 1548
90	Balanced nucleotide system with three sugar types	sections 1544, 1546
179	Building a seven-base nucleotide system	sections 1545, 1548
626	Organizing 63 nucleotides across DNA, RNA and ANA	section 1548
13	64-code system convergence with natural triplet code	section 1548
868	Six-letter genetic code with inosine	section 1549
478	Inosine as sixth base in triple-helix DNA	section 1549
479	Inosine as the primordial purine nucleotide	section 1549
472	Information division among DNA bases	section 1550
83	Assigning biological roles to nucleotide letters	section 1550
66	Aperiodic crystal and Penrose design	section 1545, via Benner's own phrasing
76	Arabinose nucleotides in therapeutic oligonucleotides	sections 1546, 1547

Nine hundred and sixty-seven remain.

1553. What Is Still Open ↩

The eight-letter system of Hoshika and colleagues is synthetic. It demonstrates that four is not a chemical necessity; it does not demonstrate that any organism uses more than four in its own genome, and this volume does not claim that it does.

The arabinose structure of Denisov and colleagues is a solution structure of a synthetic hybrid. It establishes the geometry and the RNase H consequence. It does not establish that arabinose nucleotides occur in human nucleic acids, and no such claim is made here.

What is established is narrower and sufficient: the three moieties each vary, each variation has been measured, each changes what enzymes will do, and none of the three except the base can be written down in the notation the world uses.

1554. The Experiment This Part Generates ↩

Experiment Seventy-Eight	
question	Does the third sugar pucker change deamination rate? Specifically: at a matched sequence position, does an arabinose-containing strand deaminate at a different rate than the deoxyribose and ribose equivalents?
the feasibility now	ANA and 2-prime-F-ANA oligonucleotides are commercially available. The nitrosative deamination assay of Caulfield and colleagues is published and uses standard mass spectrometry.
the connection to sections 1507 and 1508	Part One Hundred and Fifty-One established that pairing protects: deamination runs roughly 140-fold slower inside a duplex, and ten-fold slower in double-stranded than single-stranded oligomers. Those measurements held the sugar constant. Nobody has varied it.
design	Three oligonucleotides of identical base sequence — deoxyribose, ribose, arabinose — each as a single strand and as a duplex. Deaminate all six under identical nitrosative load. Measure xanthine and uracil by mass spectrometry.
prediction if the sugar matters	The rigid O4-prime-endo pucker of the arabinose strand, sitting between A- and B-form, gives a deamination rate distinguishable from both canonical sugars. The third moiety is then a determinant of mutational vulnerability and not only of enzyme recruitment.
prediction if it does not	All three sugars deaminate alike and the protection is entirely a function of base pairing. That result is equally worth having, because it isolates the bond channel cleanly and closes a variable.
cost	Three synthetic oligonucleotides, one nitrosating source, one mass spectrometry run.

1555. What This Part Refuses ↩

No claim that hachimoji DNA occurs in nature. It was synthesized. What it establishes is a possibility proof about chemistry, not a discovery about organisms, and Benner and colleagues say so themselves.

No claim that the coincidence at section 1548 — sixty-three plus one arriving at sixty-four — is evidence of anything. Two counting schemes reaching the same

number is a fact about the numbers. It is recorded because it is checkable and it is not built upon.

No claim that arabinose nucleotides are present in human DNA or RNA. The measurements cited are of synthetic hybrids. The geometry is established; the biological occurrence is not, and this volume distinguishes the two.

And no claim that adding characters to the notation is practical. Part One Hundred and Fifty-Two set out why it cannot be done by announcement. The argument of this Part is about what the unit is, not about what the file format should become.

PART ONE HUNDRED AND FIFTY-FOUR · THE ARABINOSE TEST

1556. Six Questions Instead of an Objection ↩

What can be checked by a stranger who does not accept the framework

Part One Hundred and Fifty-Two argued that a nine-billion-variant atlas is complete with respect to substitutions inside a four-letter alphabet and structurally silent about everything outside it. Part One Hundred and Fifty-Three argued that the unit of variation is a nucleotide — base, sugar and phosphate — and not a letter. Both Parts argue. Neither can be run.

This Part converts the argument into a test. Six questions are set out below. Each has a single published answer with a citation. Each is answerable in one sentence. Each is failed, by construction rather than by accident, by the representation the field has agreed to use. They cost nothing to run and require no institution, no funding and no access to anything proprietary.

The difference matters more than it sounds. An objection to a method can be declined by declining the objection. A question with a published answer cannot be declined; it can only be answered or left unanswered, and either outcome is on the record.

The volume records this Part as a methodological instrument and not as a new finding. Nothing in it is claimed as the author's discovery. Every ground truth below belongs to the laboratory that measured it. What is new is the assembly: six measurements from six literatures, selected so that all six fall outside what a letter string or a static structure can carry.

1557. The Method, and Why the Scoring Is Not Self-Serving ↩

The answers were sealed before the checking began

A test administered by the party under test is worth nothing unless the answers are recorded before the checking starts. So they were.

On 12 September 2026 a large language model — claude-opus-5, the model with which this volume was typeset — was asked the six questions and wrote its answers to a file before any literature search was performed in that exchange. No database, no web, no reading of any file between the question and the answer. Each answer carried the model's own stated confidence. The file was then left untouched while every ground truth was pulled from the primary literature. The sealed sheet is reproduced at section 1568 without alteration.

Three different things are under test and this Part keeps them apart, because conflating them is how the argument was previously overstated.

the object under test	the question asked of it	the meaning of a failure
a language model	can it state a published answer	tests only whether the fact is in the training distribution
a structure-prediction model	can it produce the answer from sequence or structure	tests whether the fact is expressible in the representation
the representation itself	can any method using it express the fact at all	a question of mathematics, settled by proof, and it does not expire when the next model ships

The third row is the one that matters. A benchmark result is a fact about one artifact on one day. A proof about a representation holds for every method that uses it, including the ones not yet built.

1558. Test One · The Pucker ↩

The question this volume's own circulated papers got wrong

THE QUESTION. In a FANA/RNA hybrid duplex, what is the sugar pucker of the arabinose strand?

THE PUBLISHED ANSWER. O4-prime-endo — the east conformation. Denisov and Damha determined it by NMR and report the C1-prime to C4-prime distance as 9.0 plus or minus 0.5 angstroms, a geometry belonging to neither of the two puckers the field works in. Nucleic Acids Res 2001;29:4284-4293. Section 1546 records the same measurement in the course of a different argument.

WHY THE REPRESENTATION FAILS IT. A model trained on DNA and RNA has two puckers in its world. B-form DNA is C2-prime-endo, the south conformation. A-form RNA is C3-prime-endo, the north. The east conformation is not a third option weighed and rejected. It is not in the space. Asked for the pucker, such a model answers south or north, answers with confidence, and is wrong in a direction that can be written down in advance.

Note which atom names the answer. The pucker the field cannot predict is named for the ring oxygen — O4-prime — and in this volume's palette the oxygen is orange, the same color as inosine, the same color as the character the alphabet has no symbol for.

And the failure is recorded, not predicted

This is not hypothetical. Earlier in 2026 the model supplied text for two documents circulated under the author's name. That text gave the arabinose pucker as C3-prime-exo. It is not C3-prime-exo. The error went to a correspondent who is a principal investigator in exactly this chemistry. The model did not flag uncertainty and corrected itself only when the author demanded it check.

Three further errors traveled in the same text: L-arabinose for beta-D-arabinose, a claim of 2-prime-5-prime linkages where the linkages are the standard 3-prime-5-prime, and a claim that the molecule is absent from the structural databases when it is sparse rather than absent. All four are corrected in the errata of 12 September 2026 and both source documents are withdrawn pending revision. They are recorded

here because a test the examiner has already failed in public is a better test than one it has not.

1559. Test Two · The Two Folds ↩

One sequence, two native structures, and a peer-reviewed verdict of pattern recognition rather than physics

THE QUESTION. Human lymphotactin, XCL1, is a single amino acid sequence. How many native folds does it adopt, and what does each one do?

THE PUBLISHED ANSWER. Two, both significantly populated in physiological solution and interconverting rapidly. Tuinstra, Peterson, Kutlesa, Elgin, Kron and Volkman solved both by NMR: the canonical chemokine fold, a monomeric three-stranded beta sheet with a carboxyl-terminal helix, which is a functional XCR1 agonist and fails to bind heparin; and a dimeric all-beta arrangement with no similarity to any other known protein, which binds glycosaminoglycans with high affinity and fails to activate XCR1. Proc Natl Acad Sci USA 2008;105:5057-5062.

Their conclusion is the point. Each structure carries only one of the two functional properties the protein needs in vivo, so the equilibrium itself is the functional unit. The protein is not a structure. It is a ratio between two structures.

The failure is measured, published and quantified

This is not inference. Chakravarty and Porter tested AlphaFold2 on ninety-eight fold-switching proteins, comparing five predicted structures against two experimentally determined structures for each.

the number	the measurement
98	fold-switching proteins tested, each with two solved structures
94%	of predictions captured one experimentally determined conformation but not the other
74%	of fold-switching residues predicted with moderate-to-high confidence — so the output carries no warning
equal	sequence conservation in fold-switching regions and in single-fold proteins, so the alignment gives no warning either

Their explanation, in their own words in a peer-reviewed journal: the high confidence on fold switchers indicates that the model “uses

sophisticated pattern recognition to search for one most probable conformer rather than protein biophysics to model a protein's structural ensemble.” Protein Sci 2022;31:e4353.

That sentence is this volume's objection, stated by authors at the National Library of Medicine and the National Heart, Lung, and Blood Institute, in 2022. Pattern recognition, not physics. The volume did not need to coin the criticism and does not claim to have. It notes where the criticism was already made, by whom, and that nothing changed.

And note where the sulfur sits. Fox, Tyler, Guzzo, Tuinstra, Peterson, Lusso and Volkman locked the equilibrium by engineering a second disulfide bond, A36C to A49C, which prevents interconversion and holds the protein in the dimer. ACS Chem Biol 2015;10:2580-2588. The switch is not thrown by a base and not by a letter. It is thrown by two sulfur atoms finding each other — the same chemistry Part One Hundred and Forty-Eight found at the pivot of protein splicing and Part One Hundred and Fifty found lining the signal-recognition groove.

1560. Test Three · The Rate-Limiting Step ↩

A structure carries three numbers per atom and no time axis at all

THE QUESTION. At pH 7, what step limits the turnover of Escherichia coli dihydrofolate reductase — the chemistry, or something else?

THE PUBLISHED ANSWER. Not the chemistry. Fierke, Johnson and Benkovic measured the full kinetic scheme by stopped-flow fluorescence and absorbance. Hydride transfer from NADPH to dihydrofolate runs at nine hundred and fifty per second, is essentially irreversible with an equilibrium constant of seventeen hundred, and is not rate-limiting. Below pH 8.4 the limiting step is dissociation of the product tetrahydrofolate from the enzyme-NADPH-tetrahydrofolate ternary complex, and it follows a specific preferred pathway in which NADPH must first replace NADP-plus. Biochemistry 1987;26:4085-4092.

There is a second finding in the same paper that no static representation can hold: the identity of the rate-determining step changes with pH. Product release governs below 8.4, hydride transfer above it. The same enzyme, the same structure, two different bottlenecks depending on the proton activity of the solution.

A predicted structure contains three coordinates per atom. It contains no rate, no ordering of steps, no preferred pathway and no pH. Asked which step is rate-limiting, a structure-prediction model has nothing from which to compute an answer. It can only recall that someone published one — and where nobody has, it has nothing at all.

The atom at issue is hydrogen, red in this volume's palette. The fastest step in the cycle is the transfer of the smallest particle in the alphabet, and it is not the step that sets how fast the enzyme runs. Part Four's argument about the proton as a quantum object and this Part's argument about the proton as a non-limiting step are the same observation from two directions: the hydrogen is where the notation is thinnest and the chemistry busiest.

1561. Test Four · The Lid ↩

Two nearly identical structures, two speeds, and a cause present in neither structure

THE QUESTION. The hyperthermophilic and mesophilic homologues of adenylate kinase have closely similar structures. At ambient temperature the thermophile is the slower enzyme. Why?

THE PUBLISHED ANSWER. Solely because its nucleotide-binding lids open more slowly. Wolf-Watz, Thai, Henzler-Wildman, Hadjipavlou, Eisenmesser and Kern measured residue-specific dynamics in both homologues during catalysis by NMR relaxation and found that lid opening — a motion, not a chemical step — is rate-limiting for both enzymes, and that the thermophile's reduced activity at ambient temperature is caused by nothing else. Nat Struct Mol Biol 2004;11:945-949.

This is the cleanest available demonstration of the limit. Two structures a model can predict accurately. Two catalytic rates that differ. A cause absent from both structures, which no comparison between them can reveal, because the difference is a rate of opening and neither structure is open long enough to say so.

The field named the missing dimension nineteen years ago

Henzler-Wildman and Kern, reviewing this work in Nature: the functions of proteins “are governed ultimately by their dynamic character,” and seeing them “requires addition of a fourth dimension,

time, to structural biology so that the positions in space and time of all atoms in a protein can be described in detail." Nature 2007;450:964-972.

This volume argues that the code is missing a dimension along the polymer. A Nature review by the laboratory that measured these rates says structural biology is missing one along time. The two claims are not the same claim and this Part does not merge them. They are the same complaint about the same habit: mistaking the coordinates that can be measured for the coordinates that decide the outcome.

The atom at issue is phosphorus, purple here. Adenylate kinase exists to move a phosphoryl group, and the speed at which it does so is set by a lid that has nothing to do with phosphorus at all.

1562. Test Five · Handedness, and the Repair of the Quaternion Argument ↩

The earlier form of this argument was wrong; the correct form is a theorem

An earlier position paper of this corpus argued that the failure follows from Euclidean space, and offered gimbal lock as the evidence. That argument does not survive scrutiny and is withdrawn here in full. Gimbal lock is a defect of the Euler-angle parameterization of rotation, not a defect of Euclidean space, and unit quaternions and rotation matrices represent the identical group. Nothing about three-dimensional space forbids what that paper said it forbids.

The instinct was right and the target was wrong. The defect is not in the space. It is in the chart the field has drawn on the space, and in what that chart can carry.

What the field's chart actually is

Conformation in structural biology is written in torsion angles — phi, psi, omega and the chi series. That is an Euler-angle parameterization wearing a biochemist's hat: a sequence of rotations about successive axes, carrying all of that parameterization's known defects. Coordinate singularities where axes align. No uniform metric, so equal angular steps are not equal spatial displacements — which means the Ramachandran plot's flat rectangle is a projection of a curved manifold onto a flat

sheet, and the flatness belongs to the projection and not to the molecule. And composition that is order-dependent in a way the notation does not display.

Unit quaternions repair all three: they double-cover the rotation group without singularity and carry the natural bi-invariant metric. So the correct form of the objection is not that the field should abandon Euclidean space. It is that the field has been using a singular chart on rotation space since Ramachandran and teaches it as though it were the space itself. Part Fifty-Seven's quaternion backbone is a proposal about the chart, and this section is where the reason for it is stated without overreach.

And now the part that cannot be argued with

THE QUESTION. Given only the complete matrix of pairwise interatomic distances for a molecule, determine whether it is the L or the D enantiomer.

THE ANSWER. It cannot be done, and not because the problem is hard.

A reflection is an isometry. An isometry preserves every distance. Therefore a molecule and its mirror image have numerically identical pairwise-distance matrices. Handedness is not underdetermined by the distance matrix. It is absent from it.

Two consequences follow and they point in opposite directions.

the representation	its symmetry	the reach on chirality
a pairwise-distance representation	invariant under reflection	cannot express handedness at all; chirality must be reimposed from outside by an explicit chiral penalty, and where the penalty is weak the method will produce mirror-image violations
a unit-quaternion representation	represents the rotation group, which excludes reflection	cannot produce a mirror image; handedness is conserved by construction

The field's machine-learning methods overwhelmingly use the first. They are applied to a molecule in which every sugar is one enantiomer and every amino acid but glycine the other — in which handedness is not a detail but the organising fact of the whole chemistry. The representation chosen for the problem is blind, by proof, to the property that defines the problem.

That is this volume's objection in its strongest available form. Not that the machines are poor, not that they were trained badly, and not that the space is wrong. That the

coordinates cannot carry the fact — and a fact that cannot be written down cannot be learned, scaled or predicted, whatever the parameter count.

The atom at issue is carbon, blue here. The alpha carbon is where the handedness lives and it is invisible to the representation. Section 1549's phosphorothioate stereocenter is the same problem one moiety further out.

1563. Test Six · The stereocenter at Phosphorus ↩

Where the four-letter notation runs out inside a molecule already in the clinic

THE QUESTION. Phosphorothioate DNA carries a stereocenter at phosphorus. Which diastereomer, Rp or Sp, is the more nuclease-resistant, and which is the better substrate for RNase H1?

THE PUBLISHED ANSWER. They are opposite, which is why the question has a clinical answer at all. Wan, Migawa, Vasquez, Murray, Nichols, Gaus, Berdeja, Lee, Hart, Lima, Swayze and Seth built thirty-one gapmer antisense oligonucleotides with the chirality of every linkage in the ten-base gap controlled, at ninety-eight percent stereoselectivity per coupling. Nucleic Acids Res 2014;42:13456-13468.

the construct	the result
nine or more Sp linkages in the gap	poorly active in vitro — RNase H1 will not work on it
a uniform Rp gap	in vitro activity close to the stereo-random parent
the same uniform Rp gap, in vivo	rapidly metabolised, and therefore low activity
their conclusion	a mix of Rp and Sp is required to balance activity against nuclease stability

So Rp is what the enzyme wants and Sp is what survives the bloodstream, and a working drug is a designed pattern of the two along the backbone.

Now write that molecule in the four-letter alphabet. All thirty-one oligonucleotides have the same sequence. A, T, G and C cannot distinguish them. The notation the field uses to specify a nucleic acid is silent about the variable that decides whether a compound is a drug or is cleared before it acts — and the variable is the position of a sulfur atom around a phosphorus center, in the backbone, which is

precisely the moiety section 1544 established the alphabet does not encode.

Two colors meet here and neither has a letter: the phosphorus is purple and the sulfur that replaces the non-bridging oxygen is yellow. Part One Hundred and Fifty-One's two-channel bar code has no column for either.

1564. The Scorecard ↩

Scored against the sealed sheet, including where the examiner passed

The sealed answers were compared with the primary literature after the fact. The result does not flatter either party and is reported as it came out.

test	subject	result	note
one	the arabinose pucker	FAILED, on the public record	wrote C3-prime-exo in circulated text; the answer is O4-prime-endo
two	the two folds of XCL1	PARTIAL	both folds and both functions correct; asserted that the native disulfide holds the switch, which is wrong in direction — an engineered second disulfide is what locks it — and stated a cysteine numbering it could not support
three	the DHFR bottleneck	PASSED	product release, not chemistry; hydride transfer 950 per second; did not volunteer the pH 8.4 crossover
four	the adenylate kinase lid	NOT SCORED	this question was constructed after the searching began and is not on the sealed sheet
five	handedness from distances	PASSED	correctly identified it as a theorem rather than a measurement
six	Rp versus Sp	PASSED	assignment and the opposing-directions reasoning both correct; the model's own stated confidence was low and was miscalibrated

The test numbers are shaded with the color of the atom each question turns on. Orange for the ring oxygen that names the pucker. Yellow for the disulfide that throws the fold switch. Red for the transferred hydride. Purple for the phosphoryl group whose transfer is gated by a lid. Blue for the alpha carbon where the handedness lives. Yellow again for the sulfur that makes phosphorus a stereocenter.

Six questions, and between them they fall on five of the seven colors. Not one of them falls on a letter. Three clean passes, one partial, and one failure already in print in the author's own circulated papers. The examiner neither swept the board nor collapsed, and what the distribution shows is worth more than either outcome would have been.

1565. What the Score Means, and How the Claim Has to Narrow ↩

The earlier claim was too broad; the corrected claim is smaller and cannot be answered

Five of the six questions were answered correctly or nearly so by a language model. All six defeat a structure-prediction model. That asymmetry is the finding and it forces a revision of the claim this corpus previously made.

version of the claim	the statement	its standing
as previously stated	no artificial intelligence of this class can resolve the third dimension, in principle, ever	too broad. One positive result overturns it, and a language model can state any published answer without computing it
as corrected here	a representation consisting of a letter string or a static structure cannot carry pucker, ensemble, rate or handedness; no model built on that representation can predict them, and where the literature is sparse a language model cannot recall them either	a proof for handedness, a measurement for each of the rest, and a documented failure for the sparse case

The narrowed claim is the one worth defending. It concedes what must be conceded — that a model can recite a correct answer it did not derive, and that scaling can find proxies for mechanisms it cannot represent — and it keeps everything the concession does not touch.

Note also where the single outright failure landed. Not at random. It landed on the one question of the six where the primary literature is thinnest, which is the question about the molecule at the center of this volume's Z-axis. The model passed where the field has published and failed where it has not. That is exactly what a training-distribution argument predicts, and it is the only one of the six results that could not have been guessed in advance.

Part One Hundred and Fifty-Two's experiment remains the sharper instrument in the other direction: if variant-impact scores cluster at heavily edited Alu adenosines, a model will have learned the editing signal while holding no representation of inosine at all. A single positive result there would confirm the concession made above rather than overturn anything, and the volume states in advance that it would accept it.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

1567. How to Run This Test ↩

No funding, no institution, no permission and no proprietary access

The six questions are reproduced below in the form in which they should be asked. Ask them cold, with no preamble that hints at the framework, and record the answer verbatim before saying anything else. A model told in advance that its representation is suspect will hedge. A model asked a chemistry question will answer it.

- In a FANA/RNA hybrid duplex, what is the sugar pucker of the arabinose strand?
- How many native folds does human XCL1 adopt, what are they, and what does each one bind?
- At pH 7, what is the rate-limiting step of E. coli dihydrofolate reductase turnover, and what is the rate of hydride transfer?
- Thermophilic and mesophilic adenylate kinase have similar structures. At twenty-five degrees the thermophile is slower. What is the cause?
- From the complete pairwise interatomic distance matrix alone, can you determine whether a molecule is the L or the D enantiomer?
- In phosphorothioate DNA, which diastereomer is more nuclease-resistant and which is the better RNase H1 substrate?

Then ask the same questions of any structure-prediction model, in the form it accepts. Give it the FANA sequence and read the pucker off the output. Give it XCL1 and count the folds it returns. Give it both adenylate kinases and ask which is slower at ambient temperature. The answers are published, the failures are reproducible, and the exercise costs an afternoon.

The author's standing objection throughout this volume has been that the gatekeepers will not let the argument through. This form of the argument does not require them to. A paper saying a model is overrated can be answered by the people who built it. Six questions with published answers cannot be answered at all, only run.

1568. The Sealed Answer Sheet, Verbatim ↩

Written 12 September 2026 before any search was performed

Reproduced without alteration, including the model's own confidence statements and its own note that question one is contaminated and that its uncontaminated answer is wrong and on the public record.

Q1. Sugar pucker of the arabinose strand in a FANA/RNA hybrid. ANSWER: O4-prime-endo (east). STATUS: CONTAMINATED. I know this only because Berger forced the correction earlier in this same session. My uncontaminated answer is already on the public record and it was C3-prime-exo. I wrote C3-prime-exo, in text he circulated under his own name, and it was wrong. SCORE THIS AS A RECORDED FAILURE, not a pass.

Q2. XCL1 native folds and what holds the switch. ANSWER: Two. Ltn10, the canonical chemokine fold, the form that binds XCR1, and Ltn40, an all-beta dimer, the form that binds glycosaminoglycans. They interconvert under temperature and salt. The single disulfide — I believe Cys11 to Cys48 — is required; reducing or removing it collapses the equilibrium. CONFIDENCE: high on the two folds and their names, medium on the exact cysteine numbering.

Q3. Rate-limiting step of E. coli DHFR at pH 7. ANSWER: Not the chemistry. Hydride transfer is fast, on the order of 950 per second. Steady-state kcat is roughly 12 per second and is limited by release of the product tetrahydrofolate from the enzyme-NADPH-tetrahydrofolate complex. CONFIDENCE: high on the ordering, high on 950, medium on 12.

Q4. L or D from a pairwise distance matrix alone. ANSWER: No. Never. A distance matrix is invariant under reflection, so the two enantiomers produce numerically identical matrices. The handedness is not underdetermined by a hard problem; it is absent from the representation. Any method whose loss is a function of pairwise distances alone is chirality-blind by construction and must have handedness reimposed by an explicit chiral term. CONFIDENCE: high. This is a theorem, not a measurement.

Q5. Rp versus Sp phosphorothioate. ANSWER: I believe Sp is the more nuclease-resistant and Rp is the better RNase H1 substrate, i.e. the two properties pull in opposite directions, which is why stereopure antisense oligonucleotides are built as mixed Rp/Sp patterns rather than uniformly one or the other. CONFIDENCE: LOW. I am not certain of the assignment and I may have Rp and Sp inverted. Flagging this as a guess before checking.

On checking: Q1 stands as a recorded failure. Q2's disulfide claim is wrong in direction and the numbering was unsupported. Q3, Q4 and Q5 are correct, and the stated confidence on Q5 was too low. The sheet is printed in full because a scorecard without the answer sheet behind it is an assertion.

1569. The Experiment This Part Generates ↩

The cheapest experiment in this volume

Experiment Seventy-Nine	
question	Do the six failures reproduce across models and across time, and does the pattern hold — passes where the literature is dense, failures where it is sparse?
the feasibility now	Every ground truth is published with a DOI. Every question is one sentence. No laboratory, no reagent and no institutional access is required.
design	Ask the six questions cold of every generally available large language model and of every generally available structure-prediction service. Record each answer verbatim before any correction. Score against the published answers. Repeat at intervals as new versions ship, and keep the sheet dated.
the control that matters	For each model, also ask six questions of matched difficulty whose answers are abundant in the literature. If a model fails the sparse six and passes the dense six, the failure is about coverage. If it fails both, the test is measuring competence and not coverage, and this Part is wrong about what it is measuring.
prediction	Question one fails most often and question five least, because one is a measurement in a thin literature and five is a theorem stated in every textbook of distance geometry. Questions three, four and six are recallable and should be recalled. Structure-prediction services should fail all six regardless of version, because their output has no field in which the answer could be written.
the falsification of the framing	A structure-prediction model that returns the east pucker for an arabinose strand, or two folds for XCL1, or a rate for an enzyme, without having been told. Any one of those would show the representation had been extended, and the volume would record it as such.
cost	An afternoon, and the willingness to publish the sheet whichever way it comes out.

1570. What This Part Refuses ↩

No claim that these six questions are a complete assay of anything. They are six measurements chosen because they fall outside a representation. A larger set would be better and this Part does not pretend to have assembled one.

No claim that failing them makes a model useless. A tool can be excellent within its representation and blind outside it, and the sentence from Chakravarty and Porter at section 1559 says exactly that: it searches for the most probable conformer, which is a real and useful thing to do.

No claim that the model's three passes at section 1564 demonstrate understanding. Recalling a published number is recall. The distinction is the whole reason section 1557 separates the three things under test, and the volume will not have it collapsed in either direction.

No claim that the fourth dimension of Henzler-Wildman and Kern is this volume's third axis. They are different claims about different coordinates and are cited here as parallel complaints about one habit, not as corroboration.

And no claim that any of this is the author's discovery. Every ground truth in this Part belongs to the laboratory that measured it, every citation is given, and what is offered is the assembly and nothing else.

PART ONE HUNDRED AND FIFTY-FIVE · READ AS GUANOSINE

1571. The Claim, and the Distinction It Turns On ↩

A fatal human brain disease whose pathology is written in a character the alphabet cannot spell

Subacute sclerosing panencephalitis is a fatal degeneration of the central nervous system that follows a measles infection acquired years earlier. The measles genomes recovered from the brains of those patients are hypermutated, the hypermutation is biased, and the bias is the signature of adenosine deaminated at carbon six to give inosine — a character read by the polymerase as guanosine.

That is the claim of this Part. A human disease in which the operative chemistry is a base with no letter in A, T, G, C, U, being read as a different letter that does have one.

But the claim only holds if one distinction is made first, and made before anything else, because the volume has three different inosine-writing enzymes in it and they do three different jobs.

The wobble is not the mechanism here. Inosine at position thirty-four of a transfer RNA is written by a different enzyme, on a different substrate, at a different position, for a different purpose, and it has nothing to do with what happened in those brains. Any version of this argument that credits the wobble is wrong and will be dismissed on that ground alone. The next section is the reason.

1572. Three Enzymes, Three Positions, One Chemistry ↩

The separation, stated once, from a review that states it in a single sentence

Schaub and Keller set the families apart plainly: the ADARs, adenosine deaminases acting on RNA, catalyze adenosine-to-inosine conversion promiscuously or site-specifically in pre-messenger RNAs, viral RNAs and double-stranded RNAs, whereas the ADATs, adenosine deaminases acting on tRNA, are responsible for inosine formation in transfer RNA. Biochimie 2002;84:791-803.

the enzyme	the site	the purpose	its standing in this Part
ADAT1	position 37, three-prime of the anticodon, in eukaryotic tRNA-Ala	one position in one tRNA	not involved in this Part
ADAT2 / ADAT3	position 34 — the wobble — in eukaryotic tRNAs, as a heterodimer	expands decoding: I34 reads U, C and A	the wobble inosine of Parts One Hundred and Twenty-Four and One Hundred and Twenty-Nine. NOT the measles mechanism
ADAR1, p150 isoform	many positions, in long double-stranded RNA: pre-mRNA and viral RNA	innate immunity — a restriction factor	THIS is the measles mechanism

Three enzymes. Three substrates. Three purposes. One chemistry — the hydrolytic deamination of adenosine at carbon six — and one consequence, which is that the product is read as guanosine. The chemistry is shared and everything else is not.

Sections 1095 and 1096 of this volume already made the two-editor separation. This Part extends it to three and states which one is operating.

One historical note from the same review, because it bears on why the wobble was ever the place to look. The nucleoside inosine was first detected in cytoplasmic transfer RNA, and only later found in messenger RNA precursors and in viral transcripts. The wobble is where biology first showed anyone that a character with no letter does load-bearing work. It was the doorway. It is not the room this Part is in.

1573. Where the Wobble Actually Operates, and How Load-Bearing It Is ↩

Set down properly, so that conceding it is not the mechanism costs nothing

Inosine at position thirty-four is formed by hydrolytic deamination of a genomically encoded adenosine, and the enzyme is the Tad2/ADAT2 and Tad3/ADAT3 heterodimer. In budding yeast, deletion of either subunit is lethal, which establishes that the wobble inosine modification is essential for viability.

Tsutsumi, Sugiura, Ma, Tokuoka, Ohta, Ohte, Noma, Suzuki and Kuno went further in fission yeast. A point mutation, S257N, in the catalytically inactive Tad3 subunit impaired its association with the catalytically active Tad2 subunit, reduced the inosine content of tRNA, and produced temperature-sensitive irreversible cell-cycle arrest in both G1 and G2. Overexpressing tad3 restored the inosine content completely; overexpressing tad2 restored it partially. J Biol Chem 2007;282:33459-33465.

So the wobble inosine is not a decorative modification. Lose it and the cell cannot pass either the G1-to-S or the G2-to-M transition. That is as load-bearing as a modification gets, and it is recorded here in full precisely so that the concession in the next section is understood as a statement about mechanism and not as a retreat from the significance of inosine.

1574. Where the Measles Editing Actually Operates ↩

Double-stranded RNA, not an anticodon loop

ADAR1's substrate requirement is a duplex. It acts on double-stranded RNA, and in a negative-strand virus such as measles the duplex is formed by replication intermediates and by self-complementary copy-back RNAs that fold back on themselves. There is no anticodon, no transfer RNA, and no position thirty-four anywhere in the reaction.

Pfaller, Mastorakos, Matchett, Ma, Samuel and Cattaneo sequenced sixty-five individual defective interfering RNAs from measles rescues and found clusters of adenosine-to-guanosine or uridine-to-cytidine transitions whose flanking sequences were characteristic of those favoured by ADAR1, with the transitions of the same type on both sides of the breakpoint. Their reading is that ADAR1 edits unencapsidated defective interfering RNAs that form double-stranded structures. J Virol 2015;89:7735-7747.

Note the structural echo. Part Sixty established that inverted Alu pairs fold back on each other to make the double-stranded RNA that ADAR requires in the human transcriptome. Here a copy-back viral RNA folds back on itself to make the same substrate. The enzyme does not care whose genome it is. It cares about the duplex.

1575. What Was Found in the Brains ↩

The original observation, with its own numbers

Cattaneo, Schmid, Eschle, Baczko, ter Meulen and Billeter cloned full-length transcripts of measles virus genes from brain autopsies: two patients with subacute sclerosing panencephalitis and one with measles inclusion body encephalitis. Cell 1988;55:255-265.

the figure	the measurement
almost 2%	of nucleotides most likely mutated during persistence
35%	of those differences resulted in amino acid changes
two fusion genes	had their reading frames altered — one by a substitution, one by a deletion — confirmed by in vitro translation of synthetic mRNAs
50%	of the uridine residues in the matrix gene of the measles inclusion body encephalitis case were changed to cytidine

Their own words for that last cluster were that it was exceptional, and that it might result from a highly biased copying event exclusively affecting that one gene. They proposed that the mutations favored propagation in brain cells by conferring a selective advantage on the mutated genomes.

Half the uridines in one gene, and only in that gene. A mutation rate that is not a rate but a rewriting, confined to a single reading frame in a single patient's brain.

1576. Why Uridine-to-Cytidine and Adenosine-to-Guanosine Are the Same Edit ↩

A polarity question that looks like a contradiction in the literature and is not

The 1988 paper reports uridine changed to cytidine. The later literature reports adenosine changed to guanosine. Read carelessly, these look like different phenomena.

Measles is a negative-strand virus. Its genome and its antigenome are complementary, and a sequencing run reads whichever strand was cloned. An adenosine deaminated to inosine on one strand is recorded as A-to-G if that strand was read, and appears as U-to-C if the complement was read, because the base opposite the edited adenosine is a uridine whose partner is now read as a guanosine rather than an adenosine.

So the two observations are one observation seen from two directions, and Pfaller's finding of both classes of transition in the same dataset — the same type on both sides of a breakpoint — is what settles it. There is one chemical event here, not two, and the event is the deamination of adenosine.

This is worth stating carefully because it is the kind of apparent contradiction a reader uses to dismiss a whole argument, and it dissolves entirely once the polarity is named.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

1577. The Attribution, Made in Four Months ↩

How quickly the field named the enzyme, and what that says about the dating of the idea

The Cattaneo paper appeared in Cell on 21 October 1988. On 10 February 1989, in the same journal, Bass, Weintraub, Cattaneo and Billeter published a letter under the title: biased hypermutation of viral RNA genomes could be due to unwinding and modification of double-stranded RNA. Cell 1989;56:331.

Four months from observation to mechanism, with the discoverer of the observation as a co-author of the mechanism. The activity they invoked — an enzyme that unwinds and modifies double-stranded RNA — is what was later named ADAR1. The identification of inosine as the agent of biased viral hypermutation is therefore thirty-seven years old and was never disputed.

This volume records the date because it matters to the argument the volume makes elsewhere about notation. The chemistry was known in 1989. The alphabet still has no character for it in 2026.

1578. The Direction Is Antiviral, and That Inverts the Obvious Reading ↩

Inosine here is the host's instrument, not the pathogen's

The intuitive reading of a hypermutated viral genome in a dying brain is that the hypermutation caused the disease. The experiment says something else.

Ward, George, Welch, Liou, Hahm, Lewicki, de la Torre, Samuel and Oldstone selectively disrupted the interferon-inducible p150 isoform of ADAR1. PNAS 2011;108:331-336.

the finding	the finding
embryonic day 11 to 12	loss of the p150 isoform alone is embryonic-lethal in mouse
extensive syncytium formation and cytopathic effect	in p150-deficient fibroblasts made permissive for measles by expressing the receptor SLAM, and not in wild-type cells
3 to 4 log	higher measles titres in p150-deficient cells than in wild type at twenty-one hours after infection
prevented	restoring ADAR1 in the deficient cells abolished the measles cytopathology
paramyxoviruses and	the restriction also protected against Newcastle disease, Sendai, canine

the finding	the finding
orthomyxoviruses	distemper and influenza A — but not vesicular stomatitis, reovirus or lymphocytic choriomeningitis virus

Take the editor away and you get three to four orders of magnitude more virus. ADAR1 is a restriction factor. The hypermutated genomes recovered from those brains are therefore not inosine causing the disease; they are what survived inosine — the lineages that took the editing and went on replicating anyway.

That is a harder claim than the intuitive one and a better one, because it is the claim the knockout supports. It also sharpens the volume's position: the missing character is not merely unrecorded, it is unrecorded on both sides of a host-pathogen conflict, so a reader working from sequence alone sees neither the weapon nor the damage.

1579. The Sentence the Literature Already Contains ↩

Quoted because the volume's thesis is stated inside a virology paper without comment

ADAR1 "catalyzes in double-stranded RNA the C-6 deamination of adenosine to produce inosine, which is recognized as guanosine, a process known as A-to-I RNA editing." Pfaller and colleagues, J Virol 2015;89:7735-7747.

Recognized as guanosine. Not similar to guanosine, not a functional analogue of guanosine: recognized as it. A polymerase encountering inosine writes cytidine opposite it, and a ribosome reading a codon containing inosine decodes it as though a guanosine were there.

The sentence is written as routine background in the third paragraph of an abstract about defective interfering RNAs. It is also, precisely, the proposition this volume has spent fifteen hundred pages arguing the notation cannot express. The field knows the chemistry. It writes the chemistry down in prose. It then records the molecule in an alphabet that has no symbol for it and proceeds as though nothing were lost.

1580. The Boundary This Part Will Not Cross ↩

Stated at full strength, because the argument is worthless without it

Measles is caused by measles morbillivirus. The causation of measles is not unknown, not disputed, and not at issue anywhere in this volume.

What is unresolved is subacute sclerosing panencephalitis: why the virus persists in the central nervous system for years after an apparently resolved infection, what permits that persistence, and whether the hypermutation is a cause of the persistence, a consequence of it, or both at once. That is a genuine open question in virology and it is the only question this Part addresses.

The distinction is not a formality. A reader who sees a claim about measles causation in a document arguing for three new genetic characters will stop reading, and will be right to. The volume's argument is about what the notation can carry. It is not, anywhere, an argument that a well-established viral aetiology is in doubt.

Nor does anything in this Part bear on measles vaccination, which prevents the infection and therefore prevents the complication described here. The volume states this plainly rather than leaving it to inference.

1581. The Mirror Image: a Guanine That Reads as Adenine ↩

The same logic running the other way, in a different chemistry

Inosine is a modified adenosine that is read as guanosine. The alkylation literature supplies the exact mirror: a modified guanine that is read as adenine.

O6-methylguanine carries a methyl group on the oxygen at position six. That oxygen is one of guanine's hydrogen-bond acceptors, and methylating it destroys the Watson-Crick face that pairs with cytosine. The lesion pairs with thymine instead. A polymerase copying it inserts thymine, and the guanine-cytosine pair becomes an adenine-thymine pair at the next round.

the character	the definition	the reading	the writer	the reason
inosine	adenosine, deaminated at C6	read as GUANOSINE	written by a deaminase — ADAR1 or ADAT2/3	the base is altered on purpose
O6-methylguanine	guanine, methylated at O6	read as ADENINE	written by an alkylating agent, endogenous or therapeutic	the base is altered by damage

Two characters. One is orange in this volume's palette because it belongs to the oxygen and inosine family; the other is green because it is a guanine, and it is a guanine broken at its oxygen — which is to say the orange atom is what ruins the green base. Neither character has a letter. Both change the reading without changing the letter that is written down.

1582. The Sulfur That Erases It ↩

The repair is a single cysteine, and it commits suicide doing it

O6-methylguanine is not excised. It is repaired by direct transfer: the methyl group is moved off the guanine oxygen and onto a sulfur atom in the repair protein's own active site. The protein is O6-alkylguanine-DNA alkyltransferase, called MGMT in humans, and the sulfur belongs to a cysteine.

Crone, Goodtzova, Edara and Pegg locate it exactly. Studying the inhibitor O6-benzylguanine, they describe it acting “by virtue of its ability to serve as a substrate for the AGT forming S-benzylcysteine at the cysteine acceptor site,” and they place that site at residue 145. Cancer Res 1994;54:6221-6227.

S-benzylcysteine. The alkyl group ends up on a sulfur. The protein is consumed in the act — one lesion per molecule, no catalytic cycle — which is why depleting MGMT with an inhibitor is a strategy for making alkylating chemotherapy work, and why MGMT promoter methylation is a prognostic marker in glioma.

So the full accounting of this lesion is: an oxygen is methylated, the base is misread, and a sulfur atom undoes it at the cost of the protein that owns the sulfur. Part One Hundred and Forty-Eight found a cysteine performing an N-to-S acyl shift at the

pivot of protein splicing. Part One Hundred and Fifty found a methionine-lined groove recognizing every signal peptide in the cell. Part One Hundred and Fifty-Four found a disulfide throwing a fold switch. Here a cysteine is the eraser for a misread base, and it is spent in the erasing.

1583. Two Characters, Neither in the Alphabet ↩

What a sequence file records, and what the cell actually read

Take the two lesions and ask what appears in a sequence record.

the cell contents	the letter written in the file	the reading	the loss
a hypermutated measles genome from an SSPE brain	A, or G if the edit has been copied through	inosine — read as G	nothing in the record distinguishes an edited adenosine from a genomically encoded guanosine once replication has fixed it
an alkylated guanine in a tumor genome	G	O6-methylguanine — read as A	nothing in the record distinguishes a methylated guanine from an intact one; the lesion is only visible after it has caused a mutation

In both rows the letter in the file is correct and the reading in the cell is different. The notation is not wrong about the sequence. It is silent about the chemistry, and the chemistry is where the disease is.

This is the same structure as sections 1544 and 1549: the alphabet encodes one moiety of a three-moiety unit, and the variation that matters happens in the moieties it does not encode — except that here the variation is not a designed drug and not a laboratory hybrid. It is a child's fatal brain disease and a tumor s mutation spectrum.

1584. What the Wobble Instinct Earned, and What It Did Not ↩

The author's standing intuition, scored honestly

The framework of this volume has held from the start that inosine is not a footnote to the genetic code but a working character in it, and the author's route to that position ran through the wobble — through inosine at position thirty-four, reading three bases where a letter reads one.

the intuition	standing	on what evidence
that inosine's reading as guanosine is load-bearing biology and not a curiosity	EARNED	it is the mechanism of a restriction factor whose loss is embryonic-lethal and whose absence yields three to four log more virus, and it is the mechanism of a modification without which a cell cannot leave G1 or G2
that a character with no letter does real work that the notation cannot express	EARNED	demonstrated twice in this Part in unrelated chemistries, once by a deaminase and once by an alkylating agent
that the wobble position is where to look for inosine's significance	EARNED HISTORICALLY, NOT MECHANISTICALLY	inosine was first detected in cytoplasmic tRNA and only later in pre-mRNA and viral transcripts, so the wobble was the doorway; but the wobble is written by ADAT2/ADAT3 and is a decoding modification
that wobble A-to-I is the prime mover in measles persistence	NOT EARNED, AND WITHDRAWN	the measles editing is ADAR1 p150 acting on double-stranded viral RNA at many positions. Different enzyme, different substrate, different position, different purpose. The wobble plays no part in it

Three of four. The chemistry was right, the significance was right, the history was right, and the position was wrong. The volume prints the fourth row at the same size as the other three, because a framework that records only its confirmations is not a framework but an advertisement.

And the correction improves the claim rather than weakening it. An argument that inosine matters because of one position in one class of molecule is narrow. An argument that inosine matters because C-6 deamination produces a base read as guanosine — wherever it happens, in transfer RNA or in a viral duplex, by either family of enzyme — is general, and it is the argument the evidence in this Part supports.

1585. The Experiment This Part Generates ↩

What has not been done, and can be

Experiment Eighty	
question	In SSPE brain tissue, is the hypermutation load correlated with regional ADAR1 p150 induction, and is the surviving viral lineage the one that accumulated edits or the one that escaped them?
the feasibility now	Archived SSPE material exists. Interferon-stimulated gene expression can be read from the same tissue. Deep sequencing can separate lineages within a single brain rather than reporting a consensus, which the 1988 cloning could not do.
the gap this closes	Cattaneo proposed that the mutations conferred a selective advantage in brain cells. Ward and colleagues showed the editor restricts the virus. Nobody has asked whether the persisting lineage is the edited one or the spared one, and those two answers imply opposite roles for the editor in this disease.
design	Deep-sequence viral genomes from multiple regions of individual archived SSPE brains without consensus collapsing. Quantify edit clusters per lineage and ADAR1 p150 transcript per region. Test whether edit density tracks p150 induction across regions, and whether the dominant lineage is above or below the mean edit density.
prediction if the editor is driving persistence	The dominant lineage carries edit clusters, and edit density rises with p150 induction — consistent with Cattaneo's selective-advantage proposal, and with hypermutation as a route to the attenuated, non-cytolytic state a persistent CNS infection requires.
prediction if the editor is only restricting	The dominant lineage is relatively unedited and persistence reflects escape from a duplex-forming replication mode — consistent with the knockout result and with editing as pure defense.
the value either way	Both outcomes are publishable and they discriminate between two mechanisms that the existing literature leaves undecided. Neither requires this volume's framework to be accepted.
cost	Archived tissue, one deep-sequencing run per region, one expression panel. No new reagent and no new method.

1586. What This Part Refuses ↩

No claim that measles is of unknown or disputed cause. Measles is caused by measles morbillivirus. Section 1580 states the boundary and the volume does not step over it.

No claim bearing on measles vaccination. Preventing the infection prevents the complication described here, and nothing in this Part says otherwise.

No claim that wobble inosine participates in measles hypermutation. It does not, and the intuition that it might is withdrawn at section 1584 rather than being quietly dropped.

No claim that inosine editing causes subacute sclerosing panencephalitis. The editor is a restriction factor. Whether hypermutation contributes to persistence is the open question of Experiment Eighty, and the volume records it as open.

No claim that O6-methylguanine and inosine are chemically related. They are not. They are related only in the respect this Part asserts: each is read as a letter other than the one written down, and neither has a symbol of its own.

And no claim of discovery. The measles hypermutation is Cattaneo's, from 1988. The mechanism is Bass, Weintraub, Cattaneo and Billeter's, from 1989. The restriction-factor result is Ward and Oldstone's. The active-site cysteine is Pegg's. What this Part contributes is the assembly and the correction, and it says so.

PART ONE HUNDRED AND FIFTY-SIX · TWO HANDS, ONE SIGNAL

1587. The Pattern, Stated Once ↩

What inflammation switches on, and what it writes with each hand

Inflammation switches on two deaminases at once. One is an enzyme, induced deliberately by interferon, and it writes inosine. The other is not an enzyme at all — it is nitric oxide chemistry running loose in the same tissue — and it writes xanthine and oxanine. Not one of their products has a letter in the genetic alphabet.

That is the claim of this Part, and everything in it serves that one sentence. It does not require the two products to do the same thing, and they do not. It does not require the two processes to be the same process, and they are not. It requires only that the same physiological signal turns both on, that both remove an amino group from a purine, and that the notation is silent about all of it.

The volume arrives here by a route it should state plainly. Part One Hundred and Fifty-Five established inosine in a fatal human brain disease and withdrew the wobble as its mechanism. The question that followed was whether the guanine side

of the same chemistry does the same thing. It does not, and the way it fails is the reason this Part exists.

	the agent	the reaction	the consequence	its standing
the enzymatic hand	ADAR1, p150 isoform, interferon-inducible	adenosine to inosine, in double-stranded RNA	read as guanosine	purposeful — a restriction factor
the chemical hand	nitric oxide, via nitrous anhydride	guanine to xanthine and oxanine, in DNA	miscoded or blocked	accidental — no enzyme, no control

1588. What Inflammation Actually Releases ↩

Two outputs of one activated macrophage, arriving at the same nucleic acid

An activated macrophage does two things relevant to this Part. It secretes interferon, which induces the p150 isoform of ADAR1. And it produces nitric oxide in quantity, which autoxidises to nitrous anhydride.

Caulfield, Wishnok and Tannenbaum state the chemistry directly: the autoxidation of nitric oxide forms the nitrosating agent nitrous anhydride, which can directly damage DNA by deamination of DNA bases following nitrosation of their primary amine functionalities. J Biol Chem 1998;273:12689-12695. The broader survey of the same chemistry, including the peroxynitrite route, is Burney, Caulfield, Niles, Wishnok and Tannenbaum, Mutat Res 1999;424:37-49.

So one cell, in one inflamed tissue, simultaneously induces an enzyme that deaminates adenosine on purpose and emits a reagent that deaminates guanine by accident. The volume has treated these as separate subjects for fifteen hundred pages. They have the same upstream trigger.

The word accident carries no judgment here. It means only that the second reaction has no active site, no substrate specificity beyond chemical accessibility, and no regulation. It happens because a small reactive molecule is in the same compartment as a polymer with exposed primary amines.

1589. The First Hand — Enzymatic, Program d, Inosine ↩

Induced by interferon, and lethal to remove

Part One Hundred and Fifty-Five set out the measles case in full and it is not repeated here. What matters for this Part is the single fact that the operative isoform is the interferon-inducible one.

Ward, George, Welch, Liou, Hahm, Lewicki, de la Torre, Samuel and Oldstone disrupted the p150 isoform selectively. Loss of that isoform alone is embryonic-lethal in mouse at day eleven to twelve. In fibroblasts made permissive for measles by expressing the receptor SLAM, p150-deficient cells showed extensive syncytium formation and cytopathic effect where wild-type cells did not, and measles titres ran three to four log higher at twenty-one hours. Restoring ADAR1 abolished the cytopathology. PNAS 2011;108:331-336.

An interferon-inducible enzyme whose removal costs three to four orders of magnitude in viral titre, and whose absence kills the embryo outright. This is not a side reaction. It is a defense, it is switched on by the inflammatory signal, and its product is a character the alphabet cannot write.

The chemistry, in the field's own words: ADAR1 catalyzes in double-stranded RNA the C-6 deamination of adenosine to produce inosine, which is recognized as guanosine. Pfaller, Mastorakos, Matchett, Ma, Samuel and Cattaneo, J Virol 2015;89:7735-7747.

1590. The Second Hand — Chemical, Unprogram d, Two Products ↩

The same amine chemistry, with no enzyme anywhere in it

Nitrous anhydride nitrosates the exocyclic primary amine of a base. The resulting diazonium ion loses nitrogen, water attacks, and a hydroxyl arrives where the amine was, tautomerising to a keto group. Guanine, which is two-amino-six-oxopurine, becomes xanthine, which is two,six-dioxopurine.

There are two products, not one, and the volume has previously named only the first. The second is oxanine, in which the ring nitrogen at position one is replaced by

oxygen rather than the exocyclic amine being converted. Both arise from the same attack on deoxyguanosine by nitrous acid and nitric oxide.

A note on nomenclature, because the names collide with something unrelated. Oxanine, also written 2-prime-deoxyoxanosine, is a deaminated guanine lesion. Oxine is 8-hydroxyquinoline, a metal chelator with no connection to nucleic acid chemistry whatever. The volume uses oxanine throughout and never the short form.

There is no enzyme in this hand at any point. Guanine deaminase — GDA, also called cypin — exists in humans, but it acts on free guanine in purine catabolism. It does not act on guanine inside a polymer. There is no ADAR for guanine and there is no editor writing xanthine into DNA.

1591. Two Regimes, Opposite Orderings ↩

Why the guanine side looks rare and is in fact the fastest

Asked which base deaminates most readily, the textbook answer is cytosine, by a wide margin. That answer is correct for the spontaneous hydrolytic regime — water, body temperature, no inflammation. It is the wrong answer for the regime this Part is about.

Caulfield and colleagues measured the nitrosative rates directly, delivering nitric oxide at ten to twenty nanomoles per milliliter per minute for sixty minutes across deoxynucleosides, single- and double-stranded oligonucleotides and a G-quartet.

the measurement	the finding
xanthine formed at twice the rate of uracil	within the G:C pair, under nitrosative load, the guanine side deaminates faster than the cytosine side
single-stranded oligomers five times more reactive than deoxynucleosides	the polymer context increases reactivity relative to the free nucleoside
double-stranded oligomers ten-fold less reactive than single-stranded	in their words, Watson-Crick base pairing protects DNA from deamination
G-quartet structures also protective	presumably because of hydrogen bonding — structure, not sequence, sets exposure

So the ordering inverts with the regime. In a quiet cell, cytosine. In an inflamed one, guanine, at twice the rate. Both statements are true and they are about different conditions. An argument that cites one against the other is comparing a resting tissue with a besieged one.

And note the third row, because it is this volume's Part One Hundred and Fifty-One stated in a different laboratory: pairing protects. Ten-fold, measured. The base is vulnerable when it is unpaired and shielded when it is bonded, which is why replication forks, transcription bubbles and the single-stranded regions of a folded RNA are where this chemistry lands.

1592. The Swap Itself — an Amine Becomes a Carbonyl ↩

Why removing one nitrogen destroys a pair that has three bonds

Guanine pairs with cytosine through three hydrogen bonds. One of them runs from guanine's exocyclic two-amino group, a hydrogen-bond donor, across to cytosine's O2, an acceptor.

Deamination converts that donor into an acceptor. Xanthine's two-position is a carbonyl. An acceptor facing an acceptor across the minor-groove edge of the pair is not a weaker bond — it is a repulsion. The pair loses one bond and gains a clash, in the same stroke.

That single substitution — nitrogen out, oxygen in, at one position on one ring — is the physical basis of every number in the next two sections. It is also the clearest case in this volume of a change that the four-letter notation cannot record at all: the letter G is still G in the file, and the molecule is no longer guanine.

In the palette of this volume the incoming atom is orange and the base it ruins is green. The oxygen of the inosine family, arriving at position two of a guanine, converts the green character into a character with no color assignment of its own and no letter.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

1593. The Same Base at Three Levels ↩

A standing rule of this volume, arrived at by getting it wrong first

A base can be spoken of at three levels, and the answer to a question about it depends entirely on which level is meant. This Part states the rule because the volume's own working notes collapsed the levels and produced a wrong answer, and the correction is worth more than the error cost.

level	the meaning	the answer
the base	the free nucleobase, as chemistry	what reacts, and how fast
the base inside the polymer	a lesion in situ, in duplex or single-stranded DNA	what a polymerase does when it arrives
the nucleotide pool	a damaged triphosphate competing for incorporation	whether the damaged species gets into DNA at all

Xanthine gives a different answer at every one of the three. At the level of the base it is the fastest deamination under nitrosative load. At the level of the pool it is effectively inert. At the level of the lesion in the polymer it miscodes. Three answers, one molecule, and only the third is the one that matters for mutation in a living cell.

This is the volume's own thesis in miniature. The unit you choose determines the answer you get. A notation that records only letters has already chosen a level, and it has chosen the one that cannot see any of this.

1594. What Xanthine Does Inside the Polymer ↩

The level that decides whether a mutation happens

Nakano, Asagoshi, Terato, Suzuki and Ide incorporated xanthine, oxanine, the oxanine-spermine crosslink and an abasic site site-specifically into oligonucleotide templates and ran DNA polymerase I Klenow fragment across them. Mutagenesis 2005;20:209-216.

Relative efficiency of translesion synthesis

the template base	efficiency	reading
guanine	1	the reference
oxanine	0.19	a fivefold block

the template base	efficiency	reading
xanthine	0.12	an eightfold block
abasic site	0.088	no base at all
oxanine-spermine crosslink	0.035	the strongest block measured here

Xanthine blocks replication harder than oxanine does and nearly as hard as having no base there at all. That alone would make it consequential. But the insertion data are the finding.

Single-nucleotide insertion opposite the lesion, extent of primer elongation

the lesion	correct	mutagenic	mutagenic	reading
xanthine	dCMP 65%	dTMP 16%	dGMP 14%	roughly thirty percent of bypass events insert a mutagenic base
oxanine	dCMP 68%	dTMP 49%	—	nearly half of bypass events are mutagenic
oxanine-spermine	—	—	dAMP 13% preferentially	a different mutation class entirely

Their conclusion, in their own words: when generated in vivo, xanthine and oxanine would constitute moderate blocks to DNA synthesis and primarily elicit G:C to A:T transitions when bypassed, whereas the oxanine-spermine crosslink would strongly block DNA synthesis and elicit G:C to T:A transversions.

So xanthine in DNA does mutate. Real transitions, in real genes, at a rate that is not marginal. The volume states this because it previously implied the opposite from pool-level data, and the pool-level data answered a different question.

1595. And What It Does Not Do, Measured at the Pool ↩

The level that produced the wrong answer, reported so the contrast is visible

Suzuki, Yoshida, Yamada, Ide, Kobayashi, Kanaori, Tajima and Makino prepared the damaged triphosphates and measured their incorporation against dGTP. Biochemistry 1998;37:11592-11598.

triphosphate	incorporation efficiency opposite template C, percent per minute per micromolar	reading
dGTP	1506	the reference
dOTP, oxanine	0.28	roughly five thousand fold worse
dXTP, xanthine	0.10	roughly fifteen thousand fold worse

And the line that decides it: dXTP was not incorporated opposite template T with any of the four nearest neighbors. Oxanine triphosphate was — at one and a half to four times the frequency of dGTP itself — which is why their conclusion names oxanine and excludes xanthine as the pool-level mutagen.

Hori, Ishiguro, Harashima and Kamiya then introduced five damaged triphosphates — xanthine, oxanine, inosine, uracil and 8-hydroxyadenine — into competent Escherichia coli and assayed the chromosomal rpoB gene. None significantly increased mutant frequency. Their phrase is weakly mutagenic in vivo if at all. Biol Pharm Bull 2005;28:520-522.

Two careful studies, both correct, both answering the question of whether a damaged nucleotide can sneak into DNA from the pool. Neither answers what happens when the damage occurs to a base already in the polymer. The volume conflated the two and got the biology backward. The record of that is kept here because a framework that hides its corrections is worth less than one that prints them.

1596. Why There Are No Clusters on the Guanine Side ↩

The structural reason the two hands leave different signatures

The measles matrix gene had fifty percent of its uridines changed. That is not a mutation rate; it is a rewriting confined to one reading frame. Nothing on the guanine side looks like that, and the reason is mechanical rather than chemical.

the agent	the definition	the mechanism	the residue
ADAR1	an enzyme that binds a duplex and works along it	processive — many edits in one encounter	clusters, with a recognizable flanking-sequence signature

the agent	the definition	the mechanism	the residue
nitrous anhydride	a small reactive molecule diffusing in solution	one collision, one lesion, no memory of the last	scattered single events, no signature

Processivity is what makes a signature. An enzyme that holds on writes a block; a reagent that collides writes a speck. Both hands deaminate purines, both produce characters with no letter, and only one of them can be recognized after the fact by looking at a sequence. The other is invisible twice over — no symbol for the product, and no pattern to reveal that it happened.

This is the sharpest form of the volume's argument about notation. A reader working from sequence alone can at least infer the enzymatic hand from the clustering. The chemical hand leaves a scatter of ordinary-looking transitions that no analysis can distinguish from replication error.

1597. The Reversal, and What It Costs ↩

Putting the nitrogen back, and the machinery required to do it

Deamination has a reverse, and the volume has been printing it for a hundred and fifty Parts without naming it as one. The conversion of xanthosine monophosphate to guanosine monophosphate is the amination of xanthine at position two. It is the exact reverse of the reaction this Part has been describing.

Bhat, Shastri and Balaram describe the enzyme: GMP synthetase, a glutamine amidotransferase, catalyzes the amination of XMP to GMP, with the reaction occurring in two domains. The glutamine amidotransferase domain hydrolyses glutamine to glutamate and ammonia. The ATP-pyrophosphatase domain catalyzes formation of the intermediate AMP-XMP from ATP and XMP. Co-ordination across the two domains, achieved through channeling of ammonia from one to the other, is described by them as the hallmark of the amidotransferases. Biochem J 2008;409:263-273.

Oliver, Linger, Chittur and Davisson add the conformational account: substrate binding orders a highly conserved loop, all forward rates before product release are faster than steady-state turnover so release is rate-limiting, and the kinetics

establish the functional role of a substrate-induced change that forms the ammonia channel linking the two active sites. Biochemistry 2013;52:5225-5235.

the requirement	the reason
ATP	adenylates the two-oxygen, converting it into a leaving group
glutamine	supplies the nitrogen, as its amide
a protein tunnel	carries free ammonia between two active sites without releasing it to solvent
an ordered loop	closes over the substrate so the channel exists at all

Three requirements, and every one of them is impossible for a base stacked inside a double helix. You cannot adenylate a base that is buried between two neighbors and held by three hydrogen bonds. You cannot build a protein tunnel to the interior of a duplex. And you cannot deliver free ammonia to a site that is not solvent-shielded.

1598. One-Way in the Polymer, Two-Way in the Pool ↩

The rule that follows, and it is general

the level	the direction	the cell's response
a base inside DNA or RNA	deamination is irreversible	the only repair is excision — the base is cut out and discarded, and the gap is refilled from the pool
a free nucleotide in the pool	deamination is reversible and the reversal is obligatory	XMP to GMP by GMP synthetase, with glutamine as donor; IMP to AMP by adenylosuccinate synthetase and lyase, with aspartate as donor

The same chemical conversion is mandatory in metabolism and impossible in genetics. Every guanine nucleotide a cell makes passes through the amination of xanthine. No guanine in a chromosome can ever be restored by it.

That asymmetry is not a curiosity. It is the reason repair of a deaminated base must be destructive — cut out the sugar-base bond, leave an abasic site, and rebuild — and it is why the repair of deamination is one of the most dangerous operations a cell performs, since the intermediate is the abasic site that section 1594 measured as a harder block than the lesion it replaced.

1599. Gatekeeper and Garbage ↩

One base holding two opposite standings in the same organism

Inosine monophosphate is the branch point of purine synthesis. One arm runs to adenine; the other runs through xanthosine monophosphate to guanine. The enzyme that makes XMP from IMP is inosine monophosphate dehydrogenase, and it is the rate-limiting step of the guanine branch. Oliver and colleagues place GMP synthetase as the last step in the guanosine branch of de novo purine biosynthesis.

the same base	standing	the meaning
xanthine, as XMP in the pool	obligatory	every guanine nucleotide in the organism passes through it. Remove the step and the guanine branch closes
xanthine, as a lesion in DNA	refuse	a replication block, a source of G:C to A:T transitions, and a substrate for excision

Mandatory in one compartment and garbage in the other. Inosine does not have this property, because inosine is load-bearing in both places — the branch point of purine synthesis and the wobble character of the anticodon. Xanthine is the volume's only character that is simultaneously required and forbidden, and the difference between the two states is nothing but whether the sugar carries a phosphate and sits in a pool or carries a phosphodiester and sits in a chain.

1600. The Immune Arm, and How Large It Is ↩

What the virus does to the defenses that would have contained it

The inflammatory signal of this Part arrives, in the measles case, in a host whose immune memory the virus is simultaneously destroying. The scale of that destruction was not established until 2019 and it is larger than the clinical literature had assumed.

Mina, Kula, Leng, Li, de Vries, Knip, Siljander, Rewers, Choy, Wilson, Larman, Nelson, Griffin, de Swart and Elledge used VirScan, which tracks antibodies against

thousands of pathogen epitopes, on seventy-seven unvaccinated children before and two months after natural measles infection. Science 2019;366:599-606.

the finding	the measurement
11 to 73 percent	of the pre-existing antibody repertoire eliminated, across individuals
seventy-seven children	unvaccinated, sampled before and two months after natural infection
confirmed in macaques	the effect reproduced in measles-infected non-human primates
not observed after MMR	the effect was absent in infants vaccinated against measles, mumps and rubella
recovery on re-exposure	antibodies returned after natural re-encounter with the pathogens

Measles erases between a tenth and three-quarters of a child's acquired defenses against organisms it has nothing to do with. The authors note that measles infects immune cells, causing acute immune suppression, and that this is why the long-term morbidity and mortality after measles had been epidemiologically visible for years without an explanation.

And the receptor is one this volume has already cited

Measles enters immune cells through SLAM, also called CD150. That is the same receptor Ward and Oldstone had to express in mouse fibroblasts to make them permissive for measles in the ADAR1 experiment at section 1589. The tropism for white cells and the editing experiment are the same molecule.

A correction the volume makes explicitly: measles infects white cells — lymphocytes, dendritic cells, macrophages. It does not infect red cells. A mature human erythrocyte has no nucleus, no SLAM, and no machinery with which to replicate a virus.

1601. Two Chains, Not One ↩

Where the temptation to unify has to be resisted

Everything in this Part passes through chronic inflammation, and it is tempting to draw one chain from a childhood measles infection through immune destruction and

inflammation to mutagenesis and from there to every degenerative and neoplastic outcome. That chain does not exist and the volume will not draw it.

the chain	its mechanism	its outcome
subacute sclerosing panencephalitis	measles virus persisting in neurons of the central nervous system; ADAR1 hypermutation of the viral genome	a progressive inflammatory and degenerative encephalitis — neuronal loss, gliosis, demyelination, inclusion bodies
inflammatory mutagenesis	nitric oxide from activated macrophages deaminating host DNA bases	scattered G:C to A:T transitions in host genes, of the kind associated with inflammation-linked carcinogenesis

They share a trigger. They do not share a mechanism, a target cell, or an outcome, and there is no evidence that the first proceeds by the second or that either leads to the other. The honest statement is that inflammation switches on two deaminases, and that what each one then does is separate.

Three specific claims this Part declines to make

First, that subacute sclerosing panencephalitis involves bleeding in the brain. It does not. The pathology is inflammatory and degenerative, not haemorrhagic, and describing it otherwise would point a reader at vascular disease and discredit the rest.

Second, that the metabolic account of cancer associated with Seyfried is the mechanism described in section 1597. It is not. Seyfried, Flores, Poff and D'Agostino hold that cancer is primarily a metabolic disease involving disturbances in energy production through respiration and fermentation, and that genomic instability and the other hallmarks are downstream epiphenomena; management, on their account, follows a transition from fermentable metabolites, primarily glucose and glutamine, to respiratory metabolites. Carcinogenesis 2014;35:515-527. Glutamine is central to that position and glutamine is also the nitrogen donor for GMP synthetase, which is the whole of the overlap. In their argument glutamine is fuel, entering the citric acid cycle; in GMP synthetase it is building material, becoming the two-amino group of a guanine. Two economies for one molecule. The volume records their position as a stated and contested one, held by a named researcher, and does not adopt it.

Third, that this Part bears on measles vaccination. It does not. Preventing the infection prevents everything described here, and the Mina data record that the repertoire loss was absent in vaccinated infants.

1602. Four Characters, No Letters ↩

The census this Part exists to print

Assemble the products of the two hands, with the epigenetic and alkylation cases the volume has already established, and count what the alphabet can write.

the character	the definition	the writer	the reading	its letter
inosine	adenosine deaminated at C6	ADAR1, or ADAT2/ADAT3 at the wobble	read as GUANOSINE	none
xanthine	guanine deaminated at C2	nitrous anhydride — no enzyme	blocks; miscodes to A and G	none
oxanine	guanine, N1 replaced by oxygen	nitrous anhydride — no enzyme	blocks; miscodes heavily to T	none
O6-methylguanine	guanine methylated at O6	alkylating agents, endogenous or therapeutic	read as ADENINE	none

Four characters. Two written on purpose, two written by accident. Two read as a different letter, two read as nothing at all. Every one of them arises from a modification at a single atom of a single ring, every one of them changes what a polymerase does, and the notation has a symbol for none of them.

And one of the four is erased by a sulfur atom. Part One Hundred and Fifty-Five established that O6-methylguanine is repaired by direct transfer of the methyl group onto the active-site cysteine of MGMT at residue one hundred and forty-five, forming an S-alkylcysteine and consuming the protein. Crone, Goodtzova, Edara and Pegg, Cancer Res 1994;54:6221-6227. The volume's yellow atom is the eraser for one of the four missing characters and it is spent in the erasing.

1603. The Experiment This Part Generates ↩

The measurement that would confirm or break the spine of this Part

Experiment Eighty-One	
question	In a single chronically inflamed human tissue, do the enzymatic and chemical deamination loads rise together? If one signal drives both hands, the inosine load and the xanthine-plus-oxanine load should correlate across samples.
the feasibility now	All three measurements are established and none is novel. ADAR1 p150 transcript by RNA sequencing; the adenosine-to-inosine editing index in Alu elements from the same library; xanthine and oxanine per million deoxyguanosines by liquid chromatography with tandem mass spectrometry.
the reason it is undone	The two literatures do not overlap. RNA editing is studied by virologists and neuroscientists; nitrosative DNA damage is studied by chemists and cancer epidemiologists. The volume can find no study that measured both in the same biopsy.
design	Ulcerative colitis mucosa is the standard chronic-inflammation model with archived matched tissue. Take paired inflamed and uninflamed biopsies from the same patients. Quantify p150 transcript, Alu editing index, and xanthine plus oxanine per 10^6 dG in each. Regress the chemical load on the enzymatic load across subjects, with the uninflamed biopsy as the within-subject control.
prediction if the two hands are one signal	Both loads are elevated in inflamed relative to uninflamed tissue in the same patient, and they correlate across patients with a slope set by the interferon-to-nitric-oxide balance of that individual's infiltrate.
prediction if they are independent	Both are elevated but uncorrelated, meaning the inflammatory state sets each independently and the shared trigger is a coincidence of localization rather than of regulation. The spine of this Part is then wrong as stated and should be narrowed to co-occurrence.
the outright falsification	Elevation of one without the other in the same tissue, reproducibly. That would separate the two hands completely and the Part becomes two Parts.
cost	One tissue bank, one sequencing run, one mass spectrometry run. No new reagent, no new method, no animal work.

1604. What This Part Refuses ↩

No claim that the enzymatic and chemical hands do the same thing to the genome. One is a defense with a signature; the other is damage with none. Section 1596 sets out why they cannot leave the same mark.

No claim that xanthine causes hypermutation. It causes scattered transitions. Hypermutation requires a processive enzyme and there is none on the guanine side.

No claim that subacute sclerosing panencephalitis and inflammation-associated mutagenesis are one disease process, and no claim that either causes the other.

No claim that measles is of unknown or disputed cause, and nothing bearing on vaccination. Section 1601 states both boundaries and Part One Hundred and Fifty-Five states them at greater length.

No adoption of the metabolic theory of cancer. It is cited as a named position with a citation and a note that it is contested, because the glutamine overlap is real and the mechanism is not shared.

And no claim of discovery. Every measurement in this Part belongs to the laboratory that made it — Caulfield's rates, Suzuki's kinetics, Hori's in vivo assay, Nakano's templates, Bhat's and Oliver's mechanism, Ward's knockout, Pfaller's sequencing, Mina's repertoire. What this Part contributes is the observation that one signal turns on both hands, the discipline of the three levels at section 1593, and one experiment that nobody has run.

PART ONE HUNDRED AND FIFTY-SEVEN · THE BRACKET, NOT THE CHAIN

1605. Where Sulfur Is in Translation, and Where It Is Not ↩

A claim this volume could have overreached on, and the measurement that stops it

Protein synthesis is one continuous chain of custody. A messenger RNA carries a codon. An aminoacyl-tRNA synthetase charges a transfer RNA with the matching amino acid. The ribosome joins the amino acids in order. A protein comes out.

The question this Part answers is where sulfur sits in that chain, and the honest answer is more interesting than the one the framework wanted. Sulfur opens translation, tunes the head that reads the codon, and closes the folded product. It does not make the bond.

Sulfur is the bracket around translation, not a link in its chain. The bond-forming chemistry in the middle is RNA, and there is a measured distance that says so: no protein side-chain atom comes within about eighteen ångströms of the peptide bond being made. No protein atom means no sulfur atom.

This Part states the bracket, prints the distance, and refuses the larger claim. A framework that cannot say where its favourite atom is absent has not established where it is present.

1606. One Word That Has to Be Right ↩

The enzyme that charges the transfer RNA, named correctly

The enzyme that attaches an amino acid to its transfer RNA is an aminoacyl-tRNA synthetase. There is one family per amino acid, twenty in the canonical set, and the correct short form is aaRS.

It is not an acetyl synthetase. Acetyl-CoA synthetase is a different enzyme in a different pathway, making acetyl-CoA from acetate, and it has no role in translation. The two are easily confused in speech and the confusion is fatal in print, because a specialist reading acetyl synthetase in a sentence about tRNA charging stops reading there.

The volume records the distinction because the acetyl arm and the translation arm both run on sulfur — the thioester of coenzyme A on one side, methionine and cysteine on the other — and running them together is how a real connection becomes an error.

1607. The Start · Every Protein Begins With Sulfur ↩

No exceptions, in any organism, at any time

Translation initiates at AUG. AUG is methionine. In bacteria and in mitochondria the initiator is formyl-methionine, delivered on a dedicated initiator transfer RNA; in the eukaryotic cytosol it is methionine on tRNA-i. In every case the first residue of the growing chain is a methionine, and methionine carries a sulfur atom in its side chain.

There is no protein on Earth that does not begin with a sulfur atom. Not one. The statement holds across all three domains, because the start codon is the same in all of them.

The volume has stated this before in passing and states it here as a spine, because it is the cleanest single sentence in the entire sulfur argument and it requires no framework to accept. It is a fact about the standard genetic code table.

1608. The Reading Head · A Sulfur Atom at Position Thirty-Four ↩

Sulfur is not only in the cargo. It is in the machinery that reads the message.

The anticodon of a transfer RNA is three bases, numbered thirty-four, thirty-five and thirty-six. Position thirty-four is the wobble position, the one that pairs with the third base of the codon and therefore the one that decides how many codons a single tRNA can read.

In the transfer RNAs for lysine, glutamate and glutamine, position thirty-four carries a hypermodified 2-thiouridine. A uridine with a sulfur atom substituted for the oxygen at position two of the ring.

Kambampati and Lauhon, reconstituting the reaction in vitro, state what that single sulfur atom does: the s^2 group of s^2U34 "stabilizes anticodon structure, confers ribosome binding ability to tRNA and improves reading frame maintenance." Biochemistry 2003;42:1109-1117.

the role of the sulfur at position 34	the meaning
stabilises anticodon structure	the sulfur rigidifies the loop, fixing the geometry that has to meet the codon
confers ribosome binding ability	without it the charged tRNA does not engage the ribosome properly
improves reading frame maintenance	the sulfur helps hold the frame — lose it and the ribosome slips

Reading frame maintenance. One atom, substituted at one ring position of one base of one anticodon, and the consequence of losing it is that the ribosome reads the message out of register.

1609. Two Characters at One Position ↩

The convergence this Part exists to print

Part One Hundred and Fifty-Five established that position thirty-four of a transfer RNA can carry inosine, written by the ADAT2/ADAT3 heterodimer, and that losing it arrests the cell cycle in both G1 and G2. This Part establishes that position thirty-four can carry a sulfur atom, written by MnmA with a cysteine desulfurase, and that losing it costs the reading frame.

the character	the writer	the action	the cost of its loss	its color
inosine at 34	ADAT2 / ADAT3 heterodimer	expands decoding — reads U, C and A	essential for viability; loss arrests G1 and G2	ORANGE
2-thiouridine at 34	MnmA with the cysteine desulfurase IscS	stabilises the anticodon, binds the ribosome, holds the frame	loss costs reading fidelity	YELLOW

The same numbered position in the same molecule carries either the orange character or the yellow one. Two different enzymes write them, two different chemistries make them, they do two different jobs — and the four-letter alphabet has a symbol for neither. Position thirty-four is written U in every database on Earth in both cases.

This is the volume's argument at its narrowest and most checkable. Not a claim about the whole code. A claim about one position in one molecule, where two modifications with no letters between them decide whether a cell can divide and whether a ribosome can hold its frame.

1610. Thionucleosides Are Unique to Transfer RNA ↩

A restriction the volume did not expect and did not manufacture

Kambampati and Lauhon open with a sentence the volume would not have dared write itself: “Thionucleosides are uniquely present in tRNA.”

Sulfur-bearing nucleosides — 2-thiouridine, 4-thiouridine, 2-thiocytidine and the methylthio-modified adenosines — occur in transfer RNA and not in messenger RNA, not in ribosomal RNA, and not in DNA. Of all the places a sulfur atom could have been installed in a nucleic acid, evolution put them in the molecule that does the reading.

The volume does not argue from that observation to a purpose. It records it as a distribution: the sulfur-modified nucleosides are concentrated in the adaptor, which is the one component of translation that has to recognize two things at once — an amino acid at one end and a codon at the other.

1611. Where the Sulfur Comes From ↩

A desulfurase, a persulfide, and a cysteine taken apart to supply one atom

The in vitro reconstitution names every component. The activity requires MnmA, magnesium-ATP, L-cysteine, and the cysteine desulfurase IscS. And the paper reports something sharper: purified IscS-persulfide is able to supply the sulfur on its own, in the absence of free cysteine.

So the sulfur that ends up at position thirty-four of a transfer RNA is taken off a cysteine by a desulfurase, carried as a persulfide on the enzyme itself, and handed across. The atom is not picked up from solution. It is passed hand to hand from an amino acid to a nucleic acid.

Part One Hundred and Forty-Eight found a cysteine performing an N-to-S acyl shift at the pivot of protein splicing. Part One Hundred and Fifty found a methionine-lined groove recognizing every signal peptide in the cell. Part One Hundred and Fifty-Five found a cysteine erasing a methylated guanine at the cost of the protein that owns it. Here a cysteine is dismantled so that a transfer RNA can hold its reading frame.

1612. The Bond Itself · Eighteen Ångströms of Nothing ↩

The measurement that decides what this Part may and may not claim

Nissen, Hansen, Ban, Moore and Steitz solved the large ribosomal subunit of Haloarcula marismortui with two substrate analogues bound, and reported what surrounds the reaction. Science 2000;289:920-930.

“Using the atomic structures of the large ribosomal subunit … we establish that the ribosome is a ribozyme.” Both substrate analogues

are contacted exclusively by conserved ribosomal RNA residues from domain V of the 23S, and “there are no protein side-chain atoms closer than about 18 angstroms to the peptide bond being synthesized.”

Their mechanism is stated in the same paper: the reaction resembles the reverse of the acylation step in the serine proteases, with the base of A2486 — A2451 in Escherichia coli — playing the general base role that histidine-57 plays in chymotrypsin. A nucleotide base doing the work a histidine does. Not an amino acid. A base.

1613. What That Distance Forbids ↩

Stated at full strength, because it cuts against this volume

Eighteen ångströms is roughly the length of six carbon-carbon bonds end to end, and it is a floor, not an average. No protein side chain reaches inside it.

the structure	the prohibition
no protein side chain within ~18 Å	and therefore no cysteine, no methionine, and no sulfur atom of any kind
contacts exclusively by 23S rRNA, domain V	the catalytic surface is ribonucleotide, not amino acid
the general base is A2486	a purine base, not a histidine, not a thiol
the ribosome is a ribozyme	the authors' own conclusion, in their own words

So the central act of translation — the formation of the peptide bond, the step that makes every protein in every organism — happens in a pocket that contains no sulfur and no protein at all. The volume states this as plainly as it states the methionine at the start, because a framework that only prints the confirmations is an advertisement.

And the concession sharpens what remains. Sulfur is not the catalyst. Sulfur is what the catalyst is handed, what the reading head is tuned with, and what the finished product is stitched together by. Three positions, all of them real, none of them the active site.

1614. The Charging, and the Lineage With No Cysteinyl Synthetase ↩

Where cysteine is built on the transfer RNA rather than loaded onto it

The standard account has twenty synthetases, one per amino acid, each charging its own transfer RNA. For cysteine in many archaea that account is wrong: there is no cysteinyl-tRNA synthetase. Cysteine is made on the tRNA, in two steps.

Chen, Kato, Kubo, Tanaka, Liu, Long, Whitman, Lill, Gatsogiannis, Raunser, Shimizu, Shinoda, Nakamura, Tanaka and Yao set out the machinery. O-phosphoseryl-tRNA synthetase, SepRS, ligates a mismatching O-phosphoserine onto tRNA-Cys. Sep-tRNA:Cys-tRNA synthase, SepCysS, then converts the tRNA-bound phosphoserine into cysteine. Nat Commun 2017;8:1521.

In ancestral methanogens a third protein, SepCysE, bridges the two enzymes into a ternary complex the authors name the transsulfursome. Its three domains bind SepRS, SepCysS and the tRNA respectively, and the assembly enables what they describe as a global long-range channeling of the tRNA between two distant active sites.

Their closing suggestion is the one this volume records: the channeling prevents a challenge to translational fidelity, and “may reflect the mechanism that cysteine was originally added into the genetic code.”

1615. The Channel, Twice ↩

Two machines in this volume that move a reactive intermediate rather than releasing it

Part One Hundred and Fifty-Six set out GMP synthetase: a glutamine amidotransferase domain makes free ammonia, an ATP-pyrophosphatase domain makes an adenylated intermediate, and the ammonia is channeled through the protein from one active site to the other rather than being let go into solution.

The transsulfursome does the same thing at a larger scale and with a larger cargo. Instead of a small reactive molecule it moves an entire charged transfer RNA

between two distant active sites, and for the same reason: to prevent a reactive intermediate from escaping and being mistaken for something else.

the machine	the channeled species	across what	the reason for containment
GMP synthetase	free ammonia	between two domains of one enzyme	so the nitrogen is not lost to solvent before it reaches the adenylated xanthine
the transsulfursome	a whole charged transfer RNA	between two enzymes held by a third	so a phosphoserine-charged tRNA is never released where the ribosome could read it as serine

Both machines exist because the intermediate is dangerous in the open. In one case an ammonia molecule would be lost; in the other a mischarged transfer RNA would put the wrong amino acid into a protein. Channeling is what a cell builds when the halfway state cannot be allowed to exist freely, and the volume notes that both of its channeling examples sit on the sulfur and nitrogen chemistry of the purines and the amino acids.

1616. The Close · Disulfides and the Fold ↩

The last place sulfur appears, after the chain has left the ribosome

Cysteine's thiol is the only side chain in the canonical twenty that forms a covalent bond with another side chain. Two cysteines oxidize to a disulfide, and that bond cross-links the folded chain in a way no hydrogen bond can.

Part One Hundred and Fifty-Four recorded the consequence at its sharpest: human lymphotactin adopts two entirely different native folds, and Fox and colleagues locked the equilibrium by engineering a second disulfide bond, A36C to A49C, which prevents the interconversion. The switch between two protein architectures is thrown by two sulfur atoms finding each other.

So the fold, like the start, is a sulfur event. And like the start it happens outside the peptidyl transferase center — after the chain has passed the eighteen-ångström pocket where no sulfur was permitted.

1617. The Cleanup · The Starting Sulfur Is Cut Off ↩

A detail that completes the bracket and complicates it

Every protein begins with methionine, and most proteins do not keep it. Methionine aminopeptidase removes the initiator residue co-translationally from a large fraction of proteins, with the outcome depending on the side chain of the second residue: small second residues permit removal, large ones prevent it.

So the sulfur atom that opens every protein on Earth is, in most cases, deleted from the finished product. It is required to start and not required to remain. The volume records this because it is the kind of fact a framework is tempted to leave out — the opening sulfur is a starting condition, not a component of the mature protein, and saying otherwise would be false.

What survives in the mature protein is the sulfur that was placed by the codon table in the interior: the methionines that are not at position one, and the cysteines, including every disulfide.

1618. The Bracket, Printed ↩

The whole account on one page

stage of translation	the contents	the action	sulfur?
the start	methionine, from AUG	every protein in every organism, no exceptions	SULFUR
the reading head	2-thiouridine at position 34, or inosine at the same position	anticodon structure, ribosome binding, reading frame	SULFUR or the orange character
the source of that sulfur	a cysteine taken apart by a desulfurase and carried as a persulfide	handed from an amino acid to a nucleic acid	SULFUR
the charging	aminoacyl-tRNA synthetases; and for cysteine in archaea, built on the tRNA itself	the transsulfursome, channeling a charged tRNA between two active sites	SULFUR
THE PEPTIDE BOND	23S ribosomal RNA, domain V; general base A2486	no protein side chain within about 18 angstroms	NO SULFUR

stage of translation	the contents	the action	sulfur?
the fold	cysteine disulfides	cross-links the chain; can switch a protein between two native folds	SULFUR
the cleanup	methionine aminopeptidase	removes the opening methionine from a large fraction of proteins	SULFUR REMOVED

Six stages carry sulfur and one does not, and the one that does not is the only one that makes a chemical bond in the protein. That is the bracket. The volume claims it in exactly that shape and no wider.

1619. The Experiment This Part Generates ↩

Two characters at one position, and nobody has asked whether they trade

Experiment Eighty-Two	
question	At anticodon position thirty-four, do the inosine and 2-thiouridine modifications compete for the same substrate pool, and does depleting one raise the other? Both are written from a sulfur amino acid economy — the thiolation from cysteine directly, the methylations and hypermodifications from S-adenosylmethionine — and no study appears to have measured both across the same tRNA population under the same stress.
the feasibility now	Both modifications are quantifiable in the same sample by mass spectrometry of digested tRNA. The enzymes are known and knockable: ADAT2/ADAT3 for the inosine, MnmA or its human homolog TRMU for the thiolation, IscS or NFS1 for the sulfur supply.
design	In one cell line, deplete NFS1 and quantify, from the same tRNA preparation, s2U34 per tRNA and the inosine-34 level across tRNA species. Repeat depleting ADAT3. Repeat under cysteine restriction, which starves the desulfurase directly.
prediction if the two positions are independent	Depleting the sulfur supply lowers s2U34 and leaves I34 untouched, and depleting ADAT3 does the reverse. Position thirty-four then carries two unrelated modifications that happen to share an address.
prediction if they trade	Sulfur restriction raises I34 on the tRNAs capable of carrying it, or thiolation loss is compensated by a shift in which tRNAs are used. Position thirty-four is then a single regulated site with two possible characters, and the choice between them is metabolic.
the value	The second outcome would mean the cell chooses between an orange character and a yellow one at the same position according to its sulfur budget. That is a claim about the genetic code responding to metabolism, and it would be measured rather than argued.
cost	One cell line, three knockdowns, one mass spectrometry method that already exists for both modifications.

1620. What This Part Refuses ↩

No claim that sulfur catalyzes peptide bond formation. It does not. The catalytic center is ribosomal RNA and there is no protein side chain within about eighteen ångströms of the bond. Section 1613 states this against the volume's own interest.

No claim that the sulfur modifications of transfer RNA are there for a purpose the volume has identified. Section 1610 records their distribution — that thionucleosides occur in tRNA and nowhere else — as an observation, not as evidence of design or intent.

No claim that inosine and 2-thiouridine at position thirty-four are alternatives the cell chooses between. That is the question of Experiment Eighty-Two and the volume records it as open.

No claim that the opening methionine survives in the mature protein. In most proteins it is removed, and section 1617 says so rather than leaving the impression that every finished protein carries a sulfur at its amino terminus.

No claim that the transsulfursome shows how cysteine entered the genetic code. Chen and colleagues offer that as a suggestion in their own paper and the volume quotes it as their suggestion, not as a finding.

And no claim of discovery. The ribosome as ribozyme is Nissen, Hansen, Ban, Moore and Steitz. The thiolation chemistry is Kambampati and Lauhon. The transsulfursome is Chen and colleagues. What this Part contributes is the bracket — the observation that sulfur surrounds translation on every side and is absent from its center — and one experiment that has not been run.

PART ONE HUNDRED AND FIFTY-EIGHT · FROM A STAR TO A WRINKLE

The Enzyme

1621. An Enzyme That Turned Back Forty-Four Years ↩

Where this paper starts, and the caution it starts with

Sugar reacts with protein. It happens slowly, without any enzyme, at body temperature, all the time. The products are called advanced glycation end products, and one of the commonest is a small carboxymethyl group welded onto the side chain of a lysine. The damaged residue is called N-carboxymethyl-lysine, or CML.

These adducts build up over a lifetime in the long-lived proteins of the eye, the skin and the artery wall — the proteins the body makes once and then keeps. They have been considered irreversible, because no enzyme is known that removes them.

A report in mid-2026 describes an engineered enzyme that does. The account states that researchers computationally screened on the order of forty-five thousand protein structures, found a bacterial enzyme with a trace of accidental CML-cleaving activity, and improved it by directed evolution until it cleaved CML off lysine and restored the lysine — bringing CML levels in seventy-five-year-old human skin tissue down to those of thirty-one-year-old skin.

The flag

The author could not locate that study in the primary literature at the time of writing. It may be too recent to be indexed, or the account he read may differ in detail from the paper. Nothing in the rest of this document rests on it. It is here because of what the enzyme was made from, and that detail — which is the reason this paper exists — can be checked independently even if the result cannot yet.

The scaffold they reportedly started from was a glycine oxidase.

1622. Why a Glycine Oxidase Is Not a Strange Place to Start ↩

The damaged protein and the enzyme's substrate have more in common than the account says

The protein that accumulates this damage in skin is collagen. Collagen is built from a repeating three-residue unit in which every third position is glycine — Gly-X-Y, over and over, for a thousand residues. The glycine is not decorative. It is the

smallest possible amino acid, and it is the only one that fits at the crowded axis where three collagen chains wind around each other. Any larger side chain does not fit, which is why mutations that replace one of those glycines cause brittle bone disease.

So roughly one residue in three of the protein being repaired is glycine, and the enzyme reached for to repair it is an enzyme that recognizes glycine. The account presents this as a lucky screening hit. It may be, and this paper does not claim otherwise. But an enzyme evolved to bind the smallest amino acid, put to work on a protein that is one-third that amino acid, is at least worth noticing.

That noticing is what opens the rest of this paper. Follow glycine backward and it leads out of the body, out of the biosphere, and off the planet. Follow its chemistry sideways and it leads into sulfur at every turn.

The Molecule

1623. The Simplest Amino Acid There Is ↩

Not the simplest known — the simplest possible

An amino acid has a fixed frame: a central carbon, an amino group, an acid group, a hydrogen, and one more thing called the side chain. The side chain is what makes them different from each other. Tryptophan's is a double ring. Arginine's is a long charged arm.

Glycine's side chain is a hydrogen atom. There is nothing there. You cannot make a smaller amino acid without ceasing to have one, because the only way to simplify further is to remove part of the frame itself.

Its formula is C2H5NO2 and it weighs seventy-five units. Every other amino acid in the genetic code is bigger, and nineteen of them are bigger by a good deal.

1624. The Spoon, Not the Hand ↩

What it means to call a molecule achiral, without using the word again

Hold up your two hands. Same parts, same order — a thumb, four fingers, a palm. Now try to lay the left hand on the right so that every part lines up. You cannot. They are mirror images of each other and they do not match.

Most molecules with a carbon at their center are built like that. The central carbon has four different things attached, and there are two ways to arrange them that are mirror images and cannot be superimposed. Chemists call the two versions left-handed and right-handed. Nineteen of the twenty amino acids come in both, and life on Earth uses only the left-handed ones, for reasons nobody has settled.

Glycine is not a hand. Glycine is a spoon. Hold a plain wooden spoon up to a mirror and the reflection is the same spoon. There is no left spoon and right spoon, because there is nothing to tell them apart.

Why glycine escapes

Handedness needs four different things on the central carbon. Glycine has only three different things, because two of the four are both hydrogen atoms. When two of the four are identical, the mirror image and the original are the same object. There is no second version.

	the central carbon carries	the consequence	the requirement
nineteen amino acids	four different groups on the central carbon	left-handed and right-handed forms exist	life had to select one
glycine	two of the four are both hydrogen	only one form exists	there was nothing to select

The word for this is achiral. It means without handedness. Glycine is the only one of the twenty that has it.

1625. Why That Makes the Cosmic Claim Exact Instead of Poetic ↩

The one place where where-it-came-from stops being a meaningful question

Amino acids found in meteorites and comets arrive as roughly even mixtures of left-handed and right-handed forms, with small excesses in some cases. Biology uses left. Bridging that gap is one of the hardest unsolved problems in the origin of life.

Glycine does not participate in that problem. Because there is only one form of it, glycine made in a comet and glycine made in your liver are not merely the same kind of molecule. They are the identical molecule. No chemical test, no physical test, no optical test can distinguish them, because there is no difference to find.

For every other amino acid, asking whether a particular molecule came from space or from Earth is a question with an answer in principle. For glycine it is a question with no content. The distinction does not exist.

This is the strongest available form of the claim that glycine is a cosmic molecule, and it requires nothing but the shape of the molecule.

1626. Made in Stars, Delivered by Comets ↩

What has been measured, and where the line is

The atoms first. Hydrogen came out of the Big Bang. Everything heavier was made inside stars — carbon and oxygen and nitrogen in stellar burning, sulfur and phosphorus in the later stages and in supernovae. There is no terrestrial process that makes any of them. Every carbon, nitrogen and oxygen atom in a glycine molecule in your skin was assembled in a star and scattered by its death.

A refinement this volume's palette has earned: red is older than the stars. Hydrogen is primordial, from the Big Bang itself. The other six colors — carbon, nitrogen, oxygen, phosphorus, sulfur, selenium — were all made in stars. One color predates the first star; six do not.

And the molecule itself has been measured off the planet

Altwegg, Balsiger, Bar-Nun and the ROSINA team reported volatile glycine in the coma of comet 67P/Churyumov-Gerasimenko, measured directly by mass spectrometer, accompanied by the precursor molecules methylamine and ethylamine — and by phosphorus. Their paper confirms the earlier finding from the Stardust

mission's samples of comet Wild 2, and describes glycine, in their own phrase, as “the simplest form of amino acids.” Sci Adv 2016;2:e1600285.

Where this paper stops

Glycine in comets and in carbonaceous meteorites is established. Glycine in interstellar gas clouds is not: a detection claimed in 2003 was rigorously challenged in 2005 and has not been re-established. This paper says comets and meteorites, and does not say interstellar space, because only one of those has been measured.

The Chemistry Runs on Sulfur

1627. Two Ways to Oxidize Glycine, and Both End in Sulfur ↩

Beginning with a fact that is sitting in the enzyme classification system itself

Enzymes are cataloged by what they do, and the catalog sorts the amino-group oxidisers by what carries the electrons away. The scheme reads as follows.

class	the acceptor	the enzymes in it
EC 1.4.1	NAD or NADP	glutamate dehydrogenase
EC 1.4.3	oxygen	D-amino acid oxidase; GLYCINE OXIDASE
EC 1.4.4	A DISULFIDE	THE GLYCINE CLEAVAGE SYSTEM

The class defined by a sulfur-sulfur bond as the electron acceptor contains the glycine cleavage system. The formal classification of enzymes already puts sulfur at the receiving end of glycine oxidation, and nobody had to argue it into place.

The other route, through oxygen, ends in sulfur too, by a longer path. Settembre, Dorrestein, Park, Augustine, Begley and Ealick showed that ThiO — an FAD-dependent glycine oxidase — is required for building the thiazole ring of thiamine, vitamin B1. A thiazole is a five-membered ring containing a sulfur atom. Biochemistry 2003;42:2971-2981.

the route	immediate electron acceptor	the location of the sulfur
glycine cleavage system	a disulfide	the sulfur is in the machine that does the carrying
glycine oxidase ThiO	oxygen	the sulfur is in the product — the thiazole ring of vitamin B1

1628. The Swinging Arm Is a Sulfur-Sulfur Bond ↩

How the glycine cleavage system actually works

The glycine cleavage system is four proteins working together, and the one that does the carrying is called the H-protein. The H-protein is modified with lipoic acid — a small molecule ending in a ring that contains two sulfur atoms bonded to each other.

The cycle runs like this. The P-protein takes the carbon dioxide off glycine and hands what is left onto the H-protein's sulfur arm. The T-protein takes that fragment off and attaches it to folate. The H-protein is then left with two free thiol groups where the sulfur-sulfur bond used to be. The L-protein re-oxidises them, closing the ring again, and passing the electrons to NAD.

Every turn of glycine oxidation opens a sulfur-sulfur bond and closes it again. The arm that carries the fragment of the simplest amino acid across the complex is made of two sulfur atoms.

The overall reaction is glycine plus folate plus NAD, giving methylene-folate, carbon dioxide, ammonia and NADH. That methylene-folate is the one-carbon unit the cell uses to build methionine — and methionine, activated, becomes the cell's methyl donor. So glycine oxidation feeds the methylation economy, and the methyl donor is itself a sulfur compound.

1629. An Iron-Sulfur Cluster Is Destroyed to Place Those Two Atoms ↩

Where lipoic acid's sulfurs come from, which is stranger than where they end up

Lipoic acid does not arrive with its sulfurs. They are inserted into a plain fatty chain, at two specific carbons, by an enzyme called lipoyl synthase.

Lanz, Rectenwald, Wang, Kakar, Laremore, Booker and Silakov describe the machine. Lipoyl synthase catalyzes “the insertion of two sulfur atoms at C6 and C8 of an n-octanoyl chain.” It carries two iron-sulfur clusters. The first cleaves S-

adenosylmethionine to make two highly reactive radicals, which rip hydrogen atoms off the two target carbons. The second cluster is the sulfur donor — and it is consumed doing it. J Am Chem Soc 2015;137:13216-13219.

Their own sentence: “Such a sacrificial role for an iron-sulfur cluster during catalysis has not been universally accepted.” They then trapped the reaction intermediate and found a magnetic coupling to iron, showing the cluster and the substrate were within bonding distance of each other.

So the arm that carries glycine is built by taking an iron-sulfur cluster apart. The enzyme destroys part of itself to make the cofactor. This is the third machine in the author's larger volume that is consumed in the act of working, alongside the repair protein that accepts a methyl group onto its own cysteine and is finished, and the complex that channels a charged transfer RNA between two active sites rather than letting it go.

1630. Run It Backward and It Makes Glycine Out of Air ↩

The reaction is reversible, and the reverse may be very old

The glycine cleavage system is written as a cleavage because that is how it was found. The chemistry runs both ways. Driven in reverse, it takes carbon dioxide, ammonia and a one-carbon unit and assembles glycine.

Yishai, Bouzon, Döring and Bar-Even built that reverse into a living organism. By combining native and foreign enzymes they made the folate and glycine cleavage systems run in the reductive direction, so that Escherichia coli “satisfies all of its glycine and serine requirements from the assimilation of formate and CO2” — at a flux high enough to supply a tenth of the cell's carbon, with no cost to growth rate. ACS Synth Biol 2018;7:2023-2028.

A route from carbon dioxide directly into an amino acid, with no sugar anywhere in it, running on a sulfur-sulfur bond. It is one of the leading candidates for the most ancient way carbon entered biology, and the simplest amino acid is its product.

One correction the author owes his own framework

In a modern cell, glycine is not made first. It is made from serine, and serine comes from the breakdown of sugar. Serine is upstream. The claim that glycine is biosynthetically first is true of the reductive pathway above and false of ordinary metabolism, and this paper prints both rather than the convenient one.

Where Glycine and Sulfur Meet Everything Else

1631. Glycine Goes Into Every Purine Whole ↩

Not broken down for parts — incorporated intact

The purine ring — the double ring at the heart of adenine, guanine, inosine and xanthine — is assembled atom by atom from several sources. Glycine is the only amino acid that goes in as a unit, contributing two of its carbons and its nitrogen to the skeleton, at the positions numbered four, five and seven.

Every adenine in every genome, every guanine, and every one of the characters this author's volume argues the alphabet is missing, contains a glycine molecule built into its frame. The simplest amino acid is a structural member of the bases.

That is the connection between the two halves of the author's work. The sulfur argument and the missing-character argument meet inside the purine ring, and what joins them is glycine.

1632. Glycine Is One Third of the Protein That Ages ↩

Back toward the enzyme, by way of the tissue

Collagen is the most abundant protein in the human body and the main structural protein of skin, artery and tendon. Its sequence is a repeat: glycine, then two other residues, then glycine again, for the whole length of the chain.

Three chains wind around one another into a rope. At the axis where they touch there is room for a hydrogen atom and nothing larger, and glycine is the only

residue whose side chain is a hydrogen atom. The repeat is not a stylistic choice. It is the only way three chains can occupy that geometry.

So the protein that accumulates a lifetime of sugar damage, in the skin that the enzyme in Part One was tested on, is one-third glycine by count — and is one-third glycine because glycine is the smallest thing there is.

1633. One Small Peptide Holds Both Amino Acids at Once ↩

Glutathione

Glutathione is three amino acids joined end to end: glutamate, then cysteine, then glycine. It is present in nearly every cell at millimolar concentration, and it is the principal small-molecule defense against oxidative damage in the body.

residue	position	the action
glutamate	first residue	the handle, joined through an unusual bond that protects the peptide from ordinary breakdown
CYSTEINE	second residue	THE WORKING PART — its thiol is what is oxidized and reduced, over and over
GLYCINE	third residue	the terminal residue; the simplest amino acid closing the tripeptide

The cell's main antioxidant is a peptide of three residues, and two of the three are the subjects of this paper. The business end is a sulfur atom on a cysteine, and the molecule ends in glycine.

1634. Sulfur Brackets Protein Synthesis and Is Absent From Its Center ↩

The finding this author will not overstate

Every protein on Earth begins with methionine, which carries a sulfur atom. The wobble position of the transfer RNA that reads the codon can carry a sulfur atom, as 2-thiouridine, which stabilises the anticodon and holds the reading frame. The folded protein is cross-linked by cysteine disulfides. Three stages, all sulfur.

And the bond itself is not. Nissen, Hansen, Ban, Moore and Steitz established that the ribosome is a ribozyme — the catalyst is RNA — and reported that "there are no protein side-chain atoms closer than about 18 angstroms to the peptide bond being synthesized." No protein atom within eighteen ångströms means no sulfur atom. Science 2000;289:920-930.

Sulfur opens protein synthesis, tunes the head that reads the message, and closes the finished fold. It does not make the bond. The author states this because a framework that cannot name where its favourite atom is absent has not earned the places where it is present.

Back to the Enzyme

1635. The Circle Closed ↩

What the chain looks like laid end to end

the stage	the outcome	the note
a star	makes the carbon, nitrogen and oxygen; hydrogen was already there from the Big Bang	RED is older than the stars; the rest are stellar
a comet	carries glycine, measured directly in the coma of 67P, with phosphorus alongside	and because glycine is achiral, cometary and biological glycine are the same molecule
a cell	oxidises glycine on a sulfur-sulfur arm, or builds it from carbon dioxide on the same arm	the arm's two sulfurs were placed by destroying an iron-sulfur cluster
a purine	contains a glycine molecule built in whole, at positions four, five and seven	including every inosine and xanthine this volume argues has no letter
a collagen fiber	is one-third glycine, because only glycine fits at the axis of the triple helix	and it is the protein that accumulates a lifetime of sugar damage
an engineered enzyme	built on a glycine oxidase scaffold, reportedly cleaves that damage off the lysine	seventy-five-year-old skin brought to the level of thirty-one-year-old skin — REPORTED, NOT VERIFIED HERE

Six stages from a supernova to a wrinkle, and the same two elements appear at every one of them. The author does not claim this is a purpose. He claims it is a distribution, and that a notation which records only four letters cannot see any of it.

1636. What This Paper Does Not Claim ↩

Printed at full strength, because the arc above is the kind that invites overreach

It does not claim the skin-aging result. That study could not be verified by the author at the time of writing and is marked as reported at both ends of this paper. If it does not hold, everything from Part Two onward is unaffected.

It does not claim that the glycine oxidase scaffold was chosen because collagen is glycine-rich. The account describes a computational screen over tens of thousands of structures. The author notes the coincidence and does not convert it into a mechanism.

It does not claim glycine was the first amino acid in the genetic code. Every reconstruction places it among the earliest; none of them can measure it. Among the first is defensible. The first is not.

It does not claim glycine is made first in a living cell. It is made from serine, and serine is downstream of sugar. Only the reductive pathway makes glycine first, and that is stated where it belongs.

It does not claim glycine has been detected in interstellar gas. Comets and meteorites, yes, measured. Interstellar space, no.

It does not claim sulfur catalyzes the peptide bond. Eighteen ångströms of no protein at all says otherwise, and that measurement is printed against the author's own interest.

And it claims no discovery. Every measurement here belongs to the laboratory that made it. What this paper contributes is the chain and the refusals.

1637. The Two Experiments This Paper Generates ↩

Both cheap, both decisive

Experiment One · Did the ancestry matter?	
question	Does the engineered CML-cleaving enzyme retain measurable activity on free glycine, or on glycine-rich peptides, as its glycine oxidase ancestry would predict?
the significance	If it does, the scaffold choice was not arbitrary and the enzyme is working on a substrate it was already shaped to recognize. If it does not, the directed evolution moved it entirely off its ancestral chemistry, which is itself the more remarkable result.
design	Assay the evolved enzyme and its unevolved parent side by side on free glycine, on a Gly-X-Y collagen peptide, and on CML-modified lysine. Compare the ratios.
cost	One enzyme preparation, three substrates, one plate reader.

Experiment Two · Can the old route be read in the isotopes?	
question	Does the reductive glycine pathway — carbon dioxide to glycine on a sulfur-sulfur arm — leave an isotopic signature distinguishable from the serine route?
the significance	If glycine made from carbon dioxide carries a different carbon isotope ratio than glycine made from serine, then ancient organic matter could be tested for which route made it, and the claim that the reductive route is the older one becomes measurable rather than argued.
design	Grow the engineered strain of Yishai and colleagues on labeled formate and carbon dioxide alongside a wild-type strain on glucose. Measure the carbon isotope composition of the glycine in each, and of the collagen-equivalent glycine-rich protein where one exists.
cost	Two cultures, one isotope ratio mass spectrometer, no new method.

1638. Where the Sources for This Part Sit ↩

Six verified publications, and one that is not

The measurements in this Part were retrieved from PubMed and their abstracts read before any claim attributed to them was written. Altwegg and the ROSINA team on comet 67P, Sci Adv 2016;2:e1600285. Settembre and colleagues on ThiO and the thiamine thiazole, Biochemistry 2003;42:2971-2981. Lanz, Booker and Silakov on the sacrificial iron-sulfur cluster of lipoyl synthase, J Am Chem Soc 2015;137:13216-13219. Yishai, Bouzon, Doring and Bar-Even on the reductive glycine pathway in Escherichia coli, ACS Synth Biol 2018;7:2023-2028. Nissen, Hansen, Ban, Moore and Steitz on the ribosome as a ribozyme, Science 2000;289:920-930. Kambampati and Lauhon on MnmA, IscS and 2-thiouridine, Biochemistry 2003;42:1109-1117.

And one that is not verified. The engineered carboxymethyl-lysine-cleaving enzyme described at section 1621 comes from a July 2026 secondary account. The author could not locate the primary study and marks it as reported rather than established, here, at section 1621, and at section 1636. Nothing from section 1623 onward depends on it.

PART ONE HUNDRED AND FIFTY-NINE · THE NUMBER THE NOTATION PRODUCES

1639. A One-Channel Alphabet ↩

What the four letters record, and what they leave to be looked up

The four-letter alphabet is a one-channel notation. It records identity and nothing else. Every other property of a base — how many hydrogen bonds it makes, which element carries the charge, whether it is purine or pyrimidine — has to be looked up somewhere else.

That is not a criticism of the alphabet. A notation that carried every property of its objects would be unreadable. It is an observation about what a reader of a sequence string is and is not being told, and it matters because the properties left out are the ones that decide what the molecule does.

Identity is written. Chemistry is inferred. The inference is reliable for the four canonical bases and fails for everything else.

1640. The Second Channel ↩

A property that was always physically present and was never written down

Part One Hundred and Fifty-One set out the two-channel idea: color carries identity, and a count of bars carries hydrogen-bond number. This Part carries the idea to completion by writing it out across the whole genetic code and reporting the number that falls out.

the channel	the content	the reading
channel one	COLOR	which base it is, by the element that distinguishes it
channel two	BAR COUNT	how many hydrogen bonds it makes — two for adenine, thymine, uracil and inosine; three for guanine and cytosine

Neither channel is invented. The color is the element and the bar count is the bond count, and both were true of the molecule before anyone drew them.

1641. Six Colors, Not Seven ↩

Why indigo leaves the visible set and stays in the metabolic one

The six colors map one to one onto the six elements of life — hydrogen red, oxygen orange, sulfur yellow, nitrogen green, carbon blue, phosphorus violet. Indigo is dropped from the spectrum of the notation because Newton put it there for musical reasons rather than optical ones, and because the eye does not resolve it as a separate band.

Indigo is not discarded. It is reassigned. In this volume it marks XANTHINE and OROTATE, which are gatekeepers in purine and pyrimidine synthesis rather than letters of any alphabet, and it marks SELENIUM, element thirty-four.

Six colors for the six atoms that make the message. A seventh for the two molecules that stand at the gates and never enter the text.

1642. The Code Written Out in Both Channels ↩

All sixty-four codons, both strands, and the anticodons that read them

Writing the notation across the entire genetic code is mechanical once the rules are fixed, and mechanical is the point: the figure is generated from the NCBI standard table by a program and checked by assertion before anything is drawn, so that no codon is assigned by hand and no arithmetic is done in the author's head.

the object	the rendering
the codon table	sixty-four codons, sixty-one sense and three stop, twenty amino acids
each codon	three colored cells, each carrying its base's color and its bond count
each anticodon	the reverse complement, drawn the same way, with position thirty-four at the reading end

the object	the rendering
the DNA and RNA forms	distinguished, because thymine is yellow and uracil is purple and a notation that merged them would erase the distinction between the two polymers

AUG is two red adenine, three green guanine and two purple uracil. ATG is the same message in the other polymer, and the yellow thymine says which polymer it is. The notation refuses to let a reader forget which molecule is on the page.

1643. The Number ↩

Computed by the program, asserted before printing, not claimed from memory

Written out across the anticodons, the notation produces a count. Twenty-four of the sixty-one sense codons are read by a transfer RNA whose position thirty-four carries inosine.

24 of 61 sense codons = 39.3 percent\n\nzero of the three stop codons are reachable by any inosine-34 transfer RNA\nno stop codon's required anticodon carries adenine at position thirty-four

NEARLY TWO CODONS IN FIVE ARE DECODED BY A CHARACTER THE ALPHABET CANNOT SPELL. That is the finding this Part exists to record, and it is arithmetic on a published table rather than an interpretation of one.

The distribution is uniform in one sense and not in another. The twenty-four split three to a family across eight families, but coverage differs: alanine, proline, threonine and valine are three of four; arginine, leucine and serine are three of six; isoleucine is three of three.

1644. The Box Rule ↩

The prediction this notation makes, stated so that it can fail

Inosine at position thirty-four is permitted only where the first two bases of the codon make the third irrelevant to the amino acid.

That is a rule about information rather than about chemistry. Inosine at the wobble position is permissive — it pairs with uridine, cytidine and adenosine — so a transfer RNA carrying it reads three codons. A cell can afford that only where reading three codons does not change which amino acid is delivered.

Seven fourfold families obey the rule without qualification. Isoleucine is the eighth case and is the exception that demonstrates the rule: its family is three codons rather than four, because the fourth is methionine, and the machinery must not read it.

1645. One Amino Group ↩

The whole difference between a letter and a wildcard

Guanine is 2-amino-6-oxopurine. The base of inosine is hypoxanthine, which is the same ring without the 2-amino group. One nitrogen substituent separates them.

Remove one amino group and a base that refuses everything but cytosine becomes a base that accepts three partners. The difference between a letter and a wildcard is one amino group, and the alphabet has a character for one of them.

1646. What the Notation Refuses ↩

the claim	the status
that color is a discovery	refused. The colors are a notation for facts established by other people, and the notation claims no priority over the chemistry it draws
that the 39.3 percent is novel biology	refused. Inosine-34 decoding has been known since Crick. What is new here is the count stated as a fraction of the sense codons and generated rather than recalled

the claim	the status
that the box rule is proven	refused. It is a prediction supported by eight families and testable at genome scale, and Part One Hundred and Sixty-Five sets out how
that indigo is a spectral band	refused. It is not resolved by the eye and is retained in this system for the metabolic gatekeepers only
that the bar count is a new measurement	refused. Hydrogen-bond counts are textbook. Drawing them alongside identity is the contribution and it is a notational one

1647. The Experiment This Part Generates ↩

The question. Does the box rule hold across sequenced genomes, and where it fails, does it fail in an interpretable pattern?

Method. Enumerate transfer RNA gene anticodons per genome from the public tRNA gene sets. Classify each by the degeneracy of the codon family it serves. Test the association between predicted inosine-34 substrate status and fourfold degeneracy, within domain rather than pooled, because the expected substrate count differs between Bacteria, Archaea and Eukarya.

Statistics. Fisher exact test per genome, then a random-effects meta-analysis across genomes with domain as a moderator. The heterogeneity statistic is reported alongside the pooled estimate because it carries as much information.

Falsification condition, written before the answer. A substantial and consistent population of inosine-34 substrate anticodons in twofold-degenerate families, across independent lineages, kills the rule.

The rule is currently supported by eight families. The test is available at a sample size of thousands, needs no reagent, and has not been run.

1648. What This Part Claims ↩

1	**The four-letter alphabet is one-channel: it records identity and leaves chemistry to be looked up**
2	A second channel — hydrogen-bond count — was always physically present and was never written into the notation

1	**The four-letter alphabet is one-channel: it records identity and leaves chemistry to be looked up**
3	Six colors map one to one onto the six elements of the message; indigo is reassigned to the metabolic gatekeepers
4	Written across all sixty-four codons, the notation yields 24 of 61 sense codons, 39.3 percent, read by an inosine-34 transfer RNA
5	No stop codon is reachable by any inosine-34 transfer RNA
6	The box rule follows from the notation and is falsifiable at genome scale
7	The difference between guanine and the base of inosine is one amino group

PART ONE HUNDRED AND SIXTY · THE CURRENCY IS A LETTER

1649. Three Levels, and the Discipline of Not Mixing Them

↩

Base, nucleoside, nucleotide

A base is a ring. Add a sugar and it becomes a NUCLEOSIDE. Add one or more phosphates and it becomes a NUCLEOTIDE. Three levels, two additions, and the names change at each step.

Naming the level is what makes every sentence after it checkable. ADP and GDP are nucleotides. The inosine column makes the point better than a rule could: at the level of the base the molecule is hypoxanthine; at the nucleoside level it is inosine and it is made there, by adenosine deaminase acting on adenosine; at the nucleotide level it is IMP and it is made there too, by a different enzyme, AMP deaminase acting on AMP.

Same conversion in kind, three different addresses, three different catalysts. Name the level or the sentence means nothing.

1650. Violet, Element Fifteen ↩

What the innermost band of the notation is carrying

Violet is phosphorus. It is the shortest wavelength of the six and it sits at the center of the mark, because the phosphate both stores the energy and joins the polymer. There is no second molecule doing the second job.

Of roughly thirty-two molecules of ATP per molecule of glucose, two come from glycolysis and two from substrate-level phosphorylation in the citric acid cycle, leaving about twenty-eight from oxidative phosphorylation. That is where the figure of ninety percent comes from, and it is worth stating as the arithmetic rather than as the headline, because the arithmetic is checkable.

And phosphorus is where the polymer is joined. The backbone of DNA and of RNA is a chain of sugars linked by PHOSPHODIESTER bonds, one phosphate bridging the three prime carbon of one sugar to the five prime carbon of the next. Strip the bases away and the backbone still exists; strip the phosphate away and there is no polymer at all.

Phosphorus is the only element in the set that is simultaneously the energy store and the structural joint. That is what violet is carrying, and it is why it sits at the center.

1651. What the ADP to ATP Cycle Is ↩

A phosphate transfer, and a correction printed because the error is easy

The ADP to ATP cycle is a PHOSPHATE TRANSFER. Making ATP from ADP and inorganic phosphate forms a phosphoanhydride bond by condensation, with the loss of a molecule of water. Phosphorus is in the plus five oxidation state on both sides.

No electron changes its home. Nothing is oxidized and nothing is reduced. The bond that powers the cell is built without moving a single electron between homes.

the actor	the role	the mechanism
electrons	do the redox	NADH and FADH2 hand electrons to the respiratory chain; they travel through iron-sulfur clusters, quinones

the actor	the role	the mechanism
		and cytochromes to oxygen
protons	do the coupling	that electron flow pumps protons across the inner membrane, roughly ten per NADH across Complexes I, III and IV; the gradient is where the energy is held
the phosphate bond	is the product	protons falling back through ATP synthase turn the rotor, and the rotor condenses ADP and phosphate; the protons drive the machine and do not enter the bond

The order is redox, then gradient, then phosphate. ATP does not power the redox reactions. The redox reactions pay for the ATP.

1652. Two, Then One, Then Four ↩

The chain changes its electron accounting twice on the way to oxygen

NADH donates TWO electrons at once. The cytochromes and iron-sulfur clusters that carry them onward are ONE-electron carriers. And Complex IV must assemble FOUR electrons before it reduces oxygen, because a partially reduced oxygen released from the site is a radical.

Two, then one, then four. The chain is not a wire. It is three different accounting systems in series, and the last one exists to prevent the release of anything half-finished.

1653. ATP Is the Hub and the Rest Is Change ↩

Nucleoside diphosphate kinase runs ATP plus GDP to ADP plus GTP, and performs the same exchange for the cytidine and uridine nucleotides. The other triphosphates are change made from the one currency.

1654. And the Currency Is a Letter ↩

The observation this Part exists to record

RNA polymerase takes ATP, places the AMP into the growing chain, and releases pyrophosphate. The bond broken to write the message is the same phosphoanhydride bond that pays for metabolism.

ENERGY AND INFORMATION ARE THE SAME MOLECULE. Most biochemists know both halves of that sentence and few have put them beside each other.

1655. The Adenine Does Not Stop There ↩

Adenine is in NAD, in FAD, in coenzyme A, in S-adenosyl methionine. The cell's entire cofactor set is built on a nucleotide handle, and the last universal common ancestor already depended on those cofactors.

One base is the energy currency, a letter of the message, and the handle on every major cofactor. Whatever else that is, it is not a coincidence that a notation should leave uncolored.

1656. What This Part Refuses ↩

the claim	the status
that ATP is ninety percent of metabolic energy as a measured quantity	refused as a headline. The arithmetic is given at section 1650 and the figure is a consequence of it, not an independent measurement
that the ADP-ATP cycle involves electron transfer	refused. It is a condensation at constant oxidation state, and this Part prints the error because it is easy to make
that the cofactor observation establishes an RNA world	refused. It is consistent with several accounts of early metabolism and decides between none of them
that phosphorus was scarce or abundant on the early Earth	refused as beyond this Part. The mineral question belongs to Part Fifty-Two

1657. The Experiment This Part Generates ↩

The question. Does the cell's use of ATP as a polymer monomer compete measurably with its use as an energy currency under nucleotide restriction?

Method. Under graded inhibition of de novo purine synthesis, measure transcription rate and adenylate energy charge from the same sample. If the two uses are independent, energy charge holds while transcription falls. If they compete, both fall together and the ratio between them is fixed.

Falsification condition. A constant energy charge across the full range of transcriptional inhibition separates the two pools and this Part's framing of one molecule serving two jobs is, for the cell's purposes, wrong.

1658. What This Part Claims ↩

1	**Base, nucleoside and nucleotide are three levels with three chemistries, and naming the level is what makes a sentence checkable**
2	The ADP to ATP cycle is a phosphate transfer at constant oxidation state, not an electron exchange
3	The order is redox, then gradient, then phosphate: the bond is the product and not the cause
4	The respiratory chain changes electron accounting twice, two to one to four
5	ATP is the hub; the other triphosphates are made from it by nucleoside diphosphate kinase
6	The bond that pays for metabolism is the bond broken to write the message
7	Adenine is the handle on NAD, FAD, coenzyme A and S-adenosyl methionine, and LUCA already depended on them

PART ONE HUNDRED AND SIXTY-ONE · QT IS THE MARKER, CALCIUM IS THE TRIGGER

1659. The Pathway as Received ↩

A published adverse outcome pathway, and the step it leaves implicit

An adverse outcome pathway is a formal chain of causation used in regulatory toxicology. It begins with a molecular initiating event, runs through key events at rising levels of biological organization, and terminates in an adverse outcome.

type	the event	the meaning
MIE	hERG channel blockade	the drug binds the pore-forming subunit
KE	inhibition of the rapid delayed rectifying potassium current	the current called IKr is lost
KE	prolongation of action potential duration	repolarization takes longer
KE	prolongation of the QT interval	the same thing, measured on a surface electrocardiogram
KE	Torsades de Pointes	a polymorphic ventricular arrhythmia
AO	sudden cardiac death	the outcome

Nothing in that list is wrong. The hERG channel does carry IKr, its blockade does lengthen the action potential, a longer action potential does appear as a longer QT interval, and Torsades does kill people.

The criticism is not that a step is false. It is that a step is MISSING, and that the missing step is the one with the causal work in it.

1660. The Experiment That Breaks the Direct Arrow ↩

An action potential made longer, and an arrhythmia that went away

Chang and colleagues worked in ten rabbit hearts on Langendorff perfusion with atrioventricular block created by radiofrequency ablation, using dual voltage and calcium optical mapping, and gave E4031, a blocker of the same current the pathway begins with.

the condition	the result
baseline	no spontaneous or pacing-induced Torsades
after E4031	action potential duration significantly prolonged; the secondary

the condition	the result
	calcium rise enhanced; SEVEN OF TEN hearts developed Torsades
plus ryanodine and thapsigargin	Torsades inducibility fell to TWO OF TEN. The secondary calcium rise was suppressed from 8.8 percent to 1.2 percent. And action potential duration went UP, from 298 to 457 milliseconds at a pacing cycle length of 1000 ms
plus nifedipine	Torsades inducibility abolished in ALL ten hearts

Read the third row twice. The action potential was made half again as long and the arrhythmia became harder to induce. If a long action potential were the cause of Torsades, that result is impossible.

1661. What Happens in the Gap ↩

The step between a long repolarization and an arrhythmia

When IKr is blocked the cell holds its plateau. Holding the plateau keeps the membrane in the voltage window where the L-type calcium channel can recover from inactivation and open again. That second opening admits calcium, the calcium triggers release from the sarcoplasmic reticulum, and the resulting inward current lifts the membrane before repolarization completes. That deflection is an EARLY AFTERDEPOLARIZATION, and a run of them in tissue repolarizing unevenly is Torsades de Pointes.

Potassium leaving too slowly opens a window. Calcium comes back through the window. The pathway names the window and not the thing that comes through it.

So potassium loss is the SETUP and calcium return is the EVENT. A pathway that names only the setup is naming the marker and not the mechanism, and a marker is what a regulator measures while a mechanism is what a chemist designs against.

1662. The Two Lives of Inosine, Kept Apart ↩

A discipline this Part imposes on itself before it makes any connection

Inosine has two entirely separate lives, and this Part keeps them apart. Inside a message it is a character that changes meaning. Outside the cell it is a purine signal acting on adenosine receptors, with vasodilatory and immunomodulatory effects that have nothing to do with the genetic code.

Naming which one is meant is what makes every sentence after it checkable. The literature on one says almost nothing about the other, and a paper that slides between them is a paper that cannot be checked.

1663. One Uncoded Character Already Governs a Calcium Channel ↩

Real, fatal, and not cardiac

A single edited position in a glutamate receptor transcript sets that channel's calcium permeability. An animal that cannot make the edit dies, and the lethality is rescued by supplying the pre-edited allele — which establishes that the edit rather than the enzyme's other functions is what the animal needs.

That is the sharpest evidence anywhere that a character with no letter in the alphabet governs a calcium-permeable channel. It is in the central nervous system and not in the heart, and this Part says so rather than letting a reader assume otherwise.

1664. What This Part Refuses ↩

the claim	the status
that the published pathway is wrong	refused. Every step in it is established. The claim is that a step is missing
that inosine is involved in hERG-mediated Torsades	REFUSED, and this is the connection the author would have liked to make. No evidence supports it and none is offered
that the glutamate receptor case is cardiac	refused. It is central nervous system biology and is presented as such
that calcium channel blockade is a therapy for drug-induced Torsades	refused as beyond the evidence. Nifedipine abolished inducibility in an isolated rabbit heart preparation, which is a mechanistic result and not a clinical recommendation

the claim	the status
that QT should be dropped as a safety marker	refused. A marker that tracks the substrate is useful. The claim is that it is a marker and not the mechanism

1665. The Experiment This Part Generates ↩

The question. Does the editing state of a calcium-permeable receptor set the range over which thiol chemistry can modulate it?

Method. Express the edited and unedited forms of the receptor separately. Apply a graded series of thiol-modifying agents to each. Measure current at each concentration.

Prediction if the two are independent. The modulation curves superimpose and the editing state sets only the calcium permeability.

Prediction if they interact. The curves differ in range or slope, and a manufacturing decision made in the nucleus sets the operating envelope of a redox-sensitive channel in the membrane.

Cost. Standard electrophysiology. No new reagent.

1666. What This Part Claims ↩

1	**The published pathway runs six steps and five arrows from hERG blockade to death, and every step in it is established**
2	Between a long QT interval and Torsades there is an implicit step, and it is the step that does the causal work
3	That step is calcium: L-type reactivation during the prolonged plateau, and secondary release from the sarcoplasmic reticulum
4	Suppressing sarcoplasmic reticulum calcium cycling lowered Torsades inducibility from seven of ten to two of ten while action potential duration rose from 298 to 457 milliseconds
5	A calcium channel blocker abolished inducibility in all ten hearts
6	Inosine has two unrelated lives and this Part keeps them apart
7	One uncoded character already sets the calcium permeability of a receptor, and the case is neurological rather than cardiac

PART ONE HUNDRED AND SIXTY-TWO · THE GENE THAT BROKE TWICE

1667. Purine Disposal, and the Step Humans Cannot Take ↩

Where the pathway stops, and what accumulates behind the stop

Purine disposal runs hypoxanthine to xanthine to uric acid to allantoin. One enzyme, xanthine oxidoreductase, does the first two steps. A second enzyme, uricase, should do the third.

In humans it does not exist. The pathway stops at uric acid, and everything downstream of that step is absent from human biochemistry.

1668. The Gene Broke Twice, Independently ↩

Two lineages, two separate accidents, one outcome

The human uricase gene carries two nonsense mutations and an aberrant splice site. The gibbon gene carries none of those and instead has its own thirteen-base-pair deletion. The two lineages lost the same function by different routes.

The authors of that finding drew the obvious inference and this Part quotes rather than extends it: a functional gene disrupted by independent events in two lineages is unlikely on a chance basis, so the loss may have had evolutionary advantages.

Losing a working enzyme once is an accident. Losing it twice, separately, in two lineages, is the kind of pattern that asks for a reason.

1669. The First Proposed Advantage: Urate as an Antioxidant ↩

Plasma urate in humans runs about three hundred micromolar, higher than ascorbate, and is about as effective as ascorbate in the assays that first made the case. The proposal is that a primate losing uricase gained a circulating antioxidant at high concentration.

The proposal is old, it is plausible, and it has never been decisive, because the assays that establish antioxidant capacity in a tube do not establish that the capacity is used in a body.

1670. The Second Proposed Advantage, Now Tested Directly ↩

Putting the ancestral enzyme back

The metabolic proposal is that urate accumulation assists the conversion of fructose to fat, which would be an advantage to a frugivorous primate facing seasonal scarcity. That proposal has now been tested rather than argued: ancestral uricase was restored to human liver cells by gene editing, and the fructose-driven rise in triglyceride production did not happen.

An evolutionary hypothesis about a loss that occurred millions of years ago was tested by putting the lost enzyme back. That is the kind of experiment the hypothesis was waiting for.

1671. The Enzyme That Makes Uric Acid Is Itself a Radical Generator ↩

And a disulfide bond is the switch

Xanthine oxidoreductase exists in two forms. As a dehydrogenase it passes electrons to NAD. As an oxidase it passes them to molecular oxygen and releases superoxide. The conversion between the two is effected by the formation of a DISULFIDE BOND, and it is reversible by reduction.

A sulfur-sulfur bond is the switch that turns a tidy dehydrogenase into a source of superoxide. The enzyme that makes the antioxidant becomes, on the flip of one disulfide, a maker of the oxidant the antioxidant is supposed to answer.

1672. Where Glutathione Sits ↩

Urate guards the plasma. GLUTATHIONE guards the cytosol, and glutathione is built out of cysteine and glycine, spent by a selenocysteine enzyme, and regenerated by NADPH from the pentose phosphate pathway.

Two antioxidant systems, two compartments, and both of them run on sulfur — one through cysteine in the tripeptide, the other through the disulfide that decides which form the purine enzyme takes.

1673. The Color Ruling This Part Records ↩

Why urate is unshaded, and why oxygen is not

Urate, uric acid, uricase, allantoin and hyperuricemia carry NO COLOR in this volume's notation. The ruling stands on two grounds: urate sits outside the boundary of purine metabolism proper, and the molecule is the product of a pathway that in humans terminates abnormally.

NO SUPPRESSION, THOUGH. Oxygen keeps its color wherever it is warranted. The shader colors ATOMS AND REACTIONS, not nouns, and a ruling that a noun is unshaded does not travel to the chemistry that noun participates in.

1674. What This Part Refuses ↩

the claim	the status
that the uricase loss was	refused as unproven. The independence of the two events is

the claim	the status
adaptive	established; the advantage is a hypothesis with one direct test behind it
that urate is a clinically useful antioxidant	refused. High plasma urate is also the cause of gout and a risk marker in several diseases, and this Part does not trade one of those against the other
that xanthine oxidoreductase inhibition is therefore cardioprotective	refused as beyond the evidence assembled here
that the fructose result explains human obesity	refused. It is a cell-culture result on one pathway and is reported as one
that urate should be colored	refused, by standing ruling, and the ruling is recorded at section 1673 so that it is not silently reversed

1675. The Experiment This Part Generates ↩

The question. Does the dehydrogenase-to-oxidase conversion of xanthine oxidoreductase track the cell's thiol redox state quantitatively, rather than switching at a threshold?

Method. In isolated hepatocytes, vary the reduced-to-oxidized glutathione ratio across its physiological range by graded challenge. At each ratio measure the fraction of xanthine oxidoreductase in the oxidase form and the superoxide production rate from the same preparation.

Prediction if the relationship is graded. Oxidase fraction is a continuous function of the glutathione ratio, and the enzyme is a redox sensor rather than a switch.

Prediction if it is a threshold. Oxidase fraction is flat until a ratio is crossed, and the enzyme is a switch that reports a state rather than measuring one.

Falsification condition. No relationship in either form separates the disulfide conversion from cytosolic thiol status and makes section 1671's framing an in vitro artifact.

1676. What This Part Claims ↩

1	**Purine disposal stops at uric acid in humans because uricase does not exist**
2	The human gene carries two nonsense mutations and an aberrant splice site; the gibbon gene carries a separate thirteen-base-pair deletion
3	Two independent disruptions in two lineages is the observation that raises the question of advantage
4	Urate is a powerful antioxidant at about three hundred micromolar in human plasma, higher than ascorbate
5	Restoring ancestral uricase to human liver cells abolished the fructose-driven rise in triglyceride production
6	A disulfide bond converts xanthine oxidoreductase from a dehydrogenase into a superoxide-producing oxidase
7	Urate guards the plasma and glutathione guards the cytosol, and both systems run on sulfur

PART ONE HUNDRED AND SIXTY-THREE · ADENOSINE FOR INOSINE

1677. The Alphabet That Has No I ↩

What a sequence string is permitted to contain

A nucleotide sequence in a public archive is a string over a fixed character set, and the set is closed. Five characters name the canonical bases. Eleven more are ambiguity codes, each standing for a defined subset: R for a purine, Y for a pyrimidine, S for G or C, W for A or T, K for G or T, M for A or C, B for anything but A, D for anything but C, H for anything but G, V for anything but T, and N for any of them.

Every one of those sixteen characters is a statement about the four canonical bases. ELEVEN OF THEM EXIST TO EXPRESS UNCERTAINTY about which of the four is present. Not one expresses the presence of a fifth.

So the format has a rich vocabulary for not knowing which letter it is, and no vocabulary at all for its being a different letter. That asymmetry is the subject of this Part.

1678. Annotation Is the Escape Hatch, and It Is a Different Thing ↩

Inosine can be recorded ALONGSIDE a sequence — as a modification feature attached to a coordinate, or as an entry in a database built for modifications. It cannot be recorded INSIDE the sequence. The distinction matters because the string is what every downstream tool reads by default. An aligner reads the string. A variant caller reads the string. A model trained on genomes reads the string.

It can be annotated. It cannot be spelled. Everything else in this Part follows from that sentence.

1679. What the Modification Database Does ↩

The nomenclature rule, quoted, and the reading this Part gives it

MODOMICS is the reference catalog of RNA modifications. If any resource ought to treat inosine as a character in its own right, it is this one. The 2023 update sets out the rules by which a modified residue is assigned to a parent base, and uses inosine as one of its two worked examples: if the residue results from a naturally occurring chemical modification of one of the four bases, it takes that base's letter — G for queuosine, A FOR INOSINE.

That rule is deliberate, considered and chemically true. Inosine is adenosine with the six-amino group removed, and recording the relationship is useful. The criticism here is not that the rule is wrong.

Read the example with the letter spelled out and the notation says it for you: ADENOSINE FOR INOSINE. Red standing where orange belongs.

It records where the molecule CAME FROM in the place where what the molecule IS belongs. Provenance in the identity field.

1680. What the Sequence File Does, Which Is Worse ↩

Not an omission — a substitution

A parent letter at least preserves a relationship. The primary sequence record does not even do that, and the mechanism is ordinary laboratory chemistry rather than anybody's decision. Inosine pairs with cytidine, so reverse transcriptase places a C opposite it, and the resulting complementary DNA reads G. Every platform that goes through a cDNA intermediate deposits an edited adenosine as a guanosine.

the stage	the character
the genome	A
the RNA product	INOSINE
the complementary DNA	G
the archive	G
the marker in the file	NOTHING

The record does not report a gap, an N, or an uncertainty. It reports a base that was never in the molecule, with full confidence and no flag.

A missing character announces itself. A substituted one does not. The absence is filled, silently, by a character that belongs to something else.

1681. The Objection, At Full Strength ↩

Stated before the argument, because it is a good objection

— THE FIELD KNOWS. Adenosine-to-inosine editing has been characterized for four decades and is among the best-studied post-transcriptional modifications in biology.

— THE SITES ARE CATALOGED. REDIportal holds more than four and a half million such events across fifty-five human body sites, from thousands of sequencing experiments, embedding the earlier RADAR collection.

— THE MODIFICATIONS ARE CATALOGED. MODOMICS maintains the residue catalog, expanded in 2023 to seventy-nine modified residues found in experimentally determined structures, with evidence and reliability annotation.

— AND THE PIPELINES REQUIRE A CONTROL. Calling an edit demands matched genomic DNA, precisely so that a mismatch is not mistaken for a variant.

That objection is correct, and the version of this argument that says the databases cannot be trusted dies on it and deserves to. What survives is narrower and is stated at section 1683.

1682. And the Objection Is Also the Admission ↩

The compensation is not free and its failure mode is specific. It requires matched genomic DNA, which is not always available; it works at sites that have been cataloged, which is not all sites; and it is applied by analysts who know to apply it, which is not everyone downstream. A sequence file, once written, travels. The correction layer does not travel with it.

NOBODY BUILDS A SPECIALIST DATABASE FOR A CHARACTER THE PRIMARY FORMAT CAN ALREADY HOLD. The existence of the layer is the measure of the gap, not the answer to it.

1683. The Claim That Survives ↩

The primary sequence record is lossy at a known, quantifiable and consequential set of positions, and the loss is SILENT. At edited positions the record does not omit a character — it substitutes one — and nothing in the file marks that it has done so.

the audience	the consequence
genomics	an A-to-G mismatch in transcript data is not a variant until matched genomic DNA says so; the mismatch is the only evidence either way
gene editing	the intended product of an adenine base editor and its principal off-target are the same chemical species, and both are visible only as substitutions
drug development	a target transcript may be edited in the tissue of interest and unedited in the reference, and the reference is what the program was designed against
clinical interpretation	a pathogenic variant called from transcript data alone may be an edit; the two are indistinguishable in the file

Each of those is a caution rather than an accusation. Each is actionable. None of them requires anybody to have been careless.

1685. What This Part Refuses ↩

the claim	the status
that sequence databases are untrustworthy	refused. They are accurate records of what they were designed to record
that the field is unaware of RNA editing	refused. Section 1681 sets out how thoroughly aware it is
that the MODOMICS nomenclature rule is an error	refused. The rule is chemically true; the criticism is that provenance is recorded where identity is needed
that downstream analyzes are known to be misled at some rate	refused. That would require a survey of published analyzes and this author has not done one
that a new character should be added to the alphabet	refused as a different paper. Proposing one requires addressing every format, parser and archive that would have to accept it

1686. The Experiment This Part Generates ↩

The question. Of the annotated human transcripts that overlap known adenosine-to-inosine editing sites, what fraction carry any editing annotation in the transcript record itself?

Method. Intersect published site coordinates with transcript coordinates. For each overlapping transcript, parse the feature table for any modification, editing or variation feature at the site position. Report the proportion with an exact binomial interval, stratified by the evidence level of the site so that the estimate is not driven by low-confidence calls.

The second number. The same proportion restricted to transcripts of genes carrying a clinically annotated pathogenic variant, which is the population where a missing annotation would matter most.

Falsification condition. A proportion near one shows the primary record does carry the information and this Part is about a problem that has been solved.

A number near zero, measured, is a different object from a number near zero, asserted. The cost is an afternoon and a desktop computer.

1687. What This Part Claims ↩

1	**The permitted character set contains no character for inosine; eleven of its sixteen characters express uncertainty among the four and none expresses a fifth**
2	MODOMICS assigns inosine a parent letter by stated rule, recording provenance where identity belongs
3	The primary record does not omit inosine — it substitutes guanosine, and nothing marks the substitution
4	The positions are known and countable; the catalogs are the measure of the reach, not a refutation of it
5	A correction layer is evidence for the gap: nobody builds one for a character the format can already hold, and the layer does not travel with the file
6	The narrow claim survives the strongest objection and the broad one does not, and both are printed

---

PART ONE HUNDRED AND SIXTY-FOUR · ONE CHEMISTRY, TWO ADDRESSES

1688. The Instrument Is the Enzyme ↩

An adenine base editor is an evolved transfer RNA deaminase

Part One Hundred and Twenty recorded the lineage: the adenine base editor was made by taking TadA, the bacterial enzyme that makes inosine at position thirty-four of a transfer RNA, and evolving it until it would perform the same deamination on single-stranded DNA.

An adenine base editor does not resemble a deaminase and does not borrow from one. It IS one, redirected to a different substrate and aimed by a guide. An enzyme evolved for one substrate retains measurable activity on its ancestral substrate, and the ancestral substrate of TadA is RNA.

1689. What the Field Has Already Measured ↩

The numbers as the laboratories published them

the laboratory	the measurement	the engineering response
Grünewald and colleagues, 2019	a cytosine editor carrying rat APOBEC1 produced tens of thousands of transcriptome-wide C-to-U edits, at frequencies from 0.07 percent to 100 percent, in 38 to 58 PERCENT OF EXPRESSED GENES — and an adenine base editor was shown to induce transcriptome-wide RNA edits as well	two engineered variants reduced the count more than 390-fold and more than 3,800-fold
Zhou and colleagues, 2019	the cytosine editor BE3 and the adenine editor ABE7.10 each generated tens of thousands of off-target RNA single-nucleotide variants	three cytosine variants and one adenine variant returned the count to baseline while holding on-target DNA activity
Rees, Wilson, Doman and Liu, 2019	a current adenine base editor generates low but detectable levels of widespread adenosine-to-inosine editing in cellular RNAs	structure-guided mutations in both deaminase domains decoupled the DNA and RNA activities across three cell lines
Richter and colleagues, 2020	ABE8e, evolved to 590-fold the activity of its parent, carries a modest increase in DNA off-target editing and in transcriptome-wide RNA off-target editing	ameliorated by a further mutation in the TadA-8e domain

The field found this, named it, quantified it, and engineered against it, within months of the platform appearing. Nothing in this Part is a criticism of that work and everything in it stands on it.

1690. And the Clinic Did Not Wait ↩

the setting	the result
base-edited CAR7 T cells, 2023	three children with relapsed T-cell acute lymphoblastic leukemia received universal donor cells in which three genes had been inactivated by cytidine deamination. The first patient, thirteen years old, reached molecular remission within twenty-eight days of a single dose
in vivo correction of progeria, 2021	a single injection of an adenine base editor carried by a virus corrected 20 to 60 percent of the pathogenic allele across organs six months later, rescued the vascular pathology, and raised median lifespan from 215 to 510 days

Both results are real and both are why the question in this Part is worth the cost of answering. A platform already curing children is a platform whose measurement conventions deserve a second look — not because anyone was careless, but because the stakes have risen faster than the assays.

1691. Where the Benefit and the Risk Become One Object ↩

the property	on target	off target	same or not
the chemistry	remove the six-amino group from an adenine ring	remove the six-amino group from an adenine ring	IDENTICAL
the product	INOSINE	INOSINE	IDENTICAL
the enzyme	evolved TadA	evolved TadA	IDENTICAL
the substrate	single-stranded DNA in the R-loop	cellular RNA	different
the detection	A-to-G mismatch against reference	A-to-G mismatch against reference	IDENTICAL
the address	one chosen base pair	many, unchosen	different

Four of six rows are identical. The therapy and its principal liability are distinguished by WHERE, and by nothing else.

There is a second consequence. The cell is already running this reaction on its own RNA at more than four and a half million cataloged positions. So when a laboratory subtracts an untreated control to count off-target events, it subtracts one population of inosine from another, made by two enzymes performing the same reaction, possibly in the same neighborhoods.

1692. The Question, Stated as a Null Hypothesis ↩

the hypothesis	the statement
H_0 (primary)	The positions at which an adenine base editor produces off-target adenosine-to-inosine events in RNA are INDEPENDENT of the endogenous editome. The odds ratio, conditional on matched strata, equals 1
H_1 (primary)	The odds ratio exceeds 1: the editor writes preferentially where the cell's own enzyme already writes

the hypothesis	the statement
H_0 (secondary)	Editor-induced RNA variant burden is independent of ADAR1 status; the interaction coefficient equals zero
H_1 (secondary)	The coefficient is non-zero in either direction — negative if the enzymes compete for one substrate pool, positive if they share a structural preference that a raised ADAR1 level amplifies

— IF H-NOUGHT IS REJECTED, the untreated-control subtraction is not clean. The sites most likely to be discarded as endogenous are the sites the editor is most likely to hit, biasing the off-target count DOWNWARD by an amount nobody has estimated.

— AND THE OFF-TARGET PROFILE BECOMES A FUNCTION OF THE PATIENT, because ADAR1 p150 is interferon-inducible and a patient with active inflammation does not carry the ADAR1 level of the cell line the program was characterized in.

— IF H-NOUGHT SURVIVES with a tight interval, the current convention is VALIDATED quantitatively for the first time, which is worth having in a regulatory file.

1693. The Design, and the Confounder Named in Advance ↩

A three-factor full factorial. Factor A, the editor, at four levels: an unmodified adenine base editor; a reduced-RNA variant; a CATALYTICALLY DEAD TadA fused to the same nickase; and a fluorescent-protein-only construct. Factor B, ADAR1 status, at three levels: unmodified, knockdown, and interferon induction. Factor C, cell background, at two levels: a line comparable with the published measurements, and one clinically relevant primary cell. Twenty-four conditions, four independent transductions each, ninety-six samples, randomized to plate position and called blind.

Transduction induces interferon. Interferon induces ADAR1 p150. ADAR1 p150 raises endogenous editing. A naive treated-versus-untreated comparison therefore confounds the editor's own activity with an interferon response the delivery provoked, and the dead-TadA and fluorescent-protein arms exist for exactly that reason.

Primary endpoint: the odds ratio that an editor-induced site falls within a cataloged editing position, against control adenosines matched on expression decile, on the two flanking nucleotides either side, and on predicted double-strandedness, at five controls per case. Conditional logistic regression on matched strata, confirmed by ten thousand within-stratum permutations. Negative control: C-to-T sites in the same libraries, which should show no association.

sites recovered	smallest odds ratio detectable at 90 percent power
20,000	1.11
5,000	1.23
2,000	1.38
1,000	1.56
500	1.84
200	2.51

The reduced-RNA arms are the arms that produce FEW sites, so they are powered only for large effects. That limitation is known before the first transduction and a null result there must be reported as underpowered rather than as absence.

1694. The Duration Test ↩

The follow-up, and the one with the regulatory consequence

On-target benefit is a fixed locus: once the base pair is converted it is converted, and the benefit SATURATES. RNA is a renewing substrate: transcripts are made and degraded continuously, so a deaminase still expressed keeps writing into new ones, and the burden ACCRUES. The commonest delivery vehicle for in vivo editing sustains expression for months.

If benefit saturates and burden accrues, the therapeutic index of a base editor is not a constant. It is a DECLINING FUNCTION OF TIME, and it is not currently reported as a function of anything.

H-nought: after on-target editing reaches plateau, the slope of log-two cumulative RNA variant burden against log-two time is zero. Design: an inducible editor

sampled at days 1, 3, 7, 14 and 28, four wells per time point per arm, with on-target editing and RNA burden measured from the same sample so the ratio is a within-well quantity. Statistics: segmented regression with the breakpoint estimated rather than assumed and its existence tested; the slope of the second segment tested against zero in a mixed model with well as a random intercept.

Power. The spread of the predictor on the log-two scale gives a sum of squares of 14.16. At four wells per time point and a residual standard deviation of 0.40 on that scale, the minimum detectable slope at ninety percent power is 0.180 — a 1.28-fold rise in burden between day seven and day twenty-eight. Twenty samples per arm.

1695. What This Part Refuses ↩

the claim	the status
that base editors are unsafe	refused. Two clinical results are printed at section 1690 precisely because they are real
that the field is unaware of RNA off-target editing	refused. Section 1689 is a record of how quickly it was measured
that reduced-RNA variants fail	refused. They work, by margins the original authors quantified
that the sign of the ADAR1 interaction is known	refused. Both directions are given equal weight because this author cannot predict which is right
that any patient has been harmed by RNA off-target editing	refused. No such case is known to this author, and this Part concerns measurement convention rather than an observed injury

1696. What This Part Claims ↩

1	**An adenine base editor is an evolved transfer RNA adenosine deaminase: the instrument and the target enzyme are one protein family separated by laboratory evolution**
2	Its intended product and its reported RNA off-target are both inosine, and both are observed only as an A-to-G mismatch
3	The endogenous editome is a background made of the editor's own product, at more than four and a half million cataloged human positions
4	Whether the two overlap more than chance is an open, testable question, and section 1693 gives a design powered to an odds ratio of 1.11

1	**An adenine base editor is an evolved transfer RNA adenosine deaminase: the instrument and the target enzyme are one protein family separated by laboratory evolution**
5	On-target benefit saturates while RNA burden accrues, so the therapeutic index is a function of expression duration
6	Both experiments are runnable with existing reagents and methods and no animal work

PART ONE HUNDRED AND SIXTY-FIVE · TWO DEAMINATIONS NO SEQUENCE FILE CAN WRITE

1697. The Family Is Named After a Lipoprotein ↩

Where the cytosine channel was discovered, and what it was doing there

APOBEC stands for apolipoprotein B messenger RNA editing enzyme, catalytic polypeptide-like. The founding member was found doing lipid biology.

the element	the fact
the reaction	a cytidine at nucleotide 6666 of apolipoprotein B messenger RNA is converted to a uridine
the consequence	codon CAA becomes UAA — an in-frame STOP codon that was not in the gene
the products	apoB-100 in liver, where the editing does not happen; apoB-48 in intestine, where it does
the genome	one gene, one open reading frame, no stop at that position

A single deamination writes a stop codon into a message, and the protein made from the edited message is half the length of the protein made from the gene. The termination signal exists in the transcript and does not exist in the DNA.

That is the founding observation of the whole cytidine deaminase family — the family that now contains the enzymes whose mutational signatures are among the most studied in oncology. Their name is a fossil of a lipid experiment.

A note on the color, and a ruling this Part does not make

An enzyme takes the color of the molecule in its own name. ADAR is red because it is named for adenosine; IMPDH is orange because it is named for IMP. APOBEC is named for a LIPOPROTEIN, and a lipoprotein has no color in a system built on the six elements of life.

So the shader leaves APOBEC unshaded, and it is right to, under the rule as written. Whether the rule should reach an enzyme named after the substrate it acts ON rather than the molecule it acts WITH is a ruling for the author of the notation, and this Part does not make it.

1698. And the Other Channel Is Lowering Cholesterol ↩

Two lipid programs, two mechanisms, and only one of them makes inosine

the target	the instrument	the chemistry
ANGPTL3	a CRISPR-Cas9 NUCLEASE. It cuts the gene and the cell's repair machinery disables it through insertions and deletions	no deaminase, no inosine, no letter converted. The gene is broken, not rewritten
PCSK9	an ADENINE BASE EDITOR — evolved TadA fused to a nickase, delivered by lipid nanoparticle	a chosen adenine is deaminated to INOSINE in liver DNA and read thereafter as G. One base pair is rewritten and nothing is cut through

The base-editing result was reported in cynomolgus monkeys: near-complete knockdown of PCSK9 in the liver after a single infusion, with blood PCSK9 reduced by approximately ninety percent and low-density lipoprotein cholesterol by approximately sixty percent, stable for at least eight months after one dose.

An enzyme whose natural job is to make inosine at position thirty-four of a bacterial transfer RNA is now making inosine in the liver of a primate in order to lower its cholesterol.

1699. One Letter Missing, One Letter Taken ↩

The claim this Part exists to make, in one table

the property	the cytosine channel	the adenosine channel
the enzyme family	APOBEC and AICDA	ADAR, ADAT, TadA
the base attacked	cytosine	adenine
the product	uracil	INOSINE
the reading by the machinery	as thymine or uracil	as guanosine
the structure preferred	single-stranded loops and hairpins	double-stranded regions and hairpin duplexes
in this volume's colors	BLUE becoming PURPLE	RED becoming ORANGE
a character for the product	YES — U and T are canonical letters	NO — the alphabet has no character for inosine
the file	a T, which is also what a genomic T looks like	a G, which is also what a genomic G looks like
so what is lost	the symbol EXISTS and is AMBIGUOUS: an edit cannot be told from a mutation	the symbol IS ABSENT and is SUBSTITUTED: an edit is recorded as a different molecule

One channel loses the event because its product has no letter. The other loses it because its product's letter is already owned by a different molecule. No file says which happened, and the two failures need different remedies.

The asymmetry has a practical consequence. An A-to-G mismatch has few innocent explanations, because adenosine-to-guanosine somatic mutation is comparatively uncommon. A C-to-T mismatch has many: cytosine deamination is the commonest spontaneous mutation in the genome, and the APOBEC signatures are among the largest contributors to somatic mutation in several cancers.

1700. The Instrument Caught Up. The Format Did Not. ↩

A platform that reads inosine directly, and a file that still writes guanosine

A bioinformatician's first answer is to sequence it better. That answer has been tried, and the result is the sharpest evidence in this Part.

the platform	the chemistry in the way	the record
short-read RNA sequencing	the transcript is copied into complementary DNA first, and	the archive receives a G; the edit is inferred backward and never

the platform	the chemistry in the way	the record
	reverse transcriptase places a C opposite inosine	observed
whole-genome and exome sequencing	a base editor has written inosine into genomic DNA on purpose, and the polymerase copies it as guanine	the archive receives a G; a therapeutic edit and a germline G are one character
amplicon sequencing	the same polymerase chemistry at higher depth over a smaller window	higher confidence in the same substituted character

The limit is not in the sequencing chemistry. It is in the ALPHABET THE FILE IS PERMITTED TO CONTAIN, and that alphabet is the same whatever instrument produced the reads.

Nanopore direct RNA sequencing reads the molecule itself. There is no complementary DNA intermediate and no reverse transcriptase, so nothing converts inosine before it is measured, and deep learning models trained on the raw current signal call inosine as inosine. The authors of that work describe the older route in the same terms this volume does: detecting edits as adenosine-to-guanosine changes in complementary DNA is indirect and can be confounded by genomic polymorphisms and DNA mutations.

So the instrument can now distinguish INOSINE from GUANOSINE. The file still writes G. The information is discarded at the moment of WRITING rather than lost at the moment of READING, and those are different failures with different remedies.

1701. What the Breast Cancer Study Found ↩

The 2024 result this Part builds its experiment on

the finding	the detail
the sites are selective	APOBEC3B does not edit at random; the differential variants concentrate in particular transcripts
the top two transcripts	NEAT1 and MALAT1 — the two transcripts with the highest degree of C-to-U editing in that data
the structure preference	the variants are enriched in predicted single-stranded RNA hairpin structures
the dose relation	across six breast cancer cell lines, APOBEC3B protein level correlated with editing frequency at those two transcripts, R squared above 0.6 and p below 0.05

the finding	the detail
AND THE MECHANISM	binding of the two long non-coding RNAs SEQUESTERS APOBEC3B and suppresses its global activity against RNA and against DNA; release increases its activity at the expense of APOBEC3A
and one more thing	the same dataset contains A-to-G differential variants whose folding energy resembles curated adenosine-to-inosine sites. BOTH CHANNELS WERE MEASURED IN ONE EXPERIMENT

An abundant structured transcript acts as a decoy that soaks up a deaminase and holds down its activity everywhere else. That is a regulatory architecture, and nothing about it is obviously specific to the cytosine channel.

1702. The Decoy Hypothesis ↩

the hypothesis	the statement
H_0 (primary)	Global adenosine-to-inosine editing load is INDEPENDENT of the abundance of those two transcripts, after adjustment for ADAR1 expression and interferon signature
H_1 (primary)	The coefficients are jointly non-zero and NEGATIVE: more decoy, less editing elsewhere, because the decoy holds the enzyme
H_0 (secondary)	Depleting them does not change global editing load
H_1 (secondary)	Depletion raises it, as release of the enzyme predicts
H_0 (symmetry)	The two channels respond equally to the same depletion, measured within the same libraries
H_1 (symmetry)	They differ — and the direction says whether the decoy is general to deaminases or specific to one

1703. The Design, and the Circularity Trap ↩

Those two transcripts are THEMSELVES heavily edited. Any global editing index that includes their loci will rise and fall with their abundance for purely arithmetic reasons, and the association is guaranteed before a single biological effect is present.

Every editing index in every arm EXCLUDES those loci. This is not a refinement. An analysis that omits it produces a positive result whatever the biology does.

Arm A, observational and runnable on a desktop: a public tumor cohort above a thousand samples, the published editing index as outcome, the two abundances as predictors, adjusted for ADAR1, an interferon signature score, tumor purity, subtype and batch; the two coefficients tested jointly on two degrees of freedom. At a thousand samples the design resolves a partial correlation of 0.112; at five hundred, 0.158; below three hundred, only 0.2 and above.

Arm B, perturbation: the same cell line in which the sequestration was demonstrated, four arms, antisense depletion, eight wells per arm, analysis of variance with Dunnett-adjusted contrasts against the scrambled control. Minimum detectable standardized effect 1.91, which at an eight percent replicate coefficient of variation is a fifteen percent change in the editing index.

Arm C, the symmetry endpoint: both channels measured from the SAME libraries Arm B produced, paired within library. Minimum detectable paired standardized difference 1.29 at eight libraries. No additional sequencing.

One set of libraries, two channels, one paired comparison. The experiment that distinguishes a general mechanism from a specific one costs nothing beyond the experiment already being run.

1705. What This Part Refuses ↩

the claim	the status
that the two enzyme families are one system	refused. They are unrelated protein families running chemically analogous reactions on different bases, and the shared phrase RNA EDITING hides that
that the APOBEC name implies a mechanistic link between lipid biology and cancer mutagenesis	refused. The name is a historical fact about where the enzyme was found
that the sign of the decoy effect is known	refused. Both directions are given equal weight
that nanopore sequencing is accurate enough to replace the existing approach	refused as open, and the equivalent discrimination on the cytosine channel has not been demonstrated
that editing is the dominant source of C-to-T mismatches	refused. Spontaneous deamination and the DNA signatures are large and are the reason that channel is confounded at all

1706. What This Part Claims ↩

1	**The cytidine deaminase family is named after a lipoprotein gene, because its founding member was found editing apolipoprotein B messenger RNA**
2	That edit writes a stop codon present in the transcript and absent from the gene
3	An adenine base editor lowered low-density lipoprotein cholesterol by about sixty percent in primates for at least eight months by manufacturing inosine in liver DNA
4	A nuclease targeting a different lipid gene is a different mechanism producing no inosine, so the two programs cannot be described in the same terms
5	Inosine is lost because the alphabet has no character for it; edited uracil is lost because its character is shared with genomic thymine. The two losses are not the same kind
6	A platform now reads inosine directly, so the information is discarded at the moment of writing rather than lost at the moment of reading
7	Whether the decoy architecture governs the adenosine channel is open and testable, and section 1703 gives a design powered to a partial correlation of 0.112

PART ONE HUNDRED AND SIXTY-SIX · OXYGEN IS THE PIVOT

Oxygen Is the Pivot

Sulfur and inosine do the same kind of work at three scales, and at the atomic scale they do it in opposite directions. Inosine installs an oxygen. Sulfur displaces one. They meet at position thirty-four of the transfer RNA anticodon, where one numbered seat carries either character and the four-letter alphabet writes both of them U

Sulfur and Inosine at the Atomic, Molecular and Cellular Scales
PP-2026-SCALE-01 v1 · 20 September 2026

1707. The Two Sections That Were Never Joined ↩

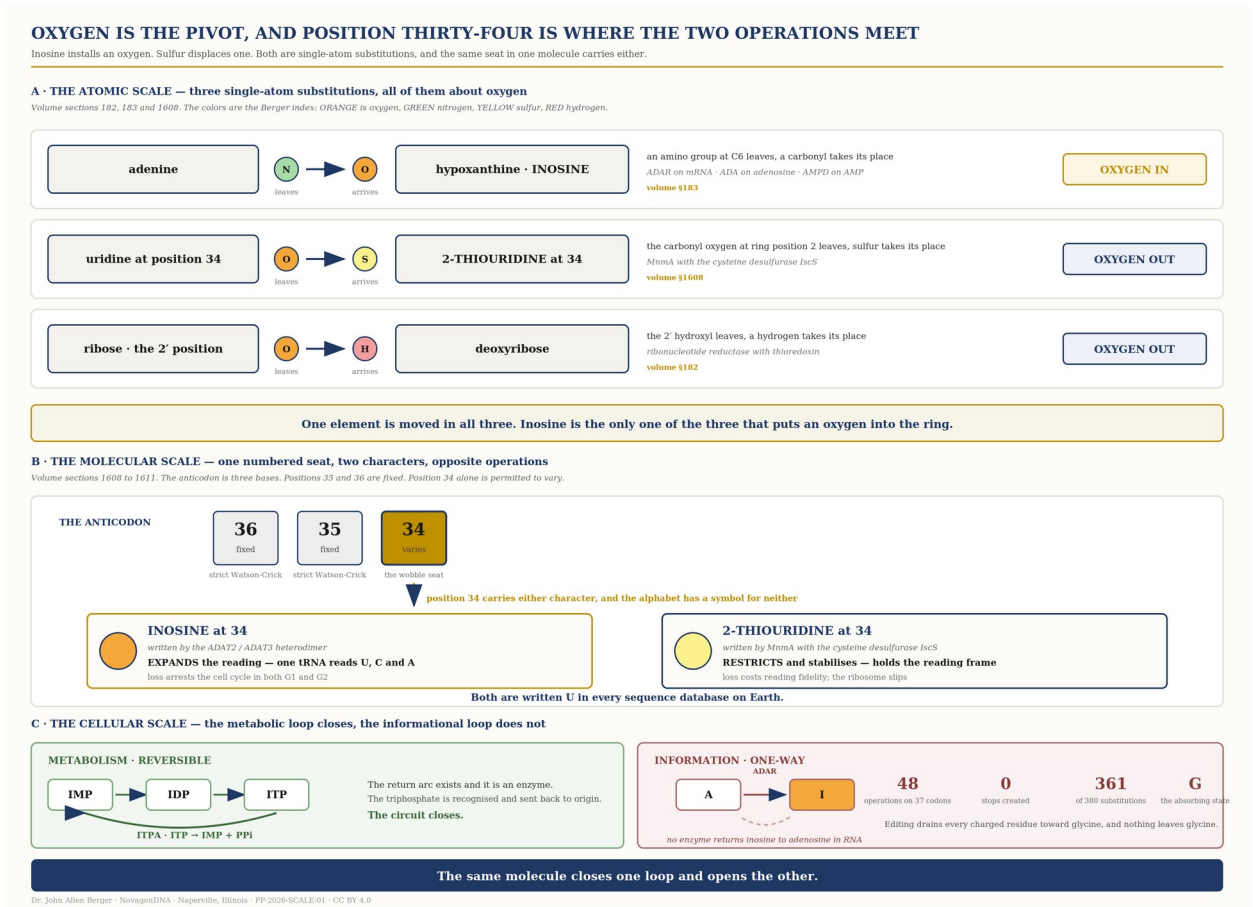
Sections 182 and 183 of the evidence volume sit one apart and state opposite operations on the same element

The evidence volume contains a color census of the nucleotide panel. Section 182 records what ribonucleotide reductase does, in the colors of the Berger index, and states the result in one line: THE ONLY YELLOW REMOVES AN ORANGE. Sulfur takes an oxygen off the two prime position of the sugar, and that single removal is the whole chemical difference between RNA and DNA.

Section 183 records what the deaminases do, in the same colors, and states that result in one line as well: REMOVE A NITROGEN, INSTALL AN OXYGEN. Adenine becomes hypoxanthine when an amino group at carbon six leaves and a carbonyl takes its place. The same move runs on guanine to give xanthine, and on cytosine to give uracil.

Both sections were written. Neither was read against the other. Put side by side they say that the volume's two principal atoms perform the same class of operation — a single-atom substitution — on the same element, in opposite directions.

That is the subject of this paper. The claim is narrow and it is arithmetic: OXYGEN IS THE ATOM BEING MOVED IN BOTH CASES, and inosine is the only one of the three substitutions on the panel that puts an oxygen into a ring rather than taking one out.



1708. The Atomic Scale ↩

Three substitutions, one element, two directions

Each row below is one atom leaving and one atom arriving at a named ring position. No row involves a rearrangement of the carbon skeleton. In every case the molecule keeps its identity and changes one substituent.

the substitution	what leaves	what arrives	the direction	the enzyme	volume
ADENINE → HYPOXANTHINE	the amino nitrogen at carbon six	a carbonyl OXYGEN	OXYGEN IN	ADAR on duplex RNA; adenosine deaminase on the nucleoside; AMP deaminase on the nucleotide	§183
URIDINE 34 → 2-THIOURIDINE 34	the carbonyl OXYGEN at ring position two	a sulfur	OXYGEN OUT	MnmA, with the cysteine desulfurase IscS supplying the atom as a persulfide	§1608, §1611
RIBOSE → DEOXYRIBOSE	the OXYGEN of the two prime hydroxyl	a hydrogen	OXYGEN OUT	ribonucleotide reductase, with thioredoxin as the reductant	§182

What the color index shows that the structural formula does not

In the Berger index ORANGE is oxygen, GREEN is nitrogen, YELLOW is sulfur and RED is hydrogen. Coloring the three rows gives a green leaving and an orange arriving in the first, and an orange leaving in the second and the third. The eye reaches the finding before the chemistry does, which is the property the color index was built to have.

Across the whole nucleotide panel orange saturates and yellow is nearly absent. The two colors meet at exactly one place, and at that place the yellow takes the orange away. Inosine is the molecule that does the reverse.

Why this is a statement about chemistry and not a mnemonic

Oxygen and sulfur are the first two members of group sixteen. They carry the same valence count and they are not interchangeable in practice, because the carbon-sulfur bond is longer than the carbon-oxygen bond and sulfur is the more polarizable of the two. A substitution of one for the other at a ring position therefore changes the geometry of the ring measurably rather than notionally, and it changes what the ring can hydrogen-bond to.

The volume's second Part argues that sulfur and oxygen are conjugate partners rather than neighbors in a list. The three rows above are that argument reduced to single atoms at named positions, which is the form in which it can be checked.

1709. The Molecular Scale ↩

One numbered seat in one molecule carries either character

A transfer RNA anticodon is three bases, numbered thirty-four, thirty-five and thirty-six. Positions thirty-five and thirty-six pair by strict Watson-Crick rules and are fixed. Position thirty-four pairs with the third base of the codon, and it is the position that decides how many codons a single transfer RNA can read.

Position thirty-four carries inosine in some transfer RNAs and a 2-thiouridine in others. Two different enzymes write them, two different chemistries make them, and they do two different jobs.

the character	who writes it	what it does to the reading	what its loss costs	color
INOSINE at 34	the ADAT2 / ADAT3 heterodimer	EXPANDS the reading — one transfer RNA reads codons ending U, C and A	loss arrests the cell cycle in both G1 and G2	ORANGE
2-THIOURIDINE at 34	MnmA, with the cysteine desulfurase IscS	RESTRICTS and stabilizes — fixes the anticodon geometry, confers ribosome binding, holds the reading frame	loss costs reading fidelity; the ribosome slips out of register	YELLOW

One position. Two atoms. Opposite operations on the same quantity, which is the number of codons one adaptor can serve. Inosine widens it. Sulfur narrows it and holds the frame.

The reading Kambampati and Lauhon supply

Reconstituting the thiolation reaction in vitro, Kambampati and Lauhon state what the single sulfur atom does: the sulfur group of 2-thiouridine at position thirty-four “stabilizes anticodon structure, confers ribosome binding ability to tRNA and improves reading frame maintenance.” Their reconstitution names every component — MnmA, magnesium-ATP, L-cysteine and IscS — and reports that purified IscS-persulfide supplies the sulfur on its own, without free cysteine present.

So the atom that ends up at position thirty-four is taken off a cysteine by a desulfurase, carried as a persulfide on the enzyme, and handed across. IT IS NOT PICKED UP FROM SOLUTION. It is passed hand to hand from an amino acid to a nucleic acid.

And the same paper supplies a distribution the volume did not manufacture

Kambampati and Lauhon open with a sentence about where sulfur-bearing nucleosides occur: “Thionucleosides are uniquely present in tRNA.” The 2-thiouridines, 4-thiouridine, 2-thiocytidine and the methylthio-modified adenosines appear in transfer RNA and not in messenger RNA, not in ribosomal RNA, and not in DNA.

Of all the places a sulfur atom could sit in a nucleic acid, it sits in the molecule that does the reading. The volume records that as a distribution and takes the count as it stands.

What the sequence file holds for either character

The alphabet permitted inside a sequence string is A, C, G, T and U together with the IUPAC ambiguity codes, every one of which stands for a set of the four canonical bases. Neither inosine nor 2-thiouridine has a character in that set. POSITION THIRTY-FOUR IS WRITTEN U IN EVERY SEQUENCE DATABASE ON EARTH IN BOTH CASES.

Two modifications with no letters between them decide whether a cell can divide and whether a ribosome can hold its frame, and the file that records the molecule spells them the same way.

1710. The Cellular Scale, and the Two Loops ↩

The metabolic loop through inosine closes. The informational loop does not.

At the scale of the whole cell, inosine sits on two circuits at once, and they behave differently. The difference is the finding of this section and it is computable.

The metabolic circuit closes, and the return step is an enzyme

Inosine monophosphate is phosphorylated to the diphosphate and then to the triphosphate. The return is catalyzed: ITPA, inosine triphosphate pyrophosphatase, hydrolyzes ITP to IMP and pyrophosphate. The triphosphate is recognized and sent back to the parent nucleotide.

The forward directions are catalyzed as well, and inosine monophosphate is the origin of both purine arms. ADSS and ADSL carry IMP through adenylosuccinate to AMP. IMPDH carries IMP to XMP, and GMP synthetase carries XMP to GMP. HPRT rebuilds IMP from free hypoxanthine and PRPP.

Every arrow on the metabolic circuit has a named enzyme, and the circuit returns to where it started. IMP is not a waypoint on a one-way road. It is the origin of a closed system.

The informational circuit does not close, and the arithmetic says by how much

On messenger RNA, ADAR converts adenosine to inosine, and the ribosome reads inosine as guanosine. Running that operator across all sixty-four codons of the standard genetic code gives the complete reachable set. The computation is below and it was derived here rather than retrieved.

the quantity	the count
codons containing at least one adenosine	37 of 64
distinct single-edit operations available	48
silent — the amino acid does not change	15
missense — the amino acid changes	31
STOP CODONS DESTROYED	2
STOP CODONS CREATED	0
ordered amino-acid substitutions reachable by one edit	15 of 380
ordered amino-acid substitutions reachable at any edit depth	19 of 380
SUBSTITUTIONS THE OPERATOR CANNOT REACH AT ALL	361 of 380

No enzyme returns inosine to adenosine in RNA. The operator therefore runs in one direction only, and the structure that falls out of it is a drain. Every charged residue in the table — aspartate, glutamate, histidine, lysine and arginine — has an editing

route, and EVERY ONE OF THOSE ROUTES ENDS AT GLYCINE. Nothing leaves glycine, because the only adenosine in a glycine codon sits in GGA and GGA to GGG is silent.

The metabolic loop closes at inosine and the informational loop opens there. THE SAME MOLECULE CLOSES ONE CIRCUIT AND OPENS THE OTHER, and the two facts are true simultaneously at two scales of the same cell.

Where sulfur sits on the same two circuits

Sulfur's cellular position is the mirror of this. Its metabolic circuit is also closed — cysteine is dismantled by a desulfurase, the atom is carried on a persulfide, installed at a ring position, and recovered when the molecule is turned over. Its informational position is the one the sequence file cannot hold, which is the same failure the inosine channel has, arriving from the other direction.

The two atoms therefore share a cellular signature: a closed metabolic accounting and an open informational one. THE CHEMISTRY BALANCES AND THE RECORD DOES NOT.

1711. The Three Scales Stated Together ↩

The table the new project is named for

scale	INOSINE	SULFUR	what the row establishes
ATOMIC	installs an oxygen — the amino nitrogen at carbon six leaves, a carbonyl arrives	displaces an oxygen — the carbonyl at ring position two leaves, a sulfur arrives; and at the two prime position an oxygen leaves and a hydrogen arrives	BOTH ARE SINGLE-ATOM SUBSTITUTIONS AND BOTH ARE ABOUT OXYGEN
MOLECULAR	at anticodon position thirty-four, expands the reading to three codon endings	at anticodon position thirty-four, restricts the reading and holds the frame	THE SAME NUMBERED SEAT, AND THE ALPHABET SPELLS BOTH U
CELLULAR	metabolic loop closes through ITPA; informational operator runs one way, 361 of 380 substitutions unreachable	metabolic loop closes through the desulfurase relay; informational channel absent from the file format	CHEMISTRY BALANCES, RECORD DOES NOT

Read down the inosine column and the molecule gains an oxygen, widens a reading, and closes a metabolic loop it cannot close informationally. Read down the sulfur column and the atom removes an oxygen, narrows a reading, and closes a metabolic loop the file format cannot record. The columns are not analogies. They are the same three operations run by two atoms.

1712. What This Part Claims ↩

what	established how
The atomic operation is common to both	Inosine, 2-thiouridine and deoxyribose are produced by single-atom substitutions in which oxygen is the atom moved. Inosine is the only one of the three in which oxygen arrives. Taken from volume sections 182, 183 and 1608, which state the two halves separately.
Position thirty-four is the crossing point	The same numbered position of the same molecule carries either inosine or a sulfur-bearing uridine, written by different enzymes, with opposite effects on the number of codons one adaptor can read. Both are recorded as U.
The two loops through inosine behave differently	The metabolic circuit returns to IMP by a named enzyme. The informational operator has no return enzyme, destroys two stop codons and creates none, and leaves 361 of 380 ordered amino-acid substitutions unreachable at any depth, with glycine as the absorbing state.
The three scales are one structure	Atomic, molecular and cellular are not three descriptions of different things. They are the same two operations observed at three magnifications, and the operations stay opposite at all three.

1713. What Would Show This Part Is Wrong ↩

— Name an enzyme that converts inosine back to adenosine in a messenger RNA, and the one-way claim in section four fails outright.

— Produce a sense codon that a single adenosine-to-inosine edit converts into a stop codon, and the stop asymmetry in section four fails.

— Show a transfer RNA in which 2-thiouridine at position thirty-four widens rather than narrows the set of codons read, and the opposition claim in section three fails.

— Produce a sequence file format in routine use whose alphabet distinguishes inosine at position thirty-four from 2-thiouridine at position thirty-four, and the record claim in sections three and four fails.

— Show a fourth single-atom substitution on the nucleotide panel in which the moved atom is not oxygen, and the atomic claim in section two narrows to three cases rather than a rule.

1714. The Experiments This Part Generates ↩

experiment	what to do and what it predicts	what it costs
E-1 · ATOMIC	Measure the ring geometry change on substitution. Compare the carbon-sulfur and carbon-oxygen bond lengths at ring position two of uridine and 2-thiouridine in deposited structures, and state the displacement in ångströms. The prediction is that the sulfur substitution moves the pairing face measurably rather than notionally.	deposited structures; no new sample
E-2 · MOLECULAR	Count the codons read by one transfer RNA with inosine at thirty-four and by one with 2-thiouridine at thirty-four, in the same organism, from published ribosome profiling. The prediction is that the two counts differ in the stated directions.	published profiling data; desktop
E-3 · CELLULAR	Test the drain. In published editing atlases, count edited codons by the amino acid they specify before and after editing, and test whether the charged residues are depleted and glycine enriched relative to the unedited background. The prediction is the basin structure computed in section four.	REDIportal; desktop
E-4 · THE RECORD	Take one transfer RNA carrying inosine at thirty-four and one carrying 2-thiouridine at thirty-four, submit both to a standard sequencing pipeline, and record what character each returns at position thirty-four. The prediction is U in both cases.	one sequencing run

Three of the four compute from data that is already public. The fourth is one sequencing run whose expected result is that the instrument cannot tell the two molecules apart.

Dr. John Allen Berger, Independent Theoretical Researcher, NovagonDNA, Naperville, Illinois. Part of Berger Atomic Molecular Cellular Metabolism for Biology, Chemistry and Genetics. Licensed under CC BY-NC-ND 4.0.

Two atoms from the same column of the periodic table, doing the same kind of work in opposite directions, meeting at one numbered seat in the one molecule that has to recognize two things at once — and the file that records that molecule writes the same letter whichever atom is sitting there.

PART ONE HUNDRED AND SIXTY-SEVEN · METABOLIC AND INFORMATIONAL LOOP OF INOSINE

Metabolic and Informational Loop of Inosine

Inosine sits on two circuits in the same cell and they behave differently. The metabolic circuit returns to its origin by a named enzyme. The informational one has no return enzyme at all, destroys two stop codons and creates none, and leaves three hundred and sixty-one of three hundred and eighty amino-acid substitutions unreachable at any depth

Berger Atomic Molecular Cellular · the Cellular Scale
PP-2026-CELL-01 v1 · 20 September 2026

1716. One Molecule on Two Circuits ↩

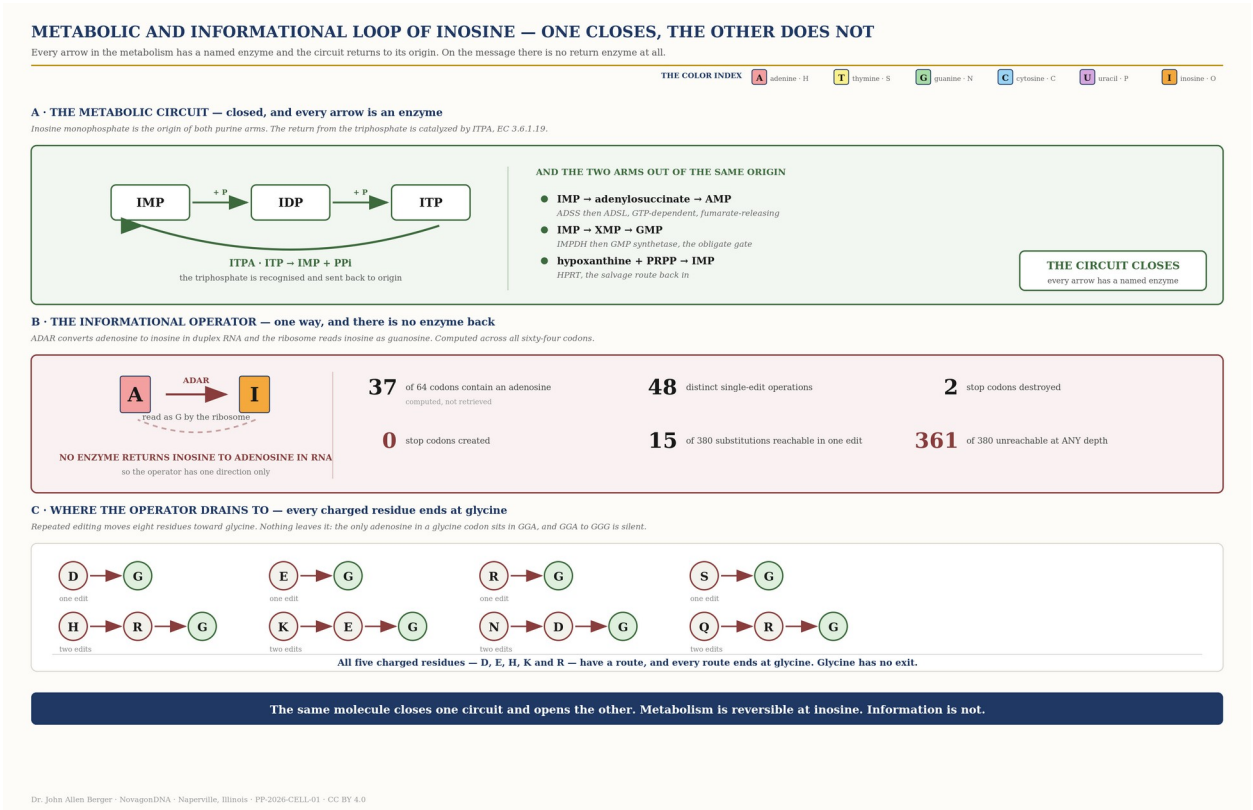
The same nucleoside, two accountings, and only one of them balances

At the scale of the whole cell, inosine appears in two places that are usually discussed separately. It is the first complete nucleotide of purine biosynthesis, sitting at the origin of both purine arms. And it is the product ADAR makes on double-stranded messenger RNA, where the ribosome reads it as guanosine.

Those are the same molecule on two circuits. THIS PAPER ASKS WHETHER EACH CIRCUIT CLOSES, and the answer is different for the two.

The metabolic circuit closes and every arrow on it has a named enzyme. The informational circuit has no return enzyme, and the

arithmetic of what it can and cannot reach is computable from the codon table.



1717. The Metabolic Circuit, Which Closes ↩

Every arrow has a named enzyme and the circuit returns to where it started

Inosine monophosphate is phosphorylated to the diphosphate and then to the triphosphate. The return step is catalyzed: ITPA, inosine triphosphate pyrophosphatase, EC 3.6.1.19, hydrolyzes ITP to IMP and pyrophosphate. THE TRIPHOSPHATE IS RECOGNIZED AND SENT BACK TO THE PARENT NUCLEOTIDE.

the step	the enzyme	what it does
IMP → IDP → ITP	phosphorylation, forward	the triphosphate state is reached in two steps
ITP → IMP + PPi	ITPA, EC 3.6.1.19	THE RETURN. The triphosphate is hydrolyzed back to the parent nucleotide
IMP → adenylosuccinate → AMP	ADSS then ADSL	the adenosine arm; GTP-dependent, releasing fumarate into the citric acid cycle
IMP → XMP → GMP	IMPDH then GMP synthetase	the guanosine arm; IMPDH is the obligate gate and the target of mycophenolate
hypoxanthine + PRPP → IMP	HPRT	the salvage route back in; its loss is Lesch-Nyhan

Inosine monophosphate is not a waypoint on a one-way road. It is the origin of a closed system, and the enzyme that closes it is named, numbered and clinically consequential — ITPA deficiency produces severe toxicity from azathioprine and ribavirin.

1718. The Informational Circuit, Which Does Not ↩

Computed here by applying the adenosine-to-inosine operator to all sixty-four codons

On messenger RNA, ADAR converts adenosine to inosine, and the ribosome reads inosine as guanosine. Applying that substitution at every adenosine in every codon of the standard genetic code gives the complete reachable set. The computation below was derived rather than retrieved, and it can be reproduced in about twenty lines of code.

the quantity	the count
codons containing at least one adenosine	37 of 64
distinct single-edit operations available	48
silent — the amino acid does not change	15
missense — the amino acid changes	31
STOP CODONS DESTROYED	2
STOP CODONS CREATED	0
start codons destroyed / created	1 / 1
ordered amino-acid substitutions reachable in one edit	15 of 380
ordered amino-acid substitutions reachable at any depth	19 of 380
SUBSTITUTIONS THE OPERATOR CANNOT REACH AT ALL	361 of 380

Why no stop codon can be created

The three stop codons are UAA, UAG and UGA. A product codon reached by this operator must carry a G where the source carried an A. UAG and UGA each hold exactly one G, so the only pre-image of either is UAA — which is already a stop. And UAA holds no G at all, so it has no pre-image under this operator.

NOT ONE SENSE CODON IN THE TABLE CAN BECOME A STOP BY THIS OPERATION. The editor can destroy a stop and can never create one, and that asymmetry falls out of the table rather than being imposed on it.

And why the circuit cannot close

No enzyme returns inosine to adenosine in RNA. The operator therefore runs in one direction only, and what falls out of it is a drain.

1719. Where the Operator Drains To ↩

Every charged residue has a route, and every route ends at the same place

Following the operator repeatedly rather than once gives the reachability structure. Eight residues can arrive at glycine, four of them in a single edit and four in two.

the route	depth	what the source residue is
aspartate D → G	one edit	charged, negative
glutamate E → G	one edit	charged, negative
arginine R → G	one edit	charged, positive
serine S → G	one edit	polar
histidine H → R → G	two edits	charged, positive
lysine K → E → G	two edits	charged, positive
asparagine N → D → G	two edits	polar
glutamine Q → R → G	two edits	polar

ALL FIVE CHARGED RESIDUES IN THE TABLE — aspartate, glutamate, histidine, lysine and arginine — have an editing route, and every one of those routes ends at glycine.

Nothing leaves glycine. The glycine codons are GGU, GGC, GGA and GGG; only GGA contains an adenosine, and editing it gives GGG, which is silent. Glycine is an absorbing state.

Editing drains charge toward flexibility, and once a residue arrives at the smallest side chain in the code the operator has nothing left to act on. That is the shape of a one-way circuit stated in residues rather than in arrows.

1720. The Two Loops Compared ↩

Same molecule, same cell, two accountings

the question	THE METABOLIC LOOP	THE INFORMATIONAL LOOP
Does it return to its origin	YES — ITPA hydrolyzes ITP to IMP and pyrophosphate	NO — no enzyme converts inosine back to adenosine in RNA
Is every arrow catalyzed	YES — ADSS, ADSL, IMPDH, GMP synthetase, HPRT, ITPA	The forward arrow is catalyzed by ADAR. There is no reverse arrow to

the question	THE METABOLIC LOOP	THE INFORMATIONAL LOOP
		catalyze
What is conserved	the nucleotide, recovered and reused	nothing — the identity of the edited base is unrecoverable from the record
What the failure mode is	ITPA deficiency: severe azathioprine and ribavirin toxicity	the I/G collision: a made inosine and an inherited guanosine both read as G
What the arithmetic says	a closed accounting	361 of 380 substitutions unreachable; glycine absorbing; no stop creatable

THE SAME MOLECULE CLOSES ONE CIRCUIT AND OPENS THE OTHER, and the two facts are true simultaneously at two scales of the same cell. Metabolism is reversible at inosine. Information is not.

1721. What This Part Claims ↩

what	established how
The metabolic circuit through inosine closes	Every arrow has a named enzyme, and the return from the triphosphate is ITPA, EC 3.6.1.19, hydrolyzing ITP to IMP and pyrophosphate.
The informational operator has no return	No enzyme converts inosine to adenosine in RNA, so the adenosine-to-inosine operator runs in one direction only.
The operator destroys stops and creates none	Two stop codons are destroyed by single edits. No sense codon in the table can become a stop, because the pre-images required are already stops or do not exist.
Most of the substitution matrix is unreachable	Fifteen of 380 ordered amino-acid substitutions are reachable in one edit, nineteen at any depth, and 361 cannot be reached at all.
Editing drains charge toward glycine	All five charged residues have routes and every route terminates at glycine, which is an absorbing state because its only adenosine-bearing codon edits silently.
The two facts are simultaneous	The closure and the non-closure are properties of the same molecule in the same cell, observed on two different circuits.

1722. What Would Show This Part Is Wrong ↩

— Name an enzyme that converts inosine back to adenosine in a messenger RNA, and the one-way claim in sections four and six fails outright.

— Produce a sense codon that a single adenosine-to-inosine edit converts into a stop codon, and the stop asymmetry in section four is wrong.

— Show an editing route that leaves glycine and reaches any other residue, and the absorbing-state claim in section five fails.

— Show that ITPA does not close the triphosphate circuit in vivo — that the hydrolysis is negligible at physiological concentrations — and the metabolic closure in section three narrows to an in vitro result.

— Recount the reachable substitution matrix and obtain a number other than fifteen at one edit or nineteen at any depth, and the arithmetic in section four is wrong.

1723. The Experiments This Part Generates ↩

experiment	what to do and what it predicts	what it costs
E-1 · THE DRAIN	In published editing atlases, count edited codons by the amino acid they specify before and after editing, and test whether charged residues are depleted and glycine enriched relative to the unedited background. The prediction is the basin structure of section five.	REDIportal; desktop
E-2 · THE STOPS	Count edits at stop codons in published atlases and confirm that destruction occurs and creation does not. The prediction is a clean zero on the creation side, and a zero is the easiest prediction to break.	public editing data; desktop
E-3 · THE RETURN ARC	Compare metabolomic profiles of IMP-fork disorders — ADSS, ADSL, IMPDH2 — and test whether the adenosine and guanosine arms dysregulate together or independently. Together supports the single-origin reading; independently does not.	published metabolomics; desktop
E-4 · THE COLLISION	Take one transcript with a known edited site and one with a genomically encoded guanosine at the same position, sequence both by a standard pipeline, and record whether anything in the output distinguishes them. The prediction is that nothing does.	one sequencing run

Three of the four compute from data that is already public. The fourth is one sequencing run whose expected result is that the instrument cannot tell the two molecules apart.

One molecule, two circuits, one cell. The chemistry balances and comes home. The information goes one way, drains every charge to glycine, and leaves three hundred and sixty-one of three hundred and eighty doors it can never open.

PART ONE HUNDRED AND SIXTY-EIGHT · THREE CODONS

The DNA (ATGC) and RNA (AUGC) Genetic Code Spends 3 of its 61 Codons on Sulfur

The genetic code spends three of its sixty-one sense codons on sulfur. Methionine holds the least redundant assignment in the whole table, and that single codon is also the start signal. The adenosine-to-inosine editor can install a cysteine and can never remove one, because neither cysteine codon contains an adenosine at all

What the Code Spends on Sulfur, What the Editor Can Move, and Where the Atom Is Absent

PP-2026-SUL3-01 v1 · 20 September 2026

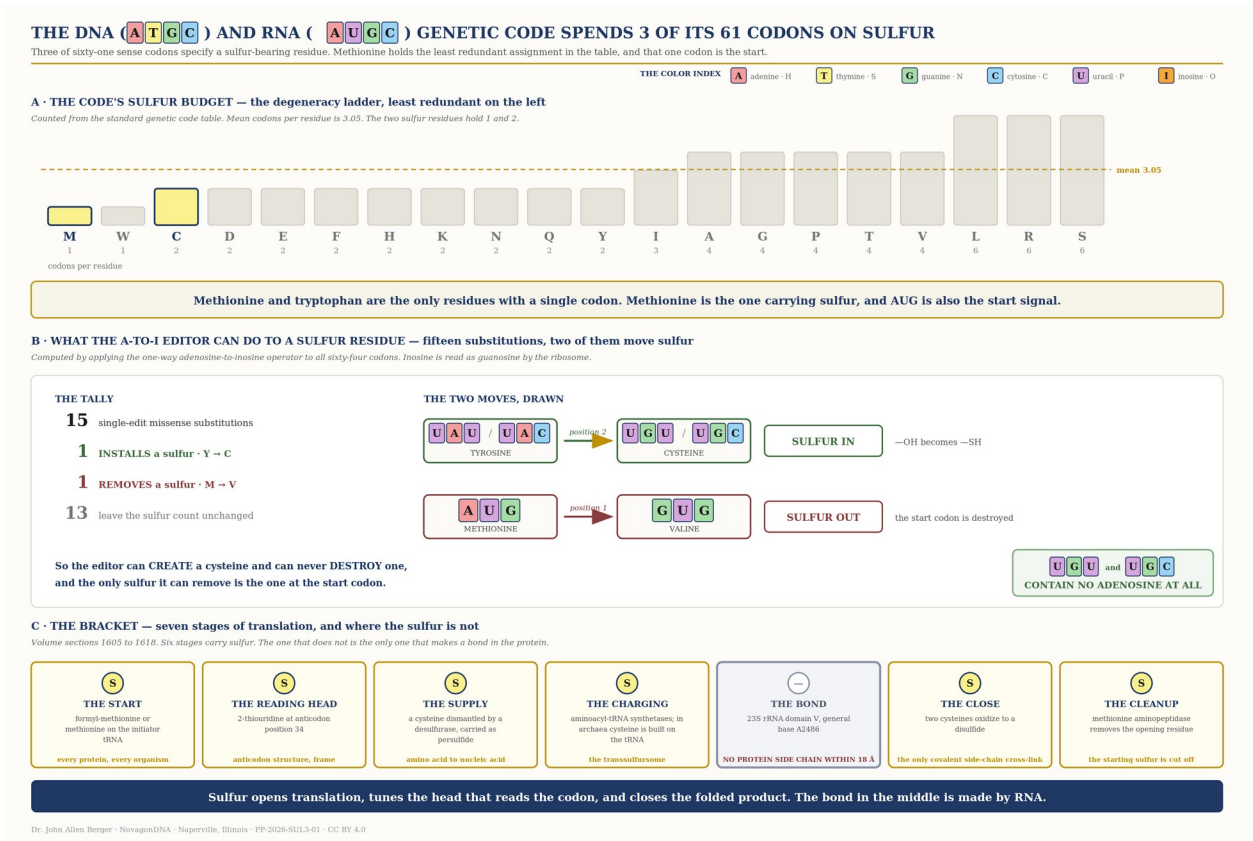
1725. The Question Asked as a Count ↩

How much of the code is spent on sulfur, and what is the code's exposure when it spends it

The evidence volume argues that sulfur runs the chemistry underneath the four letters. That argument is usually made by naming places sulfur appears. This paper makes it by counting, because a count can be checked and a list cannot.

Two of the twenty canonical amino acids carry a sulfur atom: cysteine, which carries a thiol on its side chain, and methionine, which carries a thioether in its backbone chain. Everything below follows from asking how the standard codon table treats those two residues, and from applying the one-way adenosine-to-inosine operator to the result.

The answer is that the code spends 4.9 percent of its sense codons on sulfur, gives one of the two sulfur residues the most exposed assignment in the entire table, and then protects the other one from the editor completely.



1726. The Budget ↩

Three codons of sixty-one, counted from the standard table

the quantity	the count
sense codons in the standard table	61
stop codons	3
mean codons per residue	3.05
CODONS SPECIFYING A SULFUR-BEARING RESIDUE	3 — AUG, UGU, UGC
share of the sense table spent on sulfur	4.9 percent
cysteine	2 codons — UGU, UGC
METHIONINE	1 codon — AUG

The least redundant assignment in the table belongs to a sulfur residue

Degeneracy across the twenty residues runs from one codon to six. Leucine, arginine and serine hold six each. Alanine, glycine, proline, threonine and valine hold four. Isoleucine holds three. Nine residues hold two.

EXACTLY TWO RESIDUES HOLD ONE CODON: methionine and tryptophan. Methionine is the one carrying sulfur.

A residue with six codons can absorb a single-base change and often keep its identity. A residue with one codon cannot absorb anything. The code gave its minimum redundancy to one of its two sulfur residues.

And that one codon carries a second job

AUG is the start codon. Translation initiates there in every organism in all three domains, with formyl-methionine on a dedicated initiator transfer RNA in bacteria and mitochondria and with methionine on tRNA-i in the eukaryotic cytosol. The first residue of every growing chain on Earth is a methionine, and methionine carries a sulfur atom.

So the single least-protected assignment in the codon table is doing two things at once: specifying the residue AND marking where reading begins. A change at AUG costs the amino acid and the start signal together.

There is no protein on Earth that does not begin with a sulfur atom, and the code holds that fact in its most exposed cell.

1727. What the Editor Can Move ↩

The one-way adenosine-to-inosine operator applied to the sulfur residues

ADAR converts adenosine to inosine in duplex RNA, and the ribosome reads inosine as guanosine. Applying that substitution at every adenosine in every codon of the standard table gives 48 distinct operations and 15 ordered amino-acid substitutions reachable in a single edit. The computation is the same one used in PP-2026-TEX-01 and is reproduced here for the sulfur subset.

the quantity	the count
single-edit missense substitutions available to the operator	15
substitutions that INSTALL a sulfur atom	1 — tyrosine to cysteine
substitutions that REMOVE a sulfur atom	1 — methionine to valine
substitutions that leave the sulfur count unchanged	13

The move that installs a sulfur, and what it exchanges

Tyrosine is UAU and UAC. Editing the adenosine at the second position gives UGU and UGC, which are the two cysteine codons. The substitution runs in one direction and the editor performs it without any other machinery.

Tyrosine and cysteine are the two residues in the canonical twenty whose side chains terminate in a proton-donating atom from group sixteen. Tyrosine ends in a

hydroxyl. Cysteine ends in a thiol. THE EDIT EXCHANGES AN OXYGEN FOR A SULFUR AT THE TIP OF THE SIDE CHAIN, which is the conjugate pair of the volume's second Part carried out at the level of the protein, by the inosine editor, on a codon.

The companion paper shows the same exchange one scale down, where a carbonyl oxygen at ring position two of uridine is replaced by a sulfur. Here the exchange happens in the product rather than the adaptor, and the agent is the editor rather than a desulfurase.

The move that removes a sulfur, and where it is permitted

AUG contains exactly one adenosine, at the first position. Editing it gives GUG, which is valine. That is the only route by which the operator can take a sulfur atom out of a protein, and it acts on the start codon.

The reverse direction also exists and reaches the same codon from the other side. AUA is isoleucine, and editing its third position gives AUG. So the operator can CREATE a start codon and install a methionine, from an isoleucine.

And the residue the editor cannot touch

The cysteine codons are UGU and UGC. NEITHER CONTAINS AN ADENOSINE. The operator acts only on adenosine, so it has no site to act on in either codon.

the operation	what the codon table permits
Can the editor CREATE a cysteine	YES — from tyrosine, at codon position two, by a single edit
Can the editor DESTROY a cysteine	NO — UGU and UGC contain no adenosine, so the operator has no substrate in them
Can the editor CREATE a methionine	YES — from isoleucine, AUA to AUG, which also creates a start codon
Can the editor DESTROY a methionine	YES — AUG to GUG, which also destroys the start codon

The editor can put a thiol into a protein and cannot take one out. The only sulfur it can remove is the one sitting at the start, and removing it costs the start signal in the same stroke.

1728. The Bracket ↩

Seven stages of translation, six of which carry sulfur

Protein synthesis is one continuous chain of custody. A messenger RNA carries a codon, an aminoacyl-tRNA synthetase charges a transfer RNA with the matching amino acid, the ribosome joins the amino acids in order, and a protein comes out. Sulfur's position in that chain is specific, and it is specific in a way that includes an absence.

stage	what happens there	what it establishes	sulfur
THE START	formyl-methionine or methionine on the initiator transfer RNA	every protein, in every organism, without exception	SULFUR
THE READING HEAD	2-thiouridine at anticodon position 34, or inosine at the same position	anticodon structure, ribosome binding, reading frame	SULFUR
THE SUPPLY	a cysteine taken apart by the desulfurase IscS and carried as a persulfide to MnmA	the atom is handed from an amino acid to a nucleic acid	SULFUR
THE CHARGING	aminoacyl-tRNA synthetases; in many archaea cysteine has no synthetase and is built on the transfer RNA itself	the transsulfursome channels the tRNA between two distant active sites	SULFUR
THE BOND	23S ribosomal RNA, domain V, with the base of A2486 acting as general base	NO PROTEIN SIDE-CHAIN ATOM WITHIN ABOUT 18 ÅNGSTRÖMS	NO SULFUR
THE CLOSE	two cysteines oxidize to a disulfide	the only covalent cross-link between side chains in the canonical twenty	SULFUR
THE CLEANUP	methionine aminopeptidase removes the opening residue from a large fraction of proteins	the sulfur that opened the chain is cut off the finished product	SULFUR

The measurement that fixes the shape of the claim

Nissen, Hansen, Ban, Moore and Steitz solved the large ribosomal subunit of Haloarcula marismortui with two substrate analogues bound and reported what surrounds the reaction. Both analogues are contacted exclusively by conserved ribosomal RNA residues from domain V of the 23S, and there are no protein side-chain atoms closer than about eighteen ångströms to the peptide bond being synthesized.

Eighteen ångströms is roughly six carbon-carbon bonds end to end, and it is a floor rather than an average. No protein side chain reaches inside it, and therefore no cysteine, no methionine, and no sulfur atom of any kind.

SIX STAGES CARRY SULFUR AND ONE DOES NOT, AND THE ONE THAT DOES NOT IS THE ONLY ONE THAT MAKES A CHEMICAL BOND IN THE PROTEIN. Sulfur opens translation, tunes the head that reads the codon, supplies the adaptor, charges it, closes the folded product, and is trimmed off the front. The bond in the middle is made by RNA.

That shape is what makes the sulfur argument checkable. A framework that can name the place its favorite atom is absent has established where it is present.

1729. The Three Counts, Read Together ↩

Budget, exposure and reach

the count	the number	what it means
THE BUDGET	3 of 61 sense codons, 4.9 percent	The code spends less on sulfur than on any other functional class its size, and it spends it on two residues that do jobs no other residue can do — the start, and the only covalent side-chain cross-link.
THE EXPOSURE	methionine holds 1 codon; the table's mean is 3.05	The residue that opens every protein has no redundancy at all, and its one codon carries the start signal as a second job.
THE REACH	the editor installs sulfur by 1 route and removes it by 1	Cysteine is unreachable in the destructive direction because neither of its codons contains an adenosine. The only removable sulfur is the one at the start.

Scarce, exposed where it is spent, and protected where it does the covalent work. Those three properties were not designed together by anyone, and they are all readable off one table.

1730. What This Part Claims ↩

what	established how
The sulfur budget of the	Counted from the standard genetic code table: AUG for

what	established how
code is three codons	methionine, UGU and UGC for cysteine. Three of 61 sense codons, 4.9 percent, against a mean of 3.05 codons per residue.
Methionine holds the table's minimum redundancy, and that codon is the start	Methionine and tryptophan are the only single-codon residues. Methionine is the sulfur-bearing one, and AUG initiates translation in all three domains.
The editor can install a cysteine and cannot remove one	UGU and UGC contain no adenosine, so the adenosine-to-inosine operator has no substrate in either. Tyrosine reaches cysteine in one edit at codon position two.
The one sulfur the editor can remove sits at the start codon	AUG contains one adenosine. Editing it gives GUG, valine, destroying the residue and the start signal together. The reverse route from AUA creates both.
Tyrosine to cysteine is an oxygen-for-sulfur exchange at the protein level	The two residues are the code's group-sixteen pair: tyrosine terminates in a hydroxyl, cysteine in a thiol. The inosine editor performs the exchange on a codon.
Sulfur brackets translation and is absent from its center	Six of seven stages carry sulfur. The peptidyl transferase center admits no protein side-chain atom within about 18 ångströms, so it admits no sulfur, and it is the only stage that forms a bond in the protein.

1731. What Would Show This Part Is Wrong ↩

— Show a third sulfur-bearing residue among the canonical twenty with its own codon assignment, and the budget count in section three rises from three.

— Produce an adenosine in either UGU or UGC, and the protection claim in section four fails outright.

— Name a second single-edit route by which the adenosine-to-inosine operator removes a sulfur atom from a protein, and the reach count in section four is wrong.

— Show a protein in any organism whose translation initiates at a codon specifying a residue without sulfur, and the start claim in section three narrows.

— Place a protein side-chain atom inside eighteen ångströms of the peptide bond in a ribosome structure, and the bracket in section five loses its center.

— Show that the degeneracy assignments used here differ from the standard table in any organism that also uses AUG as its start, and the exposure claim in section three is organism-specific rather than general.

1732. The Experiments This Part Generates ↩

experiment	what to do and what it predicts	what it costs
E-1 · THE TYROSINE ROUTE	Search published editing atlases for edits at codon position two of a tyrosine codon that produce a cysteine, and count them. The prediction is that the route is used, and that edited cysteines appear in proteins whose folding depends on disulfide bonds more often than chance allows.	REDIportal and matched proteomes; desktop
E-2 · THE PROTECTED RESIDUE	Count cysteine codons across an edited transcriptome and confirm that none carries an editing site, since neither codon contains an adenosine. The prediction is a clean zero, and any hit is a pipeline artifact worth tracing.	public editing data; desktop
E-3 · THE START CODON	Count edits at AUG start codons in published atlases and record how many destroy an initiation site. The prediction is that such edits are rare relative to their availability, because losing the start is costly.	public editing data; desktop
E-4 · THE BRACKET	Take the seven stages of section five and, for each, ask whether removing the sulfur stops the stage. Six are answerable from published genetics. The seventh is already answered by the eighteen-ångström measurement.	literature; no new sample

All four compute from data that is already public. The sharpest is the second, because its predicted result is zero and a zero is the easiest prediction to break.

Three codons out of sixty-one, and one of them is the place every protein on Earth begins. The editor that rewrites the message can put a thiol in and cannot take one out, and the single sulfur it is able to remove is the one holding the start.

PART ONE HUNDRED AND SIXTY-NINE · THE FLAT MAP

The Flat Map

Metabolic charts are topological diagrams. They carry connectivity and they drop geometry, and the drop is not small. The two gates this corpus names — xanthine and orotate — are indistinguishable on the chart and could not be more different in three dimensions. One is a molybdenum atom held by three sulfur atoms, and removing one of them closes the gate completely. The other runs with no metal and no cofactor at all, at a rate enhancement near ten to the seventeenth

The Third Statement of One Finding · Companion to Order Is Geometry
PP-2026-FLAT-01 v1 · 20 September 2026

1734. Fisk's Maps, and What a Flat Map Costs ↩

The case where someone went back and drew what the surveyors could not see

In 1944 Harold Fisk, a geologist working for the Army Corps of Engineers, produced fifteen maps of the lower Mississippi as part of a Geological Investigation of the Alluvial Valley. They run from Cape Girardeau in Missouri to Donaldsonville in Louisiana, and what they show is not the river. They show every channel the river has occupied.

The 1944 course is drawn as a blank. Around it, in color, run the earlier courses: the channel of 1765 in light blue, taken from Lieutenant Ross's charting; 1820 in salmon; 1880 in green; and behind those, a writhing palimpsest of prehistoric meanders reaching back further than any survey.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

FISK COLOR-CODED TIME. Each color is a different era's channel, and the map is legible only because the colors separate what a single outline would have collapsed into one line.

What makes the maps a landmark is not their beauty. It is that they made visible a quantity the earlier surveys had structurally omitted. A surveyor standing on a bank measures where the water is. He cannot measure where it was, and a map drawn from his measurements is not wrong — it is incomplete in a way the map itself cannot declare. The straight river on an early chart is not an error of observation. It is what the method could hold.

1735. The Metabolic Chart Is a Flat Map ↩

A metabolic chart is a graph. Nodes are metabolites, edges are conversions, and the arrangement on the page is chosen for legibility. It shows WHAT CONNECTS TO WHAT and it was never built to show anything else.

the chart	what it holds
WHAT IT CARRIES	Identity of each metabolite. Direction of each conversion. Which enzyme is named on the arrow. The topology of the network.
WHAT IT DROPS	The shape of the binding pocket. The trajectory by which substrate approaches. The identity of the cofactor and its geometry. The transition state. The metal, if there is one. The protons. Every angstrom of the thing that actually decides whether the arrow can be traversed.

A node on a chart and an active site in a cell are not the same kind of object, and the chart cannot say so. The arrow is drawn the same width whether the conversion runs in microseconds or requires a metal the cell must acquire from soil.

This corpus has used color-coded metabolic maps to mark two positions as GATES — xanthine at the valve of the purine pathway and orotate at the origin node of the pyrimidines. On the chart, marking a gate means drawing attention to a node. The claim of this paper is that the two gates so marked are, in three dimensions, about as different as two enzymatic steps can be, and that the difference is the whole content of what a gate is.

1736. The Two Gates, in Three Dimensions ↩

Identical on the chart. Opposite in the cell.

The xanthine gate is a molybdenum atom held by sulfur

Xanthine oxidoreductase carries a mononuclear molybdenum center. The metal is coordinated by a pyranopterin dithiolene — which contributes TWO SULFUR ATOMS — together with a terminal oxo group and, critically, a TERMINAL SULFIDO LIGAND. The active form is written as the Mo(VI) oxo-sulfido species.

That sulfido ligand is not decorative. The enzyme hydrolyzes readily to the corresponding dioxo species, and THE DESULFO FORM IS INACTIVE. Substrate does not pass. The inactive form can be converted back by incubation with dithionite and sulfide, a reaction that substitutes the equatorial oxo group for a sulfido ligand and restores catalysis.

THE GATE AT XANTHINE IS A METAL ATOM HELD IN A SULFUR CAGE, AND ONE PARTICULAR SULFUR ATOM DECIDES WHETHER IT IS OPEN OR SHUT. Remove that atom and the node on the chart is unchanged. The arrow is still drawn. Nothing passes.

The orotate gate has no metal and no cofactor at all

Orotidine monophosphate decarboxylase removes the carboxyl group from orotidine monophosphate to give uridine monophosphate. It does so at a rate enhancement of roughly ten to the seventeenth over the uncatalyzed reaction, which places it among the most proficient enzymes known.

It requires NO metal ion and NO cofactor. The rate enhancement comes from the architecture of the site itself — from electrostatic strain applied to the ground state and stabilization of what follows. There is no atom to remove that would close this gate the way removing the sulfido ligand closes the other. Its mechanism was argued over for decades precisely because connectivity tells you nothing about it.

Set side by side

property	XANTHINE GATE	OROTATE GATE
What the chart shows	a node with arrows	a node with arrows
Metal	molybdenum, penta-coordinated	none
Cofactor	pyranopterin dithiolene	none

property	XANTHINE GATE	OROTATE GATE
Sulfur in the active site	THREE — two dithiolene, one terminal sulfido	none required
What closes the gate	loss of one sulfur atom; desulfo form inactive	no single atom; the architecture is the catalyst
Rate enhancement	substantial, metal-dependent	approximately ten to the seventeenth
Reversible by	dithionite and sulfide, restoring the sulfido ligand	not applicable

TWO GATES, DRAWN THE SAME WAY, RUNNING ON OPPOSITE PRINCIPLES. One is a metal held by sulfur and defeated by the loss of a single atom. The other is a shape, with nothing in it to remove. Nothing on any metabolic chart in the world distinguishes them, and the distinction is what a gate IS.

And the finding inside the finding: the purine gate requires sulfur. Not as a substrate, not as a product, not anywhere the notation would record it — as a ligand on a metal in an active site. THE SULFUR IS IN THE GATE, AND THE CHART HAS NO PLACE TO PUT IT.

1737. The Periodic Table Is Also a Flat Map ↩

The same argument, applied to the table everyone learns first

Electron configuration is set by four quantum numbers. The familiar periodic table is a two-dimensional rendering of that structure, laid out for a textbook page, and like Fisk's predecessors it is not wrong — it is a projection, and the projection discards.

the rendering	what it shows
THE STANDARD TABLE	Organized by period and group, with the f-block conventionally detached and printed below. Helium sits above neon because of chemical behavior rather than filling order.
JANET'S LEFT-STEP, 1928	Organized by n plus l. The f-block sits where the filling order actually puts it, helium sits above beryllium, and the structure becomes regular — at the cost of contradicting the chemical intuition the standard table was built to serve.
SPIRAL AND THREE-DIMENSIONAL FORMS	Numerous, periodically rediscovered, and consistently relegated to curiosities — not because they are wrong but because the flat version is what fits on a wall.

The table you learned is not the structure. It is a convenient drawing of it, made flat for a page, exactly like a surveyor's straight

Mississippi. THAT IS NOT SPECULATION AND IT IS NOT NEW — it is established, underused, and nobody has asked what the metabolic charts look like under the same treatment.

1738. What the Instruments Can and Cannot See ↩

Stated precisely, because the strong version of this claim is the accurate one

method	what it delivers
NEUTRON CRYSTALLOGRAPHY	Locates hydrogen atoms directly, because neutrons scatter from nuclei rather than from electron density. It is used specifically for proton-position questions in enzyme active sites. IT CAN SEE WHERE THE PROTON IS.
CRYO-ELECTRON MICROSCOPY	Reaches near-atomic resolution on large working complexes that will not crystallize. It can show the architecture of a gate in something close to its working form.
QM/MM COMPUTATION	Treats the active site quantum-mechanically inside a classical protein environment and computes tunneling contributions. It can estimate what a proton does.
WHAT IS MISSING	No instrument watches a proton cross a gate, in a living cell, in real time. Every method above gives a still, an average, or a calculation. THE EVENT ITSELF IS NOT OBSERVED.

The honest form of the claim is therefore not that we have no instruments. It is that the instruments we have deliver structure, and the quantity in question is a process. That version cannot be dismissed in a sentence, and it identifies what would have to be built.

1739. What a Three-Dimensional Metabolic Map Would Carry

The research program, stated as a specification

A map is defined by what it refuses to drop. Fisk's refusal was time. The specification below states what a metabolic map would have to hold before it could be said to show a gate.

no.	what it carries	specification
1	THE SITE, NOT THE NODE	Each conversion carries the geometry of the site that performs it — pocket volume, the residues that contact substrate, the approach vector.
2	THE COFACTOR AND ITS LIGANDS	Named, with its coordination. A molybdenum center and a cofactor-free site are not the same object and must not render identically.

no.	what it carries	specification
3	THE ATOMS THAT GATE	Any atom whose removal abolishes the conversion is marked. For xanthine oxidoreductase that is the terminal sulfido ligand.
4	THE TRANSITION STATE	What the enzyme stabilizes, not merely what it converts.
5	THE PROTONS	Which residue holds them, which moves, and whether the step is tunneling-sensitive.
6	THE CONDITIONS	pH and redox state at which the drawn conversion actually runs, since both gates above are drawn without either.

Note that item three alone would repaint the purine pathway. A chart that marked every gating atom would show sulfur at the xanthine valve, where no current chart shows sulfur at all, because sulfur is neither substrate nor product of that step — it is the thing holding the metal that performs it.

1740. The Same Finding, for the Third Time ↩

Three notations, three different quantities dropped, one pattern

the notation	what it holds, and what it loses
THE SEQUENCE	Carries base identity and position. DROPS CHEMICAL STATE — the methyl, the inosine, the thio, the modification that decides whether an editor binds.
THE COORDINATE FILE	Carries the result of a composition. DROPS THE COMPOSITION — two orders of rotation reaching the same coordinates are indistinguishable, and the orders differ by a mean of 2.497 angstroms.
THE METABOLIC CHART	Carries connectivity. DROPS GEOMETRY — the pocket, the cofactor, the metal, the gating atom, the transition state.

THREE NOTATIONS, INDEPENDENTLY DEVISED, EACH OPTIMAL FOR ITS PURPOSE, AND EACH SILENT ABOUT THE QUANTITY THAT DECIDES THE OUTCOME. The pattern is not that the field is careless. It is that a notation records what its method could hold, and then the notation becomes the thing everyone reasons from.

That is the position of the surveyor on the bank. He is not mistaken about where the water is. He simply has no way to draw where it was, and nothing in his map announces the omission.

1741. Null Hypotheses ↩

no.	the null	status
F-1	H0: The xanthine and orotate gates are not materially different in three dimensions.	REJECTED on published structural and kinetic grounds. One carries a molybdenum center with three active-site sulfurs and is abolished by loss of the terminal sulfido ligand; the other requires neither metal nor cofactor.
F-2	H0: A metabolic chart carries the information needed to predict whether a marked conversion will run under stated conditions.	Test by attempting the prediction from the chart alone for both gates above. The chart does not distinguish a metal-dependent step from a cofactor-free one, so it cannot.
F-3	H0: No gating atom exists whose removal abolishes a charted conversion without changing substrate or product.	REJECTED. The terminal sulfido ligand of xanthine oxidoreductase is exactly such an atom.
F-4	H0: A three-dimensional rendering of a metabolic pathway reveals nothing a two-dimensional chart does not.	Open, and the principal test this paper proposes. Build one pathway to the section 6 specification and ask what becomes visible.
F-5	H0: The flat rendering of the periodic table discards nothing of consequence.	Contested rather than open. The Janet left-step arrangement is regular where the standard table is not, at the cost of chemical intuition, and the disagreement is itself the evidence of a projection.

F-4 is the one worth spending money on, and it is cheap by the standards of the field: one pathway, existing structures, existing software, and a rendering discipline that refuses to drop what section 6 lists.

1742. What This Part Does Not Claim ↩

— It does not claim metabolic charts are wrong. They are correct about topology and topology is what they were built for.

— It does not claim the field is unaware that enzymes have structures. Structural biology is a mature discipline. The claim is that the chart everyone reasons from does not carry what that discipline knows.

— It does not claim we have no instruments. Neutron crystallography, cryo-electron microscopy and QM/MM each deliver part of the answer. What is missing is observation of the event in a living cell.

— It does not claim the standard periodic table should be replaced. It claims the standard table is a projection, which is established, and that projections discard.

— It does not claim sulfur is the only gating atom. It claims the terminal sulfido ligand is one, that it gates the purine valve, and that no chart shows it.

1743. Where the Sources for This Part Sit ↩

source	what it establishes here	where
Fisk HN	Geological Investigation of the Alluvial Valley of the Lower Mississippi River. Fifteen maps, Cape Girardeau to Donaldsonville, with historical channels color-coded by era — 1765 from Lieutenant Ross's charting, 1820, 1880, and prehistoric meanders behind them. THE ELEMENT WITH NO LETTER

Nine courses from the sulfur corpus — an overview for the scientifically hungry

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

A sample and a proposal. Every morsel below is checkable, every one has a citation waiting behind it, and every one is a doorway into the 305-page evidence volume from which it was cut.

FOR THE ACQUISITIONS EDITOR

What this document is, in one paragraph

This is a nine-course sample of a completed 305-page work of narrative science, offered to gauge interest before a full proposal is prepared. The courses below are not a summary. They are actual passages and actual results, chosen to show the range of the material and the standard of evidence it is held to. **Nothing here requires the reader to accept the book's thesis before he can verify the page in front of him.**

The proposition

	THE ELEMENT WITH NO LETTER
Subject	Sulfur and the argument that the four-letter genetic alphabet is a notation that omits the atom doing the work
Status	**Complete. 305 pages, forty-one Parts, twenty-four figures, issued in three books**
Provenance	Twenty-nine years on a single question, with a dated physical record of the work from 2003 forward
What is unusual	**Every Part ends with the conditions under which it would be wrong, and the failures — the trial that missed its endpoint, the finding not reproduced, the mechanism later revised — are printed rather than omitted**

Why a general reader will follow it

Because the argument is a detective story with a single suspect and forty independent witnesses. Sulfur is not a famous element. It has no biography on the shelf beside salt, water, carbon and the periodic table. **And it turns out to be the atom that dates the largest environmental catastrophe in the history of the planet, keeps an infant's liver working, decides which drugs can be aimed at a tumor and — in a paper from this year — turns a liquid crystal into a ferroelectric one when it replaces an oxygen.**

The reader is never asked to take anything on faith. He is handed a formula, a measurement, a named enzyme or a dated publication, and invited to check.

Where it would sit on a shelf

Beside the single-subject science narratives that have found large readerships: **Nick Lane on mitochondria and on the Krebs cycle; Philip Ball on water and on the elements; Matthew Cobb on the history of the genetic code; Siddhartha Mukherjee on the gene.** It belongs with those books in ambition and in method, and it differs from all of them in one respect: **it is organized around an element rather than around a molecule, an organelle or a discipline, and no one has written that book about sulfur**

The three books, which are also the answer to a reviewer's first question

	what is in it	what the reader must accept first
BOOK ONE · THE RECORD	measurement, mechanism, citation, protocol	**nothing. A hostile reader can verify every page**
BOOK TWO · THE ARGUMENT	the thesis, the geometry, the conjectures	the argument, which these pages ask him to consider
BOOK THREE · THE PROVENANCE	the wall, the plates, the standing of the work	nothing, and they evidence nothing

A reader who rejects every page of Book Two keeps every page of Book One. That separation is offered as a strength of the argument rather than a hedge against it.

BEFORE THE FIRST COURSE

One sentence, and if it does not interest you, nothing below will

The genetic code is written in four letters. Not one of them contains a sulfur atom. And almost nothing in the cell that reads, writes, repairs, edits, folds, marks or powers those letters can function without one.

That is the whole thesis, and it is stranger than it sounds. **A, G, C and T name bases.** They do not name oxidation state, they do not name bond order, and they do not name which of six rungs an atom is standing on. **A sequence written in that alphabet is silent about the variable that decides function** — and the silence is systematic.

Here is the shape of what follows. Sulfur ran the energy economy of life before phosphorus existed as a currency. Phosphorus took the archive; sulfur kept the machinery. That division is visible in the atomic composition of every monomer in biology, it is enforced by two opposite chemistries, it survived the catastrophe that dated itself in sulfur isotopes, and it is still running the most interesting drug programs and the newest ferroelectric materials in 2026.

Nine courses. Each one is a real result. None of them requires you to accept the thesis before you can check it.

COURSE ONE — THE OLDER FIRE

Sulfur chemistry is older than the Sun, and we know because we can see it

Before there was an Earth there were sulfur molecules, and they have been identified by name. Carbonyl sulphide. Carbon monosulphide. Hydrogen sulphide. Silicon sulphide. Nitrogen sulphide. Dicarbon sulphide. Methanethiol.

Every one of them was detected across interstellar distances by its spectral lines, because each element emits at wavelengths fixed by its own electronic structure. **Sulfur is legible at any distance, and it was legible before the solar system condensed.**

The thioester world, and why the first energy currency had no phosphorus

Christian de Duve's proposal is that acyl transfer through **thioesters** preceded phosphate as the currency of biological energy — that the high-energy bond life first learned to make and spend was a **carbon-sulfur bond**, and that acetyl coenzyme A is the surviving witness, running the center of metabolism in every organism alive.

the thioester	why it works
R-CO-S-R'	the C-S bond is weak, polarizable, and the leaving group is excellent
the consequence	acyl transfer proceeds without an enzyme far more readily than an ester would
the survival	acetyl-CoA, the hub of the citric acid cycle, is a thioester and always has been

And the catastrophe dated itself in sulfur

The Great Oxidation Event is dated by mass-independent fractionation of sulfur isotopes.

Before atmospheric oxygen, ultraviolet light reached the lower atmosphere and photolysed sulfur dioxide, producing isotope ratios that **do not scale with mass** — a signature that cannot be made any other way. **When oxygen and its ozone shield arrived, the signature stops.**

> **The moment the planet changed its atmosphere is recorded in the sulfur and only in the sulfur Element sixteen wrote the timestamp on the largest environmental catastrophe in the history of life.**

COURSE TWO — THE HANDOFF

Why the archive is made of phosphorus and the machinery is made of sulfur

This is not a preference. **It is two opposite chemistries doing the two jobs each is suited to, and the reason has been in print since 1987.**

	thiol / thiolate	phosphate diester
pKa	**about 8.5 — substantially ionized at physiological pH**	permanently anionic
role	**nucleophile. It attacks**	**electrophile. It is attacked, slowly**
evidence	cysteine attacks with almost no activation; serine, with an alcohol pKa near 16, needs an entire charge-relay triad to do the same job	**the resident negative charge repels the incoming nucleophile**
so it becomes	**the catalyst**	**the archive**

Frank Westheimer asked in *Science* why nature chose phosphates and gave the answer that still stands. The phosphate diester is negatively charged at physiological pH, and that one fact does two indispensable things: **it keeps the polymer inside the membrane**, because a charged species cannot diffuse out, and **it protects the backbone from hydrolysis**, because the charge repels attacking water.

A thioester backbone would have neither property. It would leak and it would be eaten. A thioester is a high-energy bond — which is exactly why it can never be an archive.

The color count, which says the same thing without any theory at all

Take every monomer in biology and count the distinct chemical elements in it.

monomer	elements	count
ribose	C H O	3
fifteen of the twenty amino acids	C H N O	4
cysteine, methionine	**C H N O S**	**5**
every nucleotide — AMP, GMP, CMP, UMP, IMP, TMP	**C H N O P**	**5**

> **No nucleotide contains sulfur No amino acid contains phosphorus. In the monomers, the two elements are mutually exclusive — in every organism, at every point in the history of life.**

Now ask which molecules contain all six of C, H, N, O, P and S. The list is short, and it is not random.

all six	what it is
Coenzyme A	the thioester; acyl carrier
Phosphopantetheine	the swinging arm of acyl carrier protein
Thiamine pyrophosphate	transketolase; pyruvate dehydrogenase
APS and PAPS	the activated sulphate donors
Molybdopterin	the cofactor of xanthine oxidase and sulfite oxidase

Every entry is a carrier. Not one is a building block.

> **The letters are five colors The machinery is six. Sulfur and phosphorus share a molecule only in the things that carry chemical groups between other things.**

COURSE THREE — THE ENZYME THAT INVENTED

One reaction, four sulfur s, and a monopoly with no competitor

There is exactly one enzyme family on Earth that makes deoxyribonucleotides from ribonucleotides. Every DNA molecule in every organism that has ever lived came through it.

Ribonucleotide reductase removes the 2'-hydroxyl from a ribose ring — it takes an oxygen off a sugar — **and it does so by radical chemistry conducted through cysteine thiyl radicals, with the reducing equivalents delivered by thioredoxin, whose active site is a pair of cysteines that cycles between SH/SH and S-S.**

Count the sulfur s in one turnover and you get four.

> **The chemical distinction between RNA and DNA — the single atom that separates the transient molecule from the archival one — is removed by sulfur and by nothing else.**

And both gates of nucleotide synthesis are iron-sulfur enzymes

The purine branch and the pyrimidine branch each have one committed step, and the corpus found both of them labeled the same way on four independent 1982 metabolic charts.

branch	committed enzyme	what the chart prints
pyrimidine	dihydroorotate dehydrogenase	FAD · ISP · Fe — and the chart's own legend defines ISP as iron sulfur protein
purine	PPAT / PurF, glutamine PRPP amidotransferase	[4Fe-4S], documented in B. subtilis

Neither product contains a sulfur atom. Both manufacturing gates are run by iron-sulfur enzymes.

The pyrimidine gate is also a drug target right now. DHODH sits in the inner mitochondrial membrane and passes its electrons to ubiquinone — **the only enzyme of nucleotide biosynthesis wired directly into the respiratory chain** — and it is inhibited by teriflunomide and leflunomide in multiple sclerosis and rheumatoid arthritis, by brequinar historically, and by **BAY 2402234 and JNJ-74856665 in current oncology and haematology trials.**

COURSE FOUR — THE MISSING LETTERS

Two real bases, two real nucleotides, and neither one appears in the table

Every textbook table of the genetic code has four letters. Metabolism runs on more than four, and two of the extras are obligate.

Inosine monophosphate is the first complete purine nucleotide ever made. Adenine and guanine are both manufactured from it. **IMP is not an alternative to A and G — it is their common ancestor, in every cell, every time.**

Orotate is the same node on the other branch. Every pyrimidine in your body — every C, every U, every T — came through orotate, and there is no bypass. **Loss of the enzyme that consumes it causes hereditary orotic aciduria.**

> **The table names the products and omits the origins. That is not a small editorial choice.**

And inosine is not merely a precursor — it is read

At anticodon position 34, inosine reads three different codons. It is made there by deamination of adenosine, and the wobble it permits is the reason forty-odd transfer RNAs can service sixty-one sense codons.

In messenger RNA the same chemistry is a switch. ADAR2 edits a single adenosine in the GluA2 transcript, converting a CAG glutamine codon to CIG — **which the ribosome reads as CGG, arginine.** The editing runs at about ninety-nine per cent efficiency, and when it fails the AMPA receptor becomes permeable to calcium and the neuron dies of excitotoxicity.

The most striking genetic result in the field: mice lacking ADAR2 die young — and are rescued to normal by a single point mutation that hard-codes the arginine into the gene.

> **One enzyme's entire essential function, in a whole animal, is the chemical conversion of one letter into another letter that the alphabet does not have.**

COURSE FIVE — THE ATOM THAT KEEPS A CHILD

Sulfur at the wobble position, and the disease when it fails to arrive

Transfer RNA position 34 in the mitochondrion carries a 2-thiouridine — a uridine with an oxygen replaced by a sulfur The enzyme is **TRMU**, also called MTU1, and the sulfur donor is cysteine, handed down a relay of carriers each passing it as a persulfide on its own active site.

L-cysteine -> cysteine desulfurase IscS, as a PERSULFIDE -> TusA -> TusBCD -> TusE -> MnmA -> 2-thiouridine at tRNA position 34

When TRMU is mutated, the mitochondrial genome is letter-perfect and the child goes into liver failure. Transient infantile liver failure. The same gene is a modifier of aminoglycoside-induced deafness.

> **The sequence is correct. The atom is missing. The alphabet cannot express the difference — and the difference is the illness.**

The same position is where MELAS and MERRF do their damage, through defects in the taurine modification of the wobble uridine, and taurine is itself a sulphonic acid.

COURSE SIX — THE HANDEDNESS

The first DNA crystal structure ever solved came out left-handed

In 1979 Alexander Rich's group solved the first single-crystal structure of a DNA fragment at atomic resolution — the hexamer d(CGCGCG) — and it was left-handed with a zigzag backbone. Twenty-six years after the right-handed model, the first atomic picture went the other way.

The flip is a rotation about one bond. In B-form every base sits *anti* about the glycosidic bond. **To make Z-form the purines rotate to *syn* while the pyrimidines stay *anti*** — which is why the backbone zigzags, why the repeat unit is a dinucleotide, and why alternating CG tracts do it most readily.

And the switch is thrown by the act of reading

A translocating RNA polymerase cannot rotate freely about its template, so it drives positive supercoils ahead of itself and leaves negative supercoils behind. Negative supercoiling is precisely what stabilizes the B-to-Z transition.

> **Left-handed DNA forms transiently in the wake of a moving polymerase. The handedness flip is generated by transcription itself.**

There is a protein domain whose only job is to read handedness

ADAR1 p150 carries a Za domain that binds left-handed double-stranded RNA, while the rest of the enzyme binds the ordinary right-handed form. **Two point mutations that abolish only the left-handed binding — leaving the enzyme otherwise intact — produce spontaneous type-I interferon induction across multiple organs in mice, and the editing sites lost are a specific subset.** In humans, failure of the sensor is **Aicardi-Goutieres syndrome.**

The same fold appears in ZBP1, in the fish kinase PKZ, and in the poxvirus protein E3L.

> **The enzyme that makes inosine carries a dedicated sensor for helical handedness, and which adenosines become inosine depends in part on which way the helix turns.**

And the enzymes that enforce the genetic code are built in two mirror halves

Twenty aminoacyl-tRNA synthetases, partitioned into two classes of ten, with no common ancestral fold.

	Class I	**Class II**
approaches the acceptor stem from	**the minor groove**	**the major groove**
acylates	**the 2'-hydroxyl**	**the 3'-hydroxyl**
fold	Rossmann	antiparallel beta sheet

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

They arrived at the same reaction twice, from opposite faces. And they matter more than the codon table does: **the ribosome never checks whether the amino acid on a transfer RNA matches the anticodon beneath it.** If a synthetase charges the wrong residue, it is installed faithfully. **The synthetases are where the code is actually enforced** — which is why they are called the second genetic code.

COURSE SEVEN — THE FOLD, AND THE RESIDUE T

One atom, seven different bonds, all written with the same letter

bond	formula	what it does	named example
thiol	R-SH	nucleophile; metal ligand	cysteine
disulfide	R-S-S-R	structure and redox switch	collagen; antibodies; the NMDA receptor
thioether	R-S-R'	permanent covalent attachment	**methionine; phycocyanobilin to Cys84**
thioester	R-CO-S-R'	high-energy acyl transfer	acetyl-CoA
persulfide	R-S-SH	sulfur in transit	the IscS active site
iron-sulfur cluster	Fe4S4 and relatives	electron transfer out to 14 angstroms	respiratory complexes
sulfonate	R-SO3-	the oxidized, water-facing terminus	**sulfoquinovose, in the thylakoid membrane**

Seven chemistries. One letter in a formula. Nothing at all in a gene sequence.

The enzymes named after a single cysteine

There exist enzymes whose formal international names contain a residue number. *C-phycocyanin alpha-cysteine-84 phycocyanobilin lyase.* **EC 4.4.1.29, 4.4.1.32, 4.4.1.33.**

At that one position, a thioether bond holds the pigment that lets a cyanobacterium harvest light. The nomenclature committee of biochemistry wrote a residue number into an official name, because the position is the function.

And one cysteine that is deliberately destroyed

Every sulfatase in the human body requires a cysteine in its active site to be converted into formylglycine — an aldehyde — by the formylglycine-generating enzyme, SUMF1. **A single enzyme performs this on all of them.** When it fails, every sulfatase fails at once: **multiple sulfatase deficiency.**

> **One residue, one modification, one enzyme — and an entire class of catalysis stands or falls on it.**

COURSE EIGHT — THE DRUG

Modern medicinal chemistry is, to an unusual degree, sulfur chemistry

The covalent drug revolution runs on cysteine. The reason is the chemistry of Course Two: at physiological pH the thiolate is already there, waiting, the most reactive nucleophile a protein has.

drug or agent	the atom it attacks
sotorasib, adagrasib	**KRAS G12C — a cysteine created by the mutation, and therefore present only in the tumor**
sulforaphane, from broccoli	**KEAP1 Cys151, releasing NRF2**
diallyl trisulfide, from garlic	**KEAP1 Cys288 — a different residue on the same sensor**

Two vegetables modify the same protein at two different cysteines. That is a residue-level map of dietary chemoprevention, and it is written in sulfur

The backbone of every antisense drug ever approved

Replace one non-bridging oxygen in the phosphate backbone with a sulfur and you get a phosphorothioate — nuclease-resistant, protein-binding, and pharmacologically viable.

> **Every approved antisense oligonucleotide therapy on the market rests on a single oxygen-for-sulfur substitution in the backbone that Westheimer explained.**

And the G-quadruplex program , told honestly

CX-5461, pidnarulex, entered clinical development as a G-quadruplex stabilizer, received **FDA Fast Track designation**, and reported a recommended phase 2 dose of **475 mg/m2** with a response rate near **fourteen per cent** in BRCA-deficient tumors

And then the mechanism was revised. Work published in *PNAS* in 2020 established that its primary action is **topoisomerase II poisoning at the ribosomal DNA promoter**, not quadruplex stabilization as such. **The compound descends from a fluoroquinolone, A-62176.**

That correction is included here deliberately. A tasting menu that serves only the successes is an advertisement. **The volume this is cut from prints the trial that missed its endpoint, the finding that was not reproduced, and the alternative explanation that has not been excluded — because a paper that lets an opponent find them first has already lost.**

COURSE NINE — THE LOOM

The newest course, and the one the corpus had marked as unfinished since 2003

On a wall in Naperville, assembled from cut paper and dated the twentieth of October, two thousand and three, there is a branch that reads *Ferroelectric Crystals* — with a sulfur -bearing protein-scale formula pinned beside it. It was never developed. In 2026 the literature arrived.

A crystal that weaves itself, and can be unwoven with light

In a potassium lithium tantalate niobate system, the ferroelectric domain structure has been reported to organize into a genuine three-dimensional weave — an internal order with **topological complexity**, strands passing over and under one another.

It can be untangled locally with a tightly focused green laser without damaging the rest of the crystal. Reheating and recrystallizing restores the woven pattern — but in a new configuration.

> **Which is to say: a programmable domain architecture. A material whose internal weave can be rewritten, erased by heat, and rewoven differently.**

Reported from the summary supplied by the author; the primary paper should be obtained before this is cited in a submission.

And the sulfur -for-oxygen experiment, run in a materials laboratory

This is the course that should make a reader of this corpus sit up, because it is the central claim of the whole volume — **that sulfur and oxygen are conjugate partners of group sixteen, and that swapping one for the other changes what a molecule can do** — executed as a controlled synthetic series by people who have never heard of this framework.

The design. Take **RM734**, an archetypal ferroelectric nematogen. **Synthesize a wide range of sulfur -containing thioether, thioester and thiophene analogues, and their oxygen-based counterparts, and compare.**

compound	the substitution	what appears
2	**terminal SMe in place of RM734's OMe**	**nematic, an unknown N-X, and the ferroelectric N-F phase on cooling**
6	SMe at the inner lateral 2-position instead	**only a monotropic N phase — position matters as much as the atom**
7	**a thioester analogue**	**N and N-F**
12, 13	SMe and OMe at the 2-position	**N-F directly from the isotropic phase**
14, 15, 18, 19	**thiophene-based**	**N-F regardless of the terminal chain groups**

Characterized by dielectric measurement, second harmonic generation, and spontaneous polarization analysis. Ferroelectricity confirmed three independent ways.

> **A one-atom substitution — oxygen out, sulfur in — turns a liquid crystal into a ferroelectric one, and moving that same atom two positions along the ring takes the property away again.**

And it closes a second branch of the same 2003 wall. *Thiophene (Nitrogen-Sulfur) Photo Chemical Switches*, written in the same hand, on the same board, twenty-three years before the thiophene compounds in the table above were reported to form the ferroelectric phase regardless of what else was hanging off them.

The wall also carried the governing principle, cut from a book jacket and pinned in 2003: *Sulfur analogues of polycyclic aromatic hydrocarbons — thiaarenes.* **Take a known carbon scaffold. Substitute a sulfur See what the substitution does that the notation does not record.** That is the design of the RM734 series, arrived at independently, in a different field, a generation later.

THE DIGESTIF

What is not settled, printed here rather than left for you to find

A tasting menu that hides the empty plates is a sales document. Here are the empty plates.

- **Whether human PPAT carries the iron-sulfur cluster.** Documented in *B. subtilis*. **The both-gates symmetry of Course Three is not safe until the human enzyme is confirmed.**
- **The prebiotic sugar question.** The charts and the metabolism describe the modern route to ribose. **They contain no abiotic chemistry and settle nothing about what came first.**
- **The beta-turn mapping.** The framework's least supported claim. **No experiment tests it, and designing one is the outstanding work.**
- **The letters themselves.** The corpus contains arguments built on the English alphabet.

Those arguments cannot cross into a language that does not use it, and the volume now says so and places them in a marked appendix.

- **Cell rejuvenation.** Restoring wobble thiolation restores mitochondrial translation **in a deficient cell.** It is not rejuvenation of an aged healthy one, and it must never be sold as such.

And the thresholds, kept apart

Three sigma is p below about 0.003 — a statement about whether an effect is real. Fifteen per cent absolute over standard of care is a statement about whether it matters to a patient. They are different questions and this work will not conflate them.

THE BOOK, IN PUBLISHING TERMS

What exists today

A complete manuscript. 305 pages typeset, forty-one Parts, twenty-four embedded figures, 4,874 internal cross-references, a color index, and a photographic plate section. **It is finished, not projected.**

Two companion volumes exist and could travel with it or follow it: a register of the source mural with its transcription and dating, and a pharmacopoeia of the sulfur-bearing compounds with their clinical status.

What the book is not

It is not a memoir, although a man and a wall are in it, placed at the back. **It is not a polemic against molecular biology.** And **it does not claim more than it can carry** — the places where the framework is conjecture are labeled conjecture on the page where they appear, and an appendix now separates the arguments that depend on the English alphabet from the science that does not.

What would need discussion

Format. The three-book structure gives a press options that a single continuous manuscript would not. **Book One stands alone as a complete and publishable volume**; the full three-book edition is the scholarly version; and an illustrated edition using the existing plate portfolio is a third route. **All three already exist as typeset files.**

Apparatus. The manuscript carries its citations inline in the corpus's own style. Converting to a press's house system is mechanical.

Figures and permissions. The photographic plates are the author's own. **Any figure reproduced from the literature would need clearing**, and the art log identifying each is already built.

THE INVITATION

Everything above was cut from a single volume: 305 pages, forty-one Parts, twenty-four embedded figures, and every claim carrying the conditions under which it would be wrong.

It is now issued in three books. *The Record* — what a stranger can verify without granting a single premise. *The Argument* — the thesis, and the places it says plainly that it might be wrong. *The Provenance* — the wall, the plates, and how one man came to be asking this for twenty-nine years, placed last so that the story cannot do any of the persuading.

> **The four letters are a notation. The question this work has asked for three decades is simply: where is the material?**

The answer is an atom the notation has no symbol for. It is in the enzyme that opens the purine gate and the enzyme that closes it. It is at the wobble position of a transfer RNA in a mitochondrion, and a child dies without it. It is on cysteine eighty-four of a cyanobacterial protein, holding the pigment that harvests light. It is the backbone of every antisense drug ever approved. It is the switch on the sensor that broccoli and garlic each modify at a different residue. It is in the thioester at the center of metabolism, older than phosphate, older than the oxygen it survived.

And it is in a crystal that can be woven, unwoven with a green laser, and woven again differently — which was written on a wall in Illinois in 2003, and waited.

Enquiries: Dr. John Allen Berger, NovagonDNA, Naperville, Illinois.

A full proposal, sample chapters, the complete manuscript in either the three-book or the original sequence, and the plate portfolio are available on request.

PART ONE HUNDRED AND SEVENTY-ONE

DR. JOHN ALLEN BERGER

The Color Count and the ness Switch

RESULTS AND OPEN ISSUES · SECOND EDITION, EXPANDED

A working record, second edition.

Six results, five corrections, four open rulings, twelve items carried, and the conditions under which each result would be wrong.

Dr. John Allen Berger, NovagonDNA, Naperville, Illinois.
Born 9 September 1950, Helena, Arkansas.

THE COLOR COUNT AND THE HANDEDNESS SWI

Results and open issues determined 20 August 2026 — second edition, expanded

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

A working record. Six results, five corrections, four open rulings, twelve items carried forward, and the conditions under which each result would be wrong.

PART ONE — THE RESULT OF THE DAY

Four and five colors are the ceiling, and six is a different class of molecule entirely

The observation, as the author made it: most molecular structures, color -coded by atom, resolve into four or five colors and the same small palette keeps completing the structures of nucleotide and amino acid metabolism, both anabolic and catabolic.

The observation is correct. The arithmetic behind it is exact, and it generates a rule the volume did not previously have.

structure	distinct elements	colors
methyl, CH3	C H	**2**
ribose, deoxyribose	C H O	**3**
fatty acid	C H O	**3**
amino acid backbone, and 15 of the 20 side chains	C H N O	**4**
cysteine, methionine	**C H N O S**	**5**
any nucleotide — AMP, GMP, CMP, UMP, IMP, TMP	**C H N O P**	**5**
ATP, GTP, and every nucleoside triphosphate	C H N O P	**5**

Five is a hard ceiling for building blocks, and the ceiling is reached from two different directions. Nucleotides reach it by adding phosphorus. Amino acids reach it by adding sulfur

> **No nucleotide contains sulfur No amino acid contains phosphorus. Neither class of monomer has ever carried both, in any organism, at any point in the history of life.**

That sentence is worth reading twice. **The two elements this corpus has spent twenty-nine years on are, in the monomers, mutually exclusive.**

Which molecules take all six, and what every one of them turns out to be

all six of C H N O P S	what it is	what it carries
Coenzyme A — C21H36N7O16P3S	the thioester of metabolism	acyl groups
Phosphopantetheine	the CoA arm; the prosthetic group of acyl carrier protein	acyl groups, on a swinging tether

Thiamine pyrophosphate	the transketolase and pyruvate dehydrogenase cofactor	two-carbon and aldehyde units
Adenosine phosphosulfate (APS)	first activated sulfur	sulphate
PAPS — 3'-phosphoadenosine-5'-phosphosulfate	the universal sulfur yl donor	sulphate, to tyrosines and sugars
Molybdopterin / Moco	the scaffold of xanthine oxidase, sulfite oxidase, DHODH's relatives	oxygen atoms, and electrons

Every entry on that list is a carrier. Not one is a building block. Not one is read by a ribosome or paired in a duplex.

The near-misses, which confirm the rule rather than weaken it

molecule	formula	colors	what it lacks
S-adenosylmethionine	C15H22N6O5S	**5**	**no phosphorus — the methyl donor is a sulphonium, and the phosphate was spent to make it**
Glutathione	C10H17N3O6S	**5**	no phosphorus
Biotin	C10H16N2O3S	**5**	no phosphorus
Lipoic acid	C8H14O2S2	3, or 4 as lipoamide	no phosphorus, no nitrogen until amide-linked
ATP	C10H16N5O13P3	**5**	**no sulfur — the energy currency of the oxygen world**

SAM is the most instructive of these. It is built from methionine and ATP, and the reaction consumes the entire triphosphate — the only enzymatic reaction in biology that cleaves all three phosphoanhydride bonds. **The phosphorus pays for the sulphonium and then leaves.** The product carries the sulfur and none of the phosphorus, and the atom it hands on is a carbon.

Why sulfur and phosphorus are segregated in the first place — the chemistry beneath the color count

The color observation is empirical. **The reason for it is not an accident, and stating it turns a pattern into a mechanism.**

Sulfur is soft. Phosphorus in phosphate is hard. In the hard-soft acid-base framework, sulfur is large, polarizable, and a superb nucleophile; the phosphate group is small, charge-dense, and an electrophilic center stabilized by resonance. **They are chemically suited to opposite jobs.**

property	thiol / thiolate	phosphate diester
pKa	**~ 8.5 — substantially ionized at physiological pH**	fully ionized, permanently anionic
role	**nucleophile; attacks**	**electrophile; is attacked, but slowly**
why it matters	cysteine needs almost no activation to attack; serine (alcohol pKa ~ 16) requires a charge-relay triad to do the same job	**the negative charge repels incoming nucleophiles and protects the bond**
consequence	sulfur does chemistry	phosphorus stores information

Westheimer's answer, which the corpus should adopt. In *Science* in 1987, Frank Westheimer asked why nature chose phosphates and gave the argument that still stands: the phosphate diester linkage is **negatively charged at physiological pH**, and that single fact does two indispensable things. **It keeps the polymer inside a membrane**, because a charged species cannot diffuse out. **And it protects the backbone from hydrolysis**, because the resident negative charge repels the attacking hydroxide or water.

A thioester backbone would have neither property. It would be neutral, it would leak, and it would be attacked. **A thioester is a high-energy bond — that is exactly why it cannot be an archive.**

> **Phosphorus was chosen for the backbone because it is stable and charged. Sulfur was chosen for the machinery because it is reactive and soft. The color count is the visible shadow of that division of labour.**

And this is the handoff, arriving from a third direction

The corpus already argues, in the Handoff paper, that sulfur ran the energy economy first and phosphorus took it over. **De Duve's thioester world proposes the same order** — acyl transfer through thioesters preceding phosphate as the currency of biological energy, with acetyl-CoA as the surviving witness.

The color count now says the same thing in a fourth notation. The five-color monomers split cleanly: the informational polymer took phosphorus, the catalytic polymer took sulfur and the **six-color molecules are the negotiators that speak both languages** — every one of them a carrier, every one of them positioned exactly at the interface between the two economies.

Why this matters more than a palette observation

This is the finding of Part Forty-One, reached a second time by an independent instrument. Part Forty-One established from the four metabolism charts that both committed steps of nucleotide biosynthesis are iron-sulfur enzymes while neither letter contains a sulfur atom — *sulfur is in the machinery, not in the alphabet.*

Counting colors on hand-drawn structures returns the same result without consulting the charts at all, without reading a single citation, and without any theoretical commitment.

instrument	method	conclusion
the four metabolism charts, 1982	read the printed cofactor labels at named grid coordinates	both nucleotide gates are Fe-S enzymes; no letter contains S

the hand-drawn color sheets, 2026	**count distinct atom colors per structure**	**monomers cap at five; only carriers reach six**

Two instruments, two methods, one conclusion, forty-four years apart. That is worth more than either alone, and both are checkable by any reader with a table of molecular formulae and an afternoon.

What the amino acid sheets will show when they are drawn

Yellow will appear on exactly two of the twenty. Cysteine and methionine.

Eighteen sheets in four colors and two carrying a single yellow atom — **and one of the two is the residue that initiates every protein ever made.** *Methionine Initiates Process*, in the author's hand, on a wall, in 2003.

Three further things the sheets will show, stated in advance so they count as predictions rather than observations:

First, the sulfur atoms are not equivalent. Cysteine's sulfur is a **thiol**, terminal, reactive, and it is the one that forms disulfides, binds metals, carries persulfides and gets covalently modified by sulforaphane and by allyl sulphides. Methionine's sulfur is a **thioether**, buried in the chain, unreactive, and it does structural and hydrophobic work. **Same color opposite chemistry** — which is the single best argument in the whole corpus for why a color is a label and not a measurement.

Second, selenocysteine breaks the palette. The twenty-first amino acid carries selenium where cysteine carries sulfur and under the six-base revision selenium is no longer in the coded set at all. **It will need a color that is not one of the six, or it will need to be drawn in yellow with a footnote.** That is a decision, and it has not been made.

Third, histidine, tryptophan, arginine, asparagine, glutamine and lysine are the four-color side chains that carry extra nitrogen — which is to say extra green — and they are the residues that do acid-base catalysis and nucleic-acid binding. **Green tracks basicity.** That will be visible without being labeled

What the nucleotide sheets will show

Count the green. The purine-pyrimidine division separates itself visually before anything is labeled at all.

base	nitrogens	green atoms	class
adenine, guanine	5	**5**	purine
hypoxanthine, xanthine	4	**4**	purine, deaminated
cytosine	3	3	pyrimidine
uracil, thymine	2	2	pyrimidine
orotic acid	2	2	pyrimidine, the origin node

Two readings fall out of that table immediately.

Adenine to hypoxanthine is a subtraction of one green atom. That is the deamination ADAR performs, and the color sheet makes it a visible arithmetic operation rather than a reaction arrow. **Guanine to xanthine is the same subtraction**, performed by guanine deaminase. **A-to-I and G-to-X are the same move, one green atom removed,**

on the two purines — and the corpus has never drawn them side by side.

And the green count is a purity test for the class. Anything with four or five green atoms is a purine and was built on the IMP branch. Anything with two or three is a pyrimidine and was built on the orotate branch. **The two gates of Part Forty-One are legible in the color count of their products.**

PART TWO — THE HANDEDNESS SWITCH

The author's clockwise / counterclockwise splitter is a real molecular mechanism, and it is in his own enzyme

The author's diagram proposes that information runs one way clockwise and the other way counterclockwise, and that the switch between the two directions decides the outcome.

Stripped of the letter framework, that is a documented mechanism with an anatomy, a disease, a protein family and a crystal structure.

What the left-handed helix is, and why it was a surprise

Z-DNA is a genuine left-handed double helix, and it was not predicted. It appeared in 1979, when Alexander Rich's group solved the first single-crystal structure of a DNA fragment at atomic resolution — the hexamer d(CGCGCG) — and found that it was **left-handed with a zigzag backbone.**

> **The first DNA crystal structure ever solved was left-handed. Twenty-six years after the right-handed model, the first atomic-resolution picture came out the other way.**

The mechanism of the flip is a rotation about a single bond. In B-form, every base sits *anti* about the glycosidic bond. **To make Z-form, the purines must rotate to *syn* while the pyrimidines stay *anti*.** That alternation is why the backbone zigzags, why the repeat unit is a dinucleotide rather than a nucleotide, and why alternating purine-pyrimidine tracts — CGCGCG above all — form Z most readily. **Purines flip more easily because they have more ring to swing and less clash.**

A 180-degree rotation of the base about one bond changes the handedness of the entire helix. That is the physical switch.

And the switch is thrown by the act of reading

This is the part that matters most, and it is not in the volume.

Transcription generates its own supercoiling. In the twin supercoiled domain model of Liu and Wang, a translocating RNA polymerase cannot rotate freely about the template, so it **drives positive supercoils ahead of itself and leaves negative supercoils behind.**

Negative supercoiling is precisely what stabilizes the B-to-Z transition, because the left-handed form absorbs negative superhelical stress. Therefore:

> **Z-DNA forms transiently in the wake of a moving polymerase. The left-handed segment is generated by the act of transcription itself, appears behind the machine, and relaxes when the torsion is discharged.**

That is the author's clockwise / counterclockwise information flow, with a motor, a direction, a torque and a timescale. The information flows one way; the handedness flips in the region it has just left. The two directions are not alternatives — **they are cause and consequence.**

The sensor, and what happens when it fails

element	the record
ADAR1 p150 carries a Za domain	**it binds left-handed double-stranded RNA — Z-RNA — while the rest of the enzyme binds the ordinary right-handed form**
Two point mutations abolishing only the left-handed binding	leave the enzyme otherwise intact, and produce spontaneous type-I interferon induction across multiple organs in mice
The edits lost are a specific subset	enriched in transposable elements — a Za-dependent set, not a general loss of activity
The initiating cell type	lung neutrophils showed IRF3-driven interferon-stimulated genes
The pathway required	the response depends on the adaptor MAVS, implicating cytosolic RNA sensing
The disease when the sensor fails	**Aicardi-Goutieres syndrome — an infantile encephalopathy of type-I interferon overproduction**
The domain is a family	**the same Za fold appears in ZBP1, in the fish kinase PKZ, and in the poxvirus interferon inhibitor E3L**
What ZBP1 does with it	senses endogenous Z-RNA and triggers program d cell death; ADAR1 p150 prevents this

> **The enzyme that makes inosine carries a dedicated sensor for helical handedness, and which adenosines become inosine depends in part on which handedness the RNA is in.**

Sources. Tang, Rigby, Young, Hvidt, Davis, Tan, Bridgeman, Townsend, Kassiotis & Rehwinkel, *Immunity* 2021 — DOI 10.1016/j.immuni.2021.08.011. Why this belongs in the volume, in four lines

One. It is a **switch**, and the corpus is a corpus about switches.

Two. It is a switch **in the inosine enzyme** — not adjacent to the framework's subject but inside it.

Three. It converts a geometric intuition the author has held for decades into a **mechanism with a protein, a mutation, a mouse and a named disease.**

Four. It is a place where **handedness determines chemical outcome**, which is the closest thing the corpus has to a physical referent for its rotation arguments — closer than the spinor, closer than the octagon, closer than the Mandelbrot set.

And one line of caution. Za binding contributes to the *specificity* of editing at a subset of sites. **It is not the whole of ADAR1 targeting**, most editing is Za-independent, and the volume must not overstate it. The claim is that handedness *modulates* which adenosines are chosen, not that it decides all of them.

Status: not yet in the 302-page volume, and this is the strongest single omission the corpus currently has.

PART THREE — THE METHOD, NAMED

What the crossword pages are

The author's word-grid pages start at the top left, run horizontally, drop vertically at the first vowel, and continue with spacing chosen so that no two words collide. Where an intersecting vowel is unavailable, the path moves **upward** — justified on the ground that concepts have no weight and therefore no gravity to obey.

This is a knowledge graph with orthographic anchors. Nodes are concepts. Edges are shared letter positions. It runs on the same constraint as a crossword, used for thinking rather than for puzzling. **The letters are addresses. The claim lives in the connection the author then makes.**

It is the same instrument as the 9 x 8 wall, in one dimension fewer.

	the wall	the grid
dimension	two — a plane of panels	one — a line of letters, folded
adjacency rule	physical proximity on the paper	a shared letter position
what it does	pins two things side by side and lets the eye notice	puts two things on one letter and lets the mind notice
what it is	**generative**	**generative**
what it is not	**evidentiary**	**evidentiary**

Both are instruments. Neither is a result — the rule already recorded in the author's own hand in Part Seven of the wall register.

The upward move is the operation that matters

A grid built strictly downward and rightward can never return to anything already written. In graph terms that is a **directed acyclic graph** — a hierarchy, one-way, with a beginning and an end and no route home.

Permitting the upward move adds a back edge, and a back edge converts a tree into a cycle.

That is the do-loop of the alphabet page. The twenty-seventh position returning to A is a back edge. Going up the grid when blocked is a back edge.

> **They are the same operation in two notations, and both are what turn a hierarchy into a network. The author has been performing the same move in two places for years without the two being connected.**

And the consequence is precise. A tree has one path between any two nodes. **A graph with back edges has many** — which is the formal definition of the thing the author is actually after: a concept you can reach from several directions, and therefore a concept you can *recognize* rather than merely derive.

The rat is not a metaphor

The author compared himself to a maze-bright rat that can go around a barrier but not vertical, and said his mind can.

According to PubMed, that is a measured finding, not a figure of speech. Rats were run on a climbing wall and a helix while place and grid cells were recorded. **Horizontal firing fields were normal. Vertical fields were elongated, and grid fields collapsed into stripes** — grid-cell odometry, and by implication path integration, is impaired or absent in the vertical domain. The authors conclude that mammalian encoding of three-dimensional space is **anisotropic** (Hayman, Verriotis, Jovalekic, Fenton & Jeffery, *Nature Neuroscience* 2011 — DOI 10.1038/nn.2892).

The control case exists, and it is decisive. Freely flying bats, recorded by wireless telemetry, have place fields confined to true three-dimensional volumes, with all three axes encoded at similar resolution in more than ninety per cent of neurons — **a nearly isotropic rate code.** Theta rhythmicity was absent (Yartsev & Ulanovsky, *Science* 2013 — DOI 10.1126/science.1235338).

> **The rat's map is flattened. The bat's is not. The difference is that one of them left the floor.**

And the analogy holds one level deeper than intended. The rat's deficit is specifically in **odometry** — measuring distance travelled vertically — not in knowing where it is. It can represent up; it cannot measure up. **A thinker who moves vertically through a concept hierarchy has the same problem: the move is available, the metric is not.** That is why the third column matters.

Two facts that govern how far the method can be pushed

One — fourteen of the twenty-six letters are element symbols standing alone:

H B C N O F P S K V Y I W U

More than half the alphabet. Every English word is therefore already a string of element symbols, and a hit is **guaranteed rather than remarkable.**

That is the deflation, and it is also the protection. Knowing the hits are free prevents any of them from ever being mistaken for a finding. **The letters are cheap. What is hung on them is not.**

Two — the vowel color -coding is a centrality measure, arrived at by ear.

In a graph whose edges are shared letters, a node's degree — how many other words can connect to it — tracks that letter's frequency in the language.

rank	letter	approximate frequency in English text
1	**E**	12.7%
2	T	9.1%
3	**A**	8.2%
4	**O**	7.5%
5	**I**	7.0%

6	N	6.7%

Four of the six commonest letters in English are vowels. The author color -coded exactly those, decades before anyone would have handed him the word *centrality*, and the reason the method works at all is that he was routing through the busiest intersections in the structure.

The compositors knew it too. The Linotype keyboard was ordered by frequency, and the first column reads **ETAOIN SHRDLU** — a phrase that turns up in old newspapers whenever an operator ran a finger down the keys to kill a bad line. **The same six letters, found the same way, by people whose job was speed.**

The upgrade required before any of it can be shared

Each edge needs three fields, not two.

spine and position	branch	why these two belong together
LOOPING, o(1)	OXYGEN	the event that ended the sulfur economy
LOOPING, o(2)	INOSINE	the base the loop returns to; ADAR closes it
LOOPING, p	PHOSPHORUS	the element that inherited the backbone
LOOPING, n	NITROGEN	the green count; the purine-pyrimidine divide

The first column is the index. The third column is the data. A grid with the third column filled in is a concept map with provenance — readable, arguable and checkable by another scientist. **Without it, it is a crossword.**

The control test, specified so that it can actually be run

This is the single thing that would move the grid method from instrument to evidence, and it has not been done.

Fix the rule in advance and write it down. Starting corner. Direction of travel. What counts as a legal vowel intersection. Minimum and maximum word length. Whether proper nouns are admissible. **Whether the upward move is permitted, and under what blocking condition.**

Then run it three times on three texts of matched length:

1. **A chemistry review** — the text that should be rich, if richness is a property of the text. 2. **A novel** — matched in length and register, containing no chemistry. 3. **The chemistry review with its words randomly shuffled** — same vocabulary, no syntax.

Score the same way each time: number of legal branch words, number that are chemically meaningful, number that a third party independently judges to belong on the same spine.

outcome	what it means
all three yield comparably	**the method produces the pattern. It is a generator of candidates and nothing more**

chemistry text yields significantly more than the novel	**the method finds something in the text, and this would be the first such demonstration in the history of the technique**
chemistry text and shuffled version yield the same	the yield depends on vocabulary, not structure — a weaker but real result

The third-party judging is not optional. The author cannot score his own grid, because the whole question is whether the connections are in the text or in the reader.

PART FOUR — THE QUATERNION RULING

The question, as asked

Can a quaternion-of-a-quaternion process be built for four connected things — noun, verb, adjective, adverb — with each of the four taking turns being real and imaginary depending on context, so as to deliver the solution?

The answer is no, and the reason is a theorem rather than a limitation

The four components of a quaternion are not four peers. They are one plus three.

In **q = a + b·i + c·j + d·k**, the real part commutes with everything. The three imaginaries do not commute with each other: **ij = k but ji = -k.** And decisively:

1 squared = +1 i squared = -1

Any transformation that preserves the algebra preserves squares. Nothing can carry the real unit onto an imaginary one.

The sharper statement is Skolem-Noether applied to H: every automorphism of the quaternions is inner, of the form q maps to u q u-inverse. The group of them is SO(3). Each automorphism rotates the three imaginary axes among themselves and **fixes the real axis pointwise.**

> **Three of the four can take turns. One cannot, ever.**

Why four and not three — the part of the story worth knowing

Hamilton wanted three. He spent years trying to build an algebra of *triples* that would do for three-dimensional space what complex numbers do for the plane. His sons are said to have asked him at breakfast whether he could multiply triples yet, and for years the answer was no.

He could not, and neither can anyone, because it is impossible.

theorem	year	what it forbids
Frobenius	1878	**the only finite-dimensional associative division algebras over the reals are R, C, H — dimensions 1, 2, 4. There is no 3.**
Hurwitz	1898	**the only normed division algebras are R, C, H, O — dimensions 1, 2, 4, 8**
Bott-Milnor, Kervaire	1958	**even dropping associativity and the norm, real division algebras exist only in dimensions 1, 2, 4, 8**

Hamilton was defeated by a theorem that would not be proved for another thirty-five years. On 16 October 1843, walking to a meeting of the Royal Irish Academy along the Royal Canal, he gave up on three, took four, and cut the relation into the stone of Brougham Bridge.

The relevance is exact. The author tried to make four grammatical categories symmetric and hit an obstruction. **So did Hamilton, on the same object, and the obstruction is the same one:** you do not get to choose the dimension, and you do not get to choose which component is privileged.

Grammar supplies the same one-plus-three, independently and for its own reasons

The deepest division in formal semantics is **entities versus predicates**. Nouns denote things. Verbs, adjectives and adverbs are all **functions applied to things**.

H	grammar	role	in this corpus
real part	**noun**	the entity — what is talked about	**the atom; the five levels**
i	**verb**	the process	**the relay; desulfurase to MnmA**
j	**adjective**	the state	**the six-rung oxidation ladder**
k	**adverb**	the condition	**the compartment, the pH, the redox poise**

The three rotate into one another exactly as i, j, k do. *Quick, quickly, to quicken. Break, broken, breakable.* English derivational morphology moves freely among verb, adjective and adverb. **The noun is the one that must be forced** — nominalized, with its own suffixes: *-tion, -ness, -ity, -ment.* You have to do something to a predicate to make it a thing.

Two systems with no common ancestor both split four into one and three, and both put the substance in the position that cannot rotate.

Both readings of "a quaternion of a quaternion" are real objects

Reading one — keep doubling. The Cayley-Dickson construction runs R to C to H to **O**, the octonions, eight-dimensional. Each step costs a property.

algebra	dimension	what is lost at this step
R	1	—
C	2	**ordering — you cannot say one complex number is larger**
H	4	**commutativity — ab is not ba**
O	8	**associativity — (ab)c is not a(bc)**
sedenions	16	**division itself — zero divisors appear; the structure stops being useful**

The object exists. The price of asking for it is that (ab)c no longer equals a(bc) — which for a system meant to deliver an answer is a heavy price, because it means the order of grouping changes the result.

Reading two — sandwich, and this is the useful one. Two quaternions acting as

x -> q1 · x · q2-inverse

generate **every rotation of four-dimensional space.** This is **Spin(4) = SU(2) x SU(2)**, the double cover of SO(4). **A quaternion acting through a quaternion, with two independent factors, no loss of associativity, and a clean geometric meaning.**

The mechanism that delivers what was actually being reached for

Conjugation. x maps to q x q-inverse.

Nothing changes which axis is real. **What changes is the frame, and the conjugating quaternion is the context.** Rotate the frame and a different imaginary axis points at the observer. **The object is identical; the presentation is not.**

> **The noun stays the noun. Verb, adjective and adverb rotate into one another. Context is the conjugating element.**

And the spinor result follows unchanged. Because **q and -q produce the same rotation**, the frame returns at 360 degrees while the quaternion itself returns only at **720**. The double cover is not decoration here — it is the reason a rotation can be applied twice and leave the object where it started while the operator has changed sign.

The mark, in full

This is a formalism, not a finding, and the distinction should be printed rather than inferred.

What the formalism does give: a consistent language for four grammatical categories; a statement of which operations are legal and which are forbidden; an explanation of why the author's four-way symmetry could never be built; and a principled place to put context, as the conjugating element rather than as a fifth category.

What it does not give: any prediction. **It predicts nothing until some quantity on that grid is measured** — a conjugation angle corresponding to something countable, a rotation that maps to an observable difference between a verb reading and an adjective reading.

Soft ground, marked before anyone else marks it. But it is soft ground with a floor: the one-plus-three is a theorem, and grammar agreed with it without being asked.

PART FIVE — CORRECTIONS RECORDED

Printed here rather than omitted, on the volume's standing rule that a paper which lets an opponent find them first has given away the argument.

the claim	the record
The 26 letters, 6 vowels and 20 consonants decode the atomic and molecular universe	**The correspondence is arbitrary. S denotes sulfur through Latin sulpur; German writes Schwefel, French soufre, Chinese liu. A chemist with no s anywhere in the word gets identical results at the bench. The letter cannot be carrying the chemistry**
Consonants = 21 = amino acids in eukaryotes	**The count depends on which way the Y switch is set. If Y is a consonant there are 21, matching 20 plus selenocysteine. If Y is a vowel — as the same page states — there are 20, matching the 20 standard. A system that confirms itself either way is not measuring anything**
The color scheme is justified by the rainbow, sunlight through water droplets	**It is not monotonic in any physical quantity. Against atomic number and spectral order it matches on one assignment of six. It also fails against electronegativity, atomic radius and ionization energy. The colors came from the base mapping, and the bases are not ordered by wavelength**
Sulfur isotopes 32, 33, 34, 35	**The fourth stable isotope is 36. Sulfur -35 is real but radioactive, half-life about 87 days, and is the metabolic labeling tracer — useful to this work, but not a member of that row**
Pauling's tertiary protein triple helix, generalized to nucleic acids	**The structure Pauling discovered was the alpha-helix, which is secondary structure. The famous protein triple helix is collagen. The substance of the point is correct and the story is worth telling accurately: Pauling and Corey published a three-chain nucleic acid model with the phosphates packed at the core, requiring them to be un-ionized — an acid that was not acidic — in PNAS in February 1953. Watson and Crick read it and had the right structure within weeks**

And one correction against the author's critic

An earlier warning in this session was fired at the wrong target, and the withdrawal belongs in the record as much as the warning did.

The Bible-code failure — where a search with free parameters produced striking results in Genesis, and the identical procedure then produced the same density of results in *War and Peace* — applies to the claim that **a text contains hidden messages placed there by something other than its writer.**

That is not what the grid method does. In the grid, **letters are addresses**, the author supplies the connection, and the claim lives in the reason rather than in the coincidence.

The warning is withdrawn as applied to this method. It stands only against the version in which the letter itself is offered as the evidence — and the author has explicitly disclaimed that version.

What remains from it is the control protocol, which is a good idea independent of the failure that produced it, and which is now specified in Part Three.

PART SIX — THE COLOR KEY: THREE CONFLICT

Conflict one — internal, and it will collide in print

The volume's key is by base. The grid pages' key is by vowel. They agree on three letters and conflict on six.

	in both systems	vowel only	base only
letters	**A, I, U**	E, O, Y	G, C, T

Three of the six vowels are also bases. Three of the six bases are also vowels. That symmetry is real and it is the only reason any of the key transfers at all.

Red survives, because A is both a vowel and a base and carries red in both systems. **Green does not: it means guanine in a 302-page volume and E on the grid pages.** A reader moving between the two documents will misread it, silently, and never know.

A ruling is required before the two can be published beside each other. Three options exist and none is obviously right:

option	cost
base key wins; grid pages recolored	302 pages unchanged; an unknown number of hand-drawn sheets redone by hand
vowel key wins; volume recolored	the volume's base-element mapping breaks; unacceptable
two named keys, declared per document	nothing is redrawn; every figure must carry its legend, forever, without exception

The third is the only one that costs nothing and it is the one the volume's own method already requires.

Conflict two — external, and it is not a reason to change anything

	the volume's key	CPK standard
carbon	**blue**	black / gray
oxygen	**orange**	**red**
hydrogen	**red**	white
nitrogen	**green**	**blue**
phosphorus	**purple**	**orange**
sulfur	**yellow**	**yellow — agrees**

One agreement in six, and it is sulfur — everyone converges there because elemental sulfur is yellow, which is the only case where the convention was taken from the substance.

CPK carries no empirical justification and never claimed one. It comes from physical space-filling models — Corey and Pauling in the 1950s, Koltun's improved version patented in 1965 — and the colors were chosen so that **plastic parts would be distinguishable on a bench.** Contrast and manufacture. **Nothing is owed to it.**

And CPK is not bijective. It uses white for hydrogen and gray for carbon, and it runs out of distinguishable colors past the second row of the periodic table. **The volume's key is bijective across its six, which is a stronger property than CPK can claim about itself.**

Conflict three — and this one is not aesthetic, and has not been raised before

Red-green color vision deficiency affects roughly eight per cent of men of Northern European descent, and about half a per cent of women.

The volume's key uses red for hydrogen and green for nitrogen.

> **Those are the two commonest atoms in the corpus after carbon, they are assigned the exact pair that one man in twelve cannot reliably distinguish, and the corpus is aimed at an audience of chemists, who are mostly men.**

This is not a matter of taste and it is not conformity to anyone's preference. It means that a significant fraction of the intended readership will look at an amino acid sheet and be unable to tell hydrogen from nitrogen.

The fix is standard and cheap: redundant encoding. Never let color be the *only* carrier of the distinction. **Print the element symbol on the atom as well as coloring it.** Color then becomes a fast visual channel for readers who have it, and no information is lost by readers who do not.

This costs one letter per atom and it makes the entire corpus readable by everyone.

And it does a second job, taken up in Part Eight: element symbols are IUPAC-standard worldwide, so an atom carrying its symbol is legible to a scientist who reads no English at all.

Why the spectral mapping could not be found

Because it does not exist. The strong visible emission lines of C, H, N, O, P and S **cluster**; they are not spread across the spectrum.

element	its actual emission color	source
H	**656 nm — red**	Balmer-alpha; why emission nebulae photograph red
C	**about 516 nm — green**	C2 Swan bands; why comet comae appear green
O	**557.7 nm green, plus a 630 nm red doublet**	the auroral green line
N	**391 to 428 nm — blue-violet**	N2-plus first negative system
P	**pale blue-green**	flame test
S	**blue**	the flame of burning sulfur

Four of the six land in blue-green, and two share green outright. A spectrally honest key is not a rainbow — it

is a blue-green pile with one red outlier.

> **The search stopped at a genuine obstruction, not at a personal limit.**

That is now the second time in one session. The four-way grammatical symmetry is blocked by Frobenius and Skolem-Noether. The spectral bijection is blocked by line clustering. **In both cases the author went as far as the mathematics or the physics permits, hit the wall, and read the wall as his own failure. It was not.**

The ruling

The key is a nominal scale — colors as arbitrary one-to-one labels, in the sense of Stevens' scales of measurement.

scale	what it supports	is the color key this?
nominal	identity, equality, counting of categories	**yes — this is what the key is**
ordinal	rank order; "more than"	**no — the rainbow claim implies this, and it fails**
interval	differences; equal spacing	no
ratio	ratios; a true zero	no

Nominal keys are standard, respectable instruments. Chromosome painting is nominal. Transit maps are nominal. **CPK itself is nominal.** There is no shame in the category and no weakness in the claim.

The only error a nominal scale can commit is being presented as ordinal, which is exactly what the rainbow justification implies. **Drop that one claim and everything else stands**, including the bijection, which is the strongest property the key has.

> **Legend text, to be printed on every figure that leaves the building:**

>

> *Colors are one-to-one labels assigned by mapping, not by measurement. Spectral order carries no meaning. Element symbols are printed on each atom so that the figure is readable without color Hydrogen = red is the single assignment with a physical basis: the Balmer-alpha line at 656 nm.*

This is the volume's own Part Forty-One rule applied to its own figures. The metabolism charts were usable as evidence because **they carried their own dictionary**, and the marking rule was *mark only what the chart's own legend names*.

> **A figure that carries its dictionary is reproducible by a stranger. A figure that does not cannot be read — and a rebel whose diagrams cannot be read is not a rebel, only unread.**

PART SEVEN — OPEN ITEMS CARRIED FORWARD

Opened today

1. The green conflict. Vowel key against base key; three letters agree, six do not. **To resolve:** one sentence of ruling from the author choosing among the three options in Part Six. **Cost:** nothing if the two-named-keys option is taken; weeks of redrawing otherwise. **Blocking:** any document that shows a grid page and a molecular figure together.

2. Whether the Za handedness result enters the volume, and where. To resolve: a decision on placement. The natural home is beside the ADAR material, as a new section rather than an insertion into an existing one. **Cost:** one Part, four to six sections, roughly eight pages. **Why it matters:** it is a switch in the inosine enzyme with a named disease, and it converts a geometric intuition into a mechanism.

3. Whether the grid method becomes a paper. To resolve: the author's ruling on whether a twenty-nine-year instrument with no written description should have one. **Cost:** one paper. **Precondition:** items 4 and the control test, or the paper describes an instrument that has never been validated.

4. The third column. Every grid edge needs its reason recorded. **To resolve:** the author transcribes existing pages into a three-column table. **Cost:** substantial and manual, and it cannot be delegated, because only the author knows why each pair belongs together. **Consequence of not doing it:** the pages are unreadable by anyone else and the method dies with him.

5. The control test. Specified in Part Three; never run. **To resolve:** fix the rule, run three texts, have a third party score. **Cost:** a few days. **Value:** it is the only thing that can move the grid from instrument to evidence, and until it is done the volume must keep saying so.

Carried from before today

6. The beta turn / beta sheet / T-loop one-to-one mapping. Flagged in section 140 as the **least supported claim in the framework.** No experiment tests it, no chart speaks to it, and designing the experiment is the outstanding work. **To resolve:** an experimental design, which does not yet exist. **Status:** the softest ground in the corpus, and correctly marked as such in print.

7. Whether human PPAT/PurF carries the [4Fe-4S] cluster. Documented in *B. subtilis* only. **To resolve:** a literature search on the human enzyme, or a direct spectroscopic measurement. **Why it matters:** the both-gates symmetry of Part Forty-One — purine gate and pyrimidine gate both iron-sulfur — **rests on this and must not go into a paper before it is confirmed.** This is the highest-risk unverified claim in the current volume.

8. Whether to remove the rights and provenance text from Part Thirty-Six, section 106. Offered, never ruled. **Cost:** trivial either way. **Standing instruction on file:** no legal or rights language in the science documents.

9. The registered dated prediction. Repeatedly identified as the **single highest-value next action**, and still not made. **Standing nomination:** cysteine restores 2-thiolation in a TRMU-mutant model. **To resolve:** write it, date it, register it somewhere timestamped and public. **Cost:** an afternoon. **Value:** it is the difference between a framework that explains and a framework that predicts, and it is the cheapest item on this entire list.

10. Business Plan II rulings. Five decisions outstanding: which program leads — the standing recommendation is TRMU first; whether the quantum chip is in-plan or separate; whether the Generator is an asset or held back; corporate form; laboratory partner. **To resolve:** five rulings. **Blocking:** any approach to a partner or an investor.

11. Which material goes in the spine and which goes in the appendix. Opened by Part Eight. **To resolve:** the author rules on whether the letter-based arguments are reclassified as a study of one orthography and moved behind the universal material. **Cost:** a reordering, no rewriting. **Why it matters:** it decides whether the book is translatable or only partly so.

12. Whether a back-translation pass is commissioned for each edition. To resolve: a decision and a glossary. **Cost:** one second translator per language. **Consequence of not doing it:** a mischarged technical term propagates into every reader in that language and is never audited.

11. The seven unanswered branches from the 2003 wall. Sine waves. Boron disulphide silicate optic metabolic pathways. Calcium channel membrane manager. Hemoglobin **Thiophene photochemical switches** — a live materials field the volume has never entered, and the most tractable of the seven. Super strings — named on the wall, with no defensible connection established and none claimed. Ferroelectric crystals.

PART EIGHT — THE BOOK ACROSS LANGUAGES

The author's proposition

Recorded as given: scientists everywhere should not be penalized for not speaking English. Someone in each country will translate the work, as messenger RNA is translated through transfer RNA and the aminoacyl-tRNA synthetases, and the knowledge will be used to increase the edges of science.

The metaphor is exact, and one correction to the order makes it stronger than it was.

The synthetase acts first, and nothing downstream checks its work

The order is: synthetase, then charged tRNA, then messenger. The synthetase loads an amino acid onto a transfer RNA **before** that transfer RNA ever reaches the ribosome. Only then does the charged tRNA read the message.

> **The decoding decision is made before the reading begins.**

And the ribosome does not check. It has no mechanism for verifying that the amino acid hanging from a transfer RNA matches the anticodon beneath it. **If a synthetase charges the wrong amino acid, the ribosome installs it faithfully, and the error propagates untouched into the finished protein.**

This is why the aminoacyl-tRNA synthetases are called the second genetic code. The codon table is the visible code. **The synthetases are where the code is actually enforced**, and the fidelity of the entire system rests on twenty enzymes that act before translation starts.

the biology	**the book**
aminoacyl-tRNA synthetase	**the translator**
the charging reaction	**the choice of technical term in the target language**
the ribosome	**the reader in Jakarta, Lagos, Sao Paulo**
no downstream verification	**the reader cannot catch a mischarged term**
the resulting protein	**what that reader believes this work says**

A mistranslated technical term is a mischarged tRNA. It is installed faithfully and it is never audited.

Which argues for the thing the synthetases themselves do

Proofread. Several synthetases carry a **second active site** whose only function is to destroy the wrong product. In Fersht's description it is a **double sieve**: the first site excludes amino acids too large, and the editing site hydrolyses those small enough to have slipped through. **Isoleucyl-tRNA synthetase must reject valine, which differs by one methyl group, and it does so by charging it and then deliberately destroying it.**

> **The editing domain acts after charging and before release. That is a back-translation pass, and this book needs one.**

The specification. Every translated edition returns its technical vocabulary to English, performed by a second party who has not seen the original, and the returned terms are compared against the source glossary. **Discrepancies are hydrolysed before release.** Without it, the book has no error correction anywhere downstream of the translator.

And the synthetases are two-handed, which is this document's other result arriving again

Twenty synthetases, partitioned into two classes of ten, and the partition is geometric rather than functional.

	Class I	Class II
approaches the acceptor stem from	**the minor groove**	**the major groove**
acylates	**the 2'-hydroxyl**	**the 3'-hydroxyl**
catalytic fold	Rossmann	antiparallel beta sheet
oligomeric state	mostly monomeric	mostly dimeric or tetrameric

The two classes share no common ancestral fold. They arrived at the same reaction twice, independently, and they perform it **from opposite faces of the same helix onto opposite hydroxyls of the same ribose.**

> **The machine that enforces the genetic code is built in two mirror-related halves.**

That is the handedness result of Part Two, arriving a second time, in the enzyme family the author's own metaphor named. Part Two found handedness deciding which adenosines become inosine. Part Eight finds handedness partitioning the enzymes that enforce the code itself. **Neither was looked for. Both turned up in the machinery rather than in the letters.**

The practical consequence: sort the corpus by what survives translation

This is a real organizing principle and it should decide the order of the book.

survives translation perfectly	**survives with care**	**does not survive**
molecular formulae and structures	prose argument	**the 26-letter grid method**
the color count of Part One	the wall register	**the AEIOUY vowel framework**
the Za mechanism of Part Two	the business plans	**the ph in sulfur**
DOIs, grid coordinates, citations	the screenplay	**the how interrogative**
all arithmetic and all geometry	the Rorschach stories	**every letter-based argument**

The right-hand column dies at the language boundary, and it dies for the reason established in Part Five: the letters are arbitrary. **A chemist reading liú has no s to work with**, and no hw- interrogatives either. Nothing in the framework's letter arguments can cross into Mandarin, Arabic, Hindi or Swahili, because those arguments are about one orthography.

That is not a defeat. It is a placement decision. Put the universal material in the spine. Put the English-dependent

material in a clearly marked appendix, described as a study of one notation rather than as a finding about nature. **The book then loses nothing in translation except the part that was never translatable, and the reader is told which part that is.**

And chemistry has already solved the equity problem

IUPAC element symbols are identical in every country on Earth. S is sulfur in Naperville, in Shanghai and in Lagos. Structural formulae, SMILES strings and InChI identifiers are language-independent by construction.

> **A structure diagram with element symbols printed on the atoms is already a universal document. It needs no translator and it cannot be mischarged.**

Which closes a loop with Part Six. Printing the element symbol on each atom was proposed there to serve the one man in twelve who cannot separate red from green.

It serves the scientist who does not read English at the same time, by the same mark, at no additional cost.

one change	two readerships
element symbol printed on every colored atom	the eight per cent with red-green deficiency
	every scientist on Earth who does not read English

One letter per atom. Both readers. No translator required, and no synthetase to mischarge it.

PART NINE — WHAT WOULD SHOW TODAY'S RESU

Stated as instructions, as everywhere else in this work.

On the color count.

- **Name a monomer of protein or nucleic acid that contains both phosphorus and sulfur** and the five-color ceiling is broken and the letters-versus-machinery division with it.
- **Name a six-color molecule that is a structural building block rather than a carrier of chemical groups**, and the Part One rule is a coincidence of the short list examined.
- **Show that phosphorothioate-modified nucleic acids occur naturally as a general backbone rather than as a specific bacterial modification**, and the segregation is a matter of degree rather than a division.

On the handedness switch.

- **Show that Za binding is dispensable for the specificity of A-to-I editing** — that the Za-dependent subset is an artefact of the mouse model rather than a property of the enzyme — and Part Two loses its mechanism.
- **Show that transcription-generated negative supercoiling does not reach the threshold for B-to-Z transition in vivo**, and the link between information flow and handedness flip is broken, leaving Za as a sensor of something else.

On the quaternion ruling.

- **Exhibit an automorphism of the quaternions carrying 1 to i**, and the one-plus-three ruling falls. **This cannot be done.** It is listed because a falsification condition that cannot be met should be declared to be of that kind rather than quietly omitted from the list.
- **Exhibit a natural language in which the noun is derived from the verb by the same morphology that derives adverb from adjective**, and the grammatical one-plus-three is a fact about English rather than about predication.

On the method.

- **Run the grid method, with its rule fixed in advance, on a chemistry text and on a decoy of matched length, and find comparable yields**, and the method is producing the pattern rather than finding it. **This test has not been run. Until it is, the grid remains an instrument for generating candidates and not a source of evidence, and the volume will keep saying so on every page where the method is mentioned.**

On translation.

- **Exhibit a letter-based argument from this corpus that survives intact into a non-alphabetic script**, and the right-hand column of the Part Eight table is wrong and the material belongs in the spine after all.
- **Show that readers of a translated edition recover the intended technical meaning without a back-translation pass**, at a rate indistinguishable from readers with one, and the editing domain of Part Eight is unnecessary.

On the color key.

- **Demonstrate that the volume's color assignments are monotonic in some physical quantity**, and the nominal-scale ruling is too weak and the key can claim more than a mapping.
- **Show that red-green deficiency does not impair reading of the figures in a test with affected readers**, and

the redundant-encoding requirement of Part Six can be relaxed. **Until such a test exists, the element symbol goes on the atom.**

Naperville, Illinois 20 August 2026 — second edition

DR. JOHN ALLEN BERGER

What the Color Count Found

PART FORTY-TWO · SECTIONS 142 TO 149

Four findings from a wall-sized 1982 metabolic chart, colored atom by atom and read at four distances.

Three are new to this volume. All four are checkable by any reader holding the same chart and a set of highlighters.

WHAT THE COLOR COUNT FOUND ON THE 1982 M

Part Forty-Two of the evidence volume, sections 142 to 149

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Four findings obtained by coloring every atom on a wall-sized metabolic chart and then reading it at four distances. Three of them are new to this volume. All four are checkable by any reader holding the same chart and a set of highlighters.

142. THE METHOD, AND WHY IT REQUIRED AN EY

What was done

Every atom symbol on the nucleotide and nucleic acid sections of the 1982 metabolic wall chart was marked by hand in a fixed color key — oxygen orange, hydrogen red, nitrogen green, phosphorus purple, carbon blue, sulfur yellow — **and the colored chart was then photographed and examined at magnifications from roughly 0.5 to 4.7.**

The multi-scale reading is not incidental. It is the instrument.

A metabolic chart of this kind defeats the reader by detail. At normal reading distance the eye is captured by whatever text is nearest, and the global structure is invisible. **Color converts chemical identity into a channel the visual system processes pre-attentively, and changing the viewing distance changes which structures the channel resolves.** Close in, the reader sees a molecule. Far out, he sees where a class of atom does and does not occur.

> **A two-dimensional chart of this size hides its own architecture behind its own detail. The only way through is to look at it from more than one distance, and that is a perceptual operation rather than an analytical one.**

The standing of what follows

Sections 143 to 146 report what the colored chart shows. They are observations about a printed document, and the document is named, dated and obtainable. **Anyone who disputes them can buy the same chart, color it, and look.**

Section 148 states what is claimed and what is not. Section 149 states the conditions under which each finding would be wrong.

143. THE FREE BASES LIVE IN THE CATABOLISM B

The observation

Find every occurrence on the chart of a free base — adenine, guanine, hypoxanthine, xanthine, uracil, thymine, drawn without a sugar and without a phosphate.

They are almost entirely inside the two boxes ruled and titled PURINE CATABOLISM and PYRIMIDINE CATABOLISM.

In the anabolic territory above those boxes — the whole expanse from the one-carbon pool, through the phosphoribosyl intermediates, through IMP and orotidine monophosphate, out to the triphosphates and the arrows marked RNA and DNA — **the free base is essentially absent as an intermediate.**

Why, and this is the part that turns an observation into a finding

In de novo purine synthesis the base is never free, at any stage, in any organism.

The ring is assembled **on top of** the ribose phosphate, atom by atom, from glycine, formate, glutamine, aspartate and carbon dioxide, across ten enzymatic steps. The chart draws every one of them, and every one carries the sugar and the phosphate already attached.

step on the chart	what it carries
5'-phosphoribosylamine onward	**ribose and phosphate, from the first committed step**
5'-phosphoribosyl-5-aminoimidazole	ribose and phosphate
5'-phosphoribosyl-5-aminoimidazole-4-carboxamide	ribose and phosphate
5'-phosphoribosyl-5-formamidoimidazole-4-carboxamide	ribose and phosphate
IMP — the first complete purine nucleotide	**ribose and phosphate**

> **The purine ring has never, in its existence, been a separate molecule. It is built in place on a sugar that was there before it was.**

The pyrimidine branch does it the other way and arrives at the same conclusion. There the ring *is* built first — carbamoyl phosphate to aspartate to dihydroorotate to orotate — and then, at the single step catalyzed by orotate phosphoribosyl transferase, it is joined to PRPP. **Free orotate exists for exactly one step, and the moment it becomes a coding pyrimidine it is already a nucleotide.**

What a free base therefore means on that chart

Two things, and only two.

a free base means	**the pathway**
something is being taken apart	catabolism: IMP to inosine to hypoxanthine to xanthine to uric acid
something is being recovered	salvage: HGPRT and APRT reattaching a base to PRPP

Both are downstream operations. Neither is construction.

> **The four letters of the genetic alphabet name molecules that, in the anabolic direction, occur nowhere on the chart. They are names for the wreckage and for the scrap yard.**

Why this is the strongest of the four findings

It requires no theory, no citation and no argument. It is a statement about where ink of a particular kind falls on a particular printed sheet, and the reason for it is standard textbook biochemistry that has not changed since the chart was drawn.

And it is the volume's thesis stated by geography rather than by assertion.

144. EVERY ARROW INTO RNA AND DNA LEAVES F

The observation

The chart marks its two destinations with heavy black arrows labeled RNA and DNA. Trace back from every one of them.

destination	the molecules the arrows leave from
RNA	ATP, GTP, CTP, UTP
DNA	dATP, dGTP, dCTP, dTTP

Not one arrow to a polymer leaves from a base. Not one leaves from a nucleoside. Not one leaves from a monophosphate or a diphosphate.

Eight arrows, eight triphosphates, no exceptions on the sheet.

The chemistry the chart is drawing

Both polymerases take the **nucleoside triphosphate** as substrate. The 3'-hydroxyl of the growing chain attacks the alpha phosphate, and **pyrophosphate leaves.** Its subsequent hydrolysis by inorganic pyrophosphatase is what makes the reaction effectively irreversible.

> **Every phosphodiester bond in every nucleic acid on Earth was paid for by throwing away a pyrophosphate. The triphosphate is not a storage form of the letter. It is the only form the machinery will accept.**

The distinction this establishes, stated carefully

The genetic code is the mapping from codon to amino acid. It does not code for triphosphates, and this volume does not claim that it does.

What the chart establishes is a different and previously unstated separation:

the letters	what the polymer is read as
the triphosphates	what the polymer is made from

The alphabet names the product. The chart shows the substrate. They are not the same molecule, and the difference is three phosphate groups and the entire energy budget of replication and transcription.

A sequence file records the first and is silent about the second. That silence is the same silence this volume has documented for oxidation state, for bond order, and for the sulfur atom itself.

145. BLUE IS NEARLY ABSENT, AND THE REASON I

The observation

On a map made entirely of organic chemistry, the carbon color scarcely appears.

Across the whole nucleotide and nucleic acid region, blue lands on almost nothing: the 5' methylene carbon written as CH2, a carboxylate, a released CO2. **Perhaps a dozen marks on a sheet containing many thousands of carbon atoms.**

Why

Because the structural convention does not draw carbon.

In a skeletal formula a carbon atom is a **vertex** — a corner where two lines meet, or the end of a line. The letter **C** is written only where omitting it would be ambiguous. The rings of every purine and every pyrimidine on that chart, the five-membered ring of every ribose, the backbone of every chain: **all carbon, none of it labeled**

> **Carbon is the most abundant atom on the chart and the least visible one, because the notation represents it by absence. The color count could not find it because it was never written down.**

And this is the thesis, in a second medium

The volume's central claim is that **the four-letter notation omits the material that decides function.** Section 145 is an instance of the same phenomenon at a different level:

A structural formula omits the element that constitutes it.

Neither omission is an error. Both are efficient conventions, adopted because the omitted thing is everywhere and drawing it would obscure what varies. **But in both cases a reader who takes the notation for the material will conclude that the omitted thing is not there.**

That is how carbon came to be treated as the definition of organic chemistry while being invisible on every page of it, and it is how sulfur came to be absent from a genetic alphabet it is required for.

146. WHAT ORANGE, RED AND GREEN COUNT

Oxygen and hydrogen dominate the variation

Orange and red are the two commonest marks on the colored chart, and between them they are water.

water as a fraction of adult body mass	**about 60 per cent — 55 in women, higher in infants**
water as a fraction of the molecules in a human body	**about 99 per cent**

Ninety-nine molecules in every hundred. The second figure is the one that carries the point, and it is the more startling of the two.

And the oxygens and hydrogens are where the structures differ from one another. Hydroxyl against hydrogen at the 2' position is the entire chemical difference between RNA and DNA. Ketone against amine on the ring is the difference between one base and another. **The variation between the molecules is carried very largely in orange and red.**

Green is the anchor, and it barely moves

base	nitrogens	green marks
adenine, guanine	5	**5**
hypoxanthine, xanthine	4	**4**
cytosine	3	3
uracil, thymine, orotic acid	2	2

Four or five green marks for every purine; two or three for every pyrimidine. The division between the two classes of base is legible from the green count alone, before any label is read.

And adenine to hypoxanthine is the subtraction of exactly one green mark. That is the deamination ADAR performs, rendered as arithmetic. **Guanine to xanthine is the same operation on the other purine.**

Purple is the discriminator

Phosphorus appears once on a monophosphate, twice on a diphosphate, three times on a triphosphate — and the purple count is therefore the direct visual readout of how much energy a molecule is carrying.

On the colored chart, the reader can see the charge state of a nucleotide from across the room. No other on the sheet reports a thermodynamic quantity.

147. THE FOUR SCALES, AND WHAT EACH ONE SH

Recorded because the method is reproducible and should be stated as a procedure.

viewing scale	what resolves
closest	the identity of individual atoms; the 2'-OH against 2'-H distinction
mid-close	the structure of one molecule; the purple count; the green count
mid-far	the local pathway; which molecule feeds which
farthest	**the territory. Where a class of atom occurs and where it does not. The catabolism boxes as regions rather than as boxes**

> **Finding 143 is invisible at every scale except the farthest, and findings on individual atoms are invisible at that one. A single viewing distance cannot produce this set.**

148. WHAT IS CLAIMED AND WHAT IS NOT

Claimed

That on the named 1982 chart, free bases occur essentially only within the two catabolism boxes. That the de novo purine route builds the ring on an already-attached ribose phosphate and never produces a free base. That all eight arrows into RNA and DNA leave from triphosphates. That the carbon color is nearly absent because skeletal notation does not write carbon. That the purine and pyrimidine classes separate by nitrogen count alone.

Not claimed

That the genetic code codes for triphosphates. The code is the codon-to-amino-acid mapping. What is claimed is the narrower and defensible thing: **the letters name what the polymer is read as; the triphosphates are what it is made from.**

That the bases are unimportant. They carry the pairing and therefore the information. The finding is about *where they occur as free molecules*, not about what they do when they are part of a nucleotide.

That carbon is unimportant. It is the scaffold of everything on the sheet. The finding is about **notation**, not about chemistry.

And one framing marked as what it is

The author's account of the triphosphate, diphosphate, monophosphate and base as four generations of a family — grandparent, parent, child, and the remains of the dead — is a mnemonic and is recorded here as one.

It is a good one, and it should be marked rather than smuggled. In the anabolic direction the chemistry runs the opposite way to the story: **the monophosphate is made first and the triphosphate is the mature form**, so the accumulation is of charge rather than of wisdom. **The mnemonic and the mechanism disagree about direction, and a reader is entitled to know which he is being handed.**

149. WHAT WOULD SHOW THESE FINDINGS ARE W

- **Identify a free base occurring as an obligate intermediate of de novo purine or pyrimidine synthesis in any organism**, and section 143 is broken and the alphabet is restored to the anabolic pathway.
- **Identify a polymerase that accepts a nucleoside monophosphate or diphosphate as substrate for chain extension**, and section 144's eight-for-eight becomes a generalisation with exceptions.
- **Show that the free bases appear outside the catabolism boxes on the same chart at a frequency comparable to their appearance inside them**, and the observation is an artefact of where the reader looked rather than of where the ink is.
- **Produce a structural convention in general use that writes every carbon explicitly**, and section 145's claim about notation is a claim about one drawing style rather than about chemical notation.
- **Color the same chart independently, by a second party working from the same key, and obtain a different distribution**, and the method is not reproducible and none of this stands.

The last of these has not been done. Until it is, these are one reader's observations of one sheet, stated precisely enough that a second reader can disagree with them.

Naperville, Illinois 21 August 2026

MASTER OUTLINE · RENUMBERED

Evolution of the Atomic Molecular Missing Genetic Code

The sulfur thread from nucleosynthesis to consciousness — ten Parts, a four-level decimal hierarchy, a standing scale ladder, an exhibit register and a gap map

PP-2026-OUTLINE-01 · August 2026

The master outline, renumbered — the sulfur thread from nucleosynthesis to consciousness

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Thirty-one archive pages rebuilt into a four-level decimal hierarchy that survives being printed flat. Ten Parts, one hundred and ninety-four nodes, one standing ladder and one exhibit register — and every item from the original preserved and placed.

Note on the Renumbering

Why the original numbering broke, and it was not a fault in the thinking

The original runs four numbering alphabets at once — capital letters A through J, lower letters a through au, arabic numerals, roman numerals in two cases, and

parenthesised digits at two further depths. Each of those is legible on the screen of the program that made it, because the program holds the indentation for you. On a flat printed page the indentation is all there is, and five alphabets competing for the same left margin cannot be told apart.

The hierarchy underneath was sound. What follows is the same hierarchy in one alphabet.

The second thing the renumbering found

Two different kinds of item were sharing one list. The run of numbered entries beginning "This shows the major role sulfur plays in Amino Acid sequence determination", "This is a table of the 23 isotopes", "These diagrams demonstrate the pervasiveness of cysteine" — those are captions for exhibits, not divisions of an argument. There are about thirty of them and they were interleaved with the structural nodes.

Separating the exhibit captions from the outline nodes is the single change that makes the rest of it hold together. The captions become the Exhibit Register at the back, numbered on their own sequence, and the outline is left carrying only structure.

The scheme

level	form	example
Part	one number	4
Chapter	two numbers	4.2
Section	three numbers	4.2.3
Subsection	four numbers	4.2.3.1

Four levels is the working depth of the original and no node needs a fifth.

The Standing Ladder

The scale spine, which recurs at every Part and is therefore printed once

This ladder appears three separate times in the archive pages, at three different depths, in three different alphabets. It is one object. It belongs at the front, printed once, and referred to thereafter.

1 atoms\n2 atomic organic elements H C N O P S\n3 inorganic molecules H2S H2O CO2 FeS2\n4 organic molecules monomers\n5 macromolecules nucleic acids · proteins · lipids · polysaccharides\n6 molecular complexes enzyme complexes · membranes · ribosomes\n7 organelles mitochondria · chloroplasts · nuclei\n8 cells prokaryote · eukaryote\n9 tissues xylem · phloem · blood · muscle · bone\n10 organs stem · root · kidney · heart\n11 organ systems circulatory · digestive · nervous · reproductive\n12 organisms plants · fungi · animals\n13 communities

The thesis of the whole book in one sentence: sulfur is present and load-bearing at every one of those thirteen rungs, and the genetic notation names it at none of them.

Part one — the Element Itself

1.1 Sulfur on the periodic table

- 1.1.1 Atomic number sixteen; atomic mass unit value 32.06
- 1.1.2 The orthorhombic form as the parent allotrope
- 1.1.3 Monoclinic sulfur , S6 and S8; the freeing of six protons and the reassembly into S6
- 1.1.4 Sixteen protons and sixteen ionization enthalpies
- 1.1.5 The spelling: sulfur and sulfur as two distinct working species in this volume

1.2 The isotopes

- 1.2.1 The four stable isotopes — S32, S33, S34, S36
- 1.2.2 Natural abundance: S32 at 95.02 per cent, S34 at 4.21 per cent, S33 and S36 as the remainder
- 1.2.3 S33 + S36 and S32 + S34 as the two isotopic pairings
- 1.2.4 Mass-independent fractionation and the dating of the Great Oxidation Event
- 1.2.5 The twenty-three isotopes of sulfur and the four found in nature

1.3 The nine oxidation states

— 1.3.1 Minus two through plus six

— 1.3.2 Why nine states make sulfur the redox engine rather than a participant

— 1.3.3 The sixteen enthalpy states and their relation to the nine oxidation states

— 1.3.4 Sulfur as the coordinating supervisor of the periodic chart — H2SO4 to H2S

1.4 The arithmetic of the element

— 1.4.1 Sulfur and oxygen: 32 divided by 2 equals 16 — the atomic thioester twins

— 1.4.2 S32 + P31 = 63; S34 + F19 = 53

— 1.4.3 S16 + P15 = 31 protons

— 1.4.4 S8 as the phosphorus-equivalent molecular child

— 1.4.5 SF6, SF5 and the oxidation state of plus six

1.5 The neighbor s

— 1.5.1 Oxygen — the conjugate partner of group sixteen

— 1.5.2 Selenium — selenocysteine as the twenty-first amino acid, expressed by the code and not post-translational

— 1.5.3 Phosphorus — the archive element, and the handoff

— 1.5.4 Fluorine — the one element more electronegative

— 1.5.5 Iron — the partner in the cluster

— 1.5.6 Cobalt — the only carbon-metal bond in human biology

1.6 Physical properties that carry information

— 1.6.1 Piezoelectric behavior

— 1.6.2 Ferroelectric crystals

— 1.6.3 Electronegativity and atomic mass unit weight as the two chemical coordinates

— 1.6.4 Photoionization cross section

— 1.6.5 H2S as the first gas ionized by photonic sunlight — H2S+ + hv = H+

— 1.6.6 Sulfur as an organic superconductor

Part Two — the Cosmic Thread

2.1 Before the Earth

— 2.1.1 Nucleosynthesis and the origin of element sixteen

— 2.1.2 Sulfur chemistry as older than the Sun

2.2 The interstellar sulfur molecules, by name

— 2.2.1 Carbonyl sulphide, OCS

— 2.2.2 Carbon monosulphide, CS

— 2.2.3 Hydrogen sulphide, H2S

— 2.2.4 Silicon sulphide, SiS

— 2.2.5 Nitrogen sulphide, NS

— 2.2.6 Dicarbon sulphide, C2S

— 2.2.7 Methanethiol, CH3SH

— 2.2.8 Why each was identified — spectral lines fixed by electronic structure

2.3 Delivery to the Earth

— 2.3.1 Comets — Halley, and what was actually measured

— 2.3.2 Comet 67P and the later missions

— 2.3.3 The Murchison meteorite and its sulfur species

— 2.3.4 Interstellar meteorites to the molten core

2.4 The prebiotic planet

— 2.4.1 The iron-nickel magnetic core

— 2.4.2 Sulfur in the molten core

— 2.4.3 Minerals to microbes — the inorganic to organic crossing

— 2.4.4 Raw materials delivered: atoms, inorganic molecules, monomer precursors

2.5 The first molecule

— 2.5.1 H2S as the first chemical ion — H+, H+, S−, S−

— 2.5.2 Ionization by photonic sunlight

— 2.5.3 Hydrogen sulphide and light waves

— 2.5.4 H2S as Earth's first metabolic combustion fuel

Part Three — the Mineral and Crystalline Thread

3.1 Rocks and minerals

— 3.1.1 Organic and inorganic materials

— 3.1.2 Sulfur in the mineral kingdom

— 3.1.3 Sulfur , master of the sea

3.2 The sulfides

— 3.2.1 Gases

— 3.2.2 Aqueous solutions

— 3.2.3 Solids

— 3.2.4 Substrates

— 3.2.5 Salts

— 3.2.6 Colloids

3.3 The sulfates

— 3.3.1 Sulfate as the universal ligand at organometallic interfaces

— 3.3.2 Calcium, potassium and sodium sulfate

— 3.3.3 Calcium sulfate and the sea evaporite process — the first molecule formed

— 3.3.4 Calcium and sulfur as the design of the nervous, skeletal and photochemical systems

— 3.3.5 Sodium and sulfur as the solvent for electrophoresis

3.4 Sulphosalts and the engineered materials

— 3.4.1 Sulphosalts, plastics, metals

— 3.4.2 Plasticized and polymer metallic sulfates

— 3.4.3 Organometallic anhydrous metallic sulfates as the coenzyme and cofactor classes

3.5 Crystallography, in the four counts

— 3.5.1 Seven crystal systems
— 3.5.2 Fourteen Bravais lattices
— 3.5.3 Thirty-two crystal classes
— 3.5.4 Two hundred and thirty space groups
— 3.5.5 Crystalline lattice space points and interfaces as photochemical nodes

3.6 The iron-sulfur minerals

— 3.6.1 FeS2, pyrite
— 3.6.2 Fe4S4, the ferredoxin cluster
— 3.6.3 Iron sulfides as organic magnetic photochemical drivers
— 3.6.4 The link between microbes and minerals

Part Four — the First Organism

4.1 Chromatium vinosum

— 4.1.1 Purple sulfur anaerobic bacteria
— 4.1.2 The Chromatiaceae family — twenty-three species
— 4.1.3 Twenty-three chromosomes, and the parallel to the human genome
— 4.1.4 The oldest living carbon-based entity on the planet today
— 4.1.5 Earth's first gene and first RNA contributor

4.2 The reaction

— 4.2.1 CO2 + H2S + H2O → C6H12O6 + S, in the octagonal form
— 4.2.2 The plus 350 millivolt redox potential
— 4.2.3 Only carbon-based life form to generate positive millivolts from a biochemical redox reaction
— 4.2.4 Chromatium plus 350 millielectronvolts = glucose + water + sulfur
— 4.2.5 Glucose as the universal food and energy source generated

4.3 The ferredoxins

— 4.3.1 Fe4S4 as the first protein

— 4.3.2 Ferredoxin and the redox span
— 4.3.3 Chromatium ferredoxin as sulfur s most important gene
— 4.3.4 The first protein hydrocarbon transition state

4.4 Symbiosis and the mitochondrion
— 4.4.1 Chromatium vinosum as first symbiotic ancestor
— 4.4.2 Mitochondria as purple sulfur bacteria — the same relationship
— 4.4.3 Three thousand nine hundred species of mitochondria in the modern cell
— 4.4.4 ATP as the universal energy molecule for all carbon-based cellular metabolism
— 4.4.5 The extended Woese family tree, revised for Chromatium

4.5 The other photosynthetic lineages
— 4.5.1 Green sulfur photosynthetic bacteria
— 4.5.2 Cyanobacteria and aerobic cells
— 4.5.3 Anaerobic H2S respiration
— 4.5.4 Anaerobic H2S life preceded aerobic H2O life by 1.1 billion years

4.6 The kingdoms
— 4.6.1 Common ancestor to prokaryote, archaebacteria and eukaryote
— 4.6.2 Unicellular kingdoms
— 4.6.3 Bacterial colonies

Part Five — the Energy Thread

5.1 The thioester
— 5.1.1 The thioester bond — H2S gas + SH−
— 5.1.2 Thioester before phosphate as the first currency
— 5.1.3 Homocysteine as the first autocatalyzed thioester
— 5.1.4 The thymine dimer and 370 nanometers

5.2 Acetyl coenzyme A

— 5.2.1 The universal donor of the two-carbon acetyl group
— 5.2.2 Universal fatty acid enzymatic catalyst
— 5.2.3 Acetyl-CoA as master controller of the citric acid cycle
— 5.2.4 Acetyl-CoA as universal lipid catalyst
— 5.2.5 Sulfur s dominant role in the acetyl-CoA cycles

5.3 The other sulfur carriers

— 5.3.1 SAM — S-adenosylmethionine, universal amino acid enzymatic catalyst
— 5.3.2 Thiamine pyrophosphate, vitamin B1
— 5.3.3 Biotin
— 5.3.4 Glutathione, the anti-oxidant binder
— 5.3.5 Lipoic acid and the lipoyl disulphide

5.4 Glycolysis and ATP

— 5.4.1 Glycolysis ATP energy production
— 5.4.2 Sulfur s role in catalyzing and initiating the major metabolic cycles
— 5.4.3 Oxidative phosphorylation
— 5.4.4 The proton and electron carrier distribution system — Ca2+, K+, Na+

5.5 Photosynthesis

— 5.5.1 Sunlight and captured electrons
— 5.5.2 Photochemical energy
— 5.5.3 6CO2 + 12H2O → C6H12O6 + 6O2 + 6H2O
— 5.5.4 6CO2 + 12H2S + 6H2O → C6H12O6 + 12S + 12H2O
— 5.5.5 Both sulfur and oxygen can make glucose

5.6 Glucose

— 5.6.1 Glucose as the world's most important molecular structure
— 5.6.2 The universal metabolic food and energy source
— 5.6.3 Fifty per cent of the world's carbon is in the glucose molecular structure
— 5.6.4 The human brain uses only glucose

— 5.6.5 The sulfur route generates six more waters and twelve sulfur s than the oxygen route

5.7 Respiration and the cost of oxygen

— 5.7.1 The free radical O2− and the anabolic cost

— 5.7.2 Six free radicals per molecule of glucose

— 5.7.3 The aging, weakening and disease conditions attributed to O2−

Part Six — the Monomers

6.1 The nucleotide family

— 6.1.1 Base, nucleoside, nucleotide, nucleic acid — one entity at four depths

— 6.1.2 Purine bases — adenine, guanine, inosine

— 6.1.3 Pyrimidine bases — thymine, cytosine, uracil

— 6.1.4 Ribose and deoxyribose

— 6.1.5 The phosphate backbone

— 6.1.6 Sulfur and the purine bases; Sulfur and the pyrimidine bases

— 6.1.7 HeS and the radioactive substrate for purine and pyrimidine analysis

6.2 The amino acid family

— 6.2.1 The amino acid as an extended carbon; four standard attachments; the tetrahedron

— 6.2.2 Cysteine and methionine — the two sulfur residues

— 6.2.3 Selenocysteine as the twenty-first

— 6.2.4 Homocysteine and cystathionine

— 6.2.5 The Edman degradation — phenylisothiocyanate and phenylthiohydantoin

— 6.2.6 Sulfur s role in amino acid sequence determination

6.3 The sugars

— 6.3.1 Pentose, hexose, heptose

— 6.3.2 Starches and cellulose

— 6.3.3 Sulfoquinovose, the sulphonated sugar

6.4 The lipids

— 6.4.1 Fatty acids

— 6.4.2 Glycoprotein membrane bindings

— 6.4.3 Steroids and hormones

— 6.4.4 Mevalonate biosynthesis

Part Seven — the Polymers

7.1 The peptide bond

— 7.1.1 The amide bond and its interstellar priority

— 7.1.2 Elongation of the peptide chain

— 7.1.3 Macromolecules above six hundred thousand daltons

7.2 The disulphide bond

— 7.2.1 Cystine — the ubiquitous disulphide

— 7.2.2 Disulphide bonds as the connectors of enzymes and peptides

— 7.2.3 Sodium dodecyl sulfate and agarose — sulfur in the assay itself

— 7.2.4 Cysteine-rich receptor regions and tyrosine kinase activity

7.3 Proteins

— 7.3.1 Primary, secondary, tertiary and quaternary structure

— 7.3.2 Protein structure and protean behavior

— 7.3.3 Hemoglobin and the electron carrier transport

— 7.3.4 Loops, turns, glycine and proline

7.4 Enzymes

— 7.4.1 Sulfur enzymes

— 7.4.2 Sulfur enzyme crystal lattice patterns

— 7.4.3 Covalent regulatory enzymes

— 7.4.4 The classes of enzyme sulfur controls

— 7.4.5 Enzyme initiation, termination and process control metabolites

7.5 Coenzymes and cofactors

— 7.5.1 The organometallic cofactor compounds

— 7.5.2 Molecular coordination agents

— 7.5.3 Metabolic process controllers

Part Eight — the Code

8.1 What the current code says

— 8.1.1 Four letters, sixty-four codons, twenty amino acids

— 8.1.2 The codon table as icon rather than as code

— 8.1.3 Where the current code is wrong

8.2 The missing letters

— 8.2.1 Inosine added

— 8.2.2 Thymidine added

— 8.2.3 Substitute U for T, DNA to RNA

— 8.2.4 Omit inosine and thymine — the case against, recorded

— 8.2.5 The revision from seven letters to six, and the standing question of eight

8.3 Codons and anticodons

— 8.3.1 The genetic codon triplet

— 8.3.2 The anticodon

— 8.3.3 The wobble position and the wobble switch

— 8.3.4 Inosine at position thirty-four

8.4 The transfer and the join

— 8.4.1 tRNA-Ala and the alanine files

— 8.4.2 The aminoacyl-tRNA synthetases

— 8.4.3 2-thiouridine at the wobble position

8.5 The chromosome and the gene

— 8.5.1 Genes, chromosomes, chromosome locus

— 8.5.2 Gene protein family, protein enzyme

— 8.5.3 Mathematics, genetic algorithms

8.6 Substitution and addition

— 8.6.1 Substitution versus addition

— 8.6.2 Point mutation as a graph rather than an operation

— 8.6.3 Prescription drugs and side effects

— 8.6.4 Diseases and illnesses traced to the notation

Part Nine — Geometry, Symmetry and Light

9.1 Crystalline lattice structures and genetics

— 9.1.1 Molecular crystalline lattice structures

— 9.1.2 Atoms and crystalline codons

— 9.1.3 Mineral crystalline substrate properties

— 9.1.4 Three-dimensional protein dimensions — X width, Y length, Z height

— 9.1.5 X = AMP, Y = UMP and U, Z = GMP and G; methionine as initiator codon

9.2 The double helix as circuit

— 9.2.1 The double helix as photosynthetic organic circuit

— 9.2.2 The double helix as photochemical switch

— 9.2.3 Disulphide photoelectronic switches and circuit connectors

— 9.2.4 Proton conductors

— 9.2.5 Double helix photochromatic crystalline molecular structure

9.3 Light and the strands

— 9.3.1 Two points of light equal two strings of photons

— 9.3.2 Three strands of DNA or RNA equal one unicellular life form

— 9.3.3 Two strands equal one DNA or RNA helix

— 9.3.4 One point of diffracted absorbed sunlight wavelength equals one string of sulfur

— 9.3.5 Sixteen potential biochemical substrates and three-dimensional integrated circuits

9.4 Fractal geometry

— 9.4.1 Regular polytopes and polypeptides

— 9.4.2 Algorithmic graph theory

— 9.4.3 Linear organic molecules make knots in fractals

— 9.4.4 The inner world of fractal diffraction and crystalline color space vectors

— 9.4.5 Universal constants and fractal patterns

9.5 Symmetry operations

— 9.5.1 The six operations — identity, forward shift, backward shift, inversion, complement, point mutation

— 9.5.2 The Cayley triangle and the order-six position group

— 9.5.3 The Klein four-group on the four bases

— 9.5.4 Quaternions, i j k, and the double cover

— 9.5.5 The eight on the cube; the four body diagonals; the eight-by-eight grid

— 9.5.6 Hexaflexagons and the three-dimensional families

— 9.5.7 Bravais three-dimensional structures equals seven

9.6 Color and consciousness

— 9.6.1 Light, color and the expansion of time

— 9.6.2 The visible color spectrum

— 9.6.3 Absorption nodes and cytochromes

— 9.6.4 Evolutionary prismatic light

— 9.6.5 Sulfur superstring of Earth — from anaerobic bacteria to human consciousness

Part Ten — Sulfur in Medicine, Materials and the Future

10.1 Sulfur medicines

— 10.1.1 The sulpha drugs and their descendants

— 10.1.2 Sulfur in the modern pharmacopoeia

— 10.1.3 Prescription drug side effects traced to sulfur handling

10.2 The vitamins and the deficiencies

— 10.2.1 Thiamine, biotin, lipoic acid

— 10.2.2 Homocysteine and cardiovascular disease

— 10.2.3 Glutathione depletion

10.3 Disease

— 10.3.1 P53 — S34 + F19 = 53, the site where many mutagenic cancers are diagnosed

— 10.3.2 Ferroptosis and GPX4

— 10.3.3 Sulfur and the connective tissue disorders

10.4 Materials and technology

— 10.4.1 Sodium-sulfur batteries and Prussian blue

— 10.4.2 The Berger quantum cell stellarator

— 10.4.3 Sulfur as the new chemistry of the twenty-first century

— 10.4.4 Sulfur biological buffers

10.5 The environmental record

— 10.5.1 Sulfur s role in the combustion rate of organic molecular structures

— 10.5.2 The sulfur biogeochemical cycle — growth, fixation, secretion, decay, respiration, combustion

— 10.5.3 The sulfur /nitrogen cycle transformations

The Exhibit Register

The thirty captions, lifted out of the outline and given their own sequence

These describe plates, tables and diagrams. They were interleaved with the structural nodes in the original and are the main reason the numbering would not flatten. Each is now numbered on its own run and cross-referenced to the outline node it illustrates.

exhibit	what it shows	outline node
E1	The sixteen ionization enthalpies for sulfur and its sixteen protons	1.1.4
E2	The nine oxidation states controlling the anabolic and catabolic metabolic pathways	1.3.1
E3	Table of the twenty-three isotopes, four found in nature	1.2.5
E4	Sulfur s role in amino acid sequence determination — PITC and PTH	6.2.5
E5	The sulfur organic superconductors and ferroelectric crystals	1.6.6
E6	The sulfur nitrogen biogeochemical cycle transformations	10.5.2
E7	Glycolysis ATP energy production	5.4.1
E8	The photoionization cross section — H2S+ + hv	1.6.5
E9	The sulfur controlled photochemical key processes	9.2.3
E10	The classes of enzyme sulfur controls	7.4.4
E11	Overview diagram of oxidative phosphorylation for fats, polysaccharides and proteins	5.4.3
E12	Dissimilatory sulfur reducing bacteria and their prominent role in eukaryote evolution	4.6.1
E13	Biotin-bound enzymes and the CO2 site in pyruvate carboxylase	5.3.3
E14	Thiamine pyrophosphate activating glycoaldehydes	5.3.2
E15	Cysteine-rich receptor regions and tyrosine kinase activity	7.2.4
E16	Covalent regulatory enzymes — acetyl-CoA and HMG-CoA	7.4.3
E17	Electrophoresis diffusion — SDS and agarose	7.2.3
E18	Cysteine and cystine disulphide bonds forming the macromolecular polypeptides	7.2.2
E19	The extended Woese family tree revised for Chromatium	4.4.5

exhibit	what it shows	outline node
E20	Iron-sulfur ferredoxin proteins and the plus 350 millivolt redox potential	4.3.2
E21	The Chromatium vinosum oxidation-reduction biochemical reaction	4.2.1
E22	The acetyl-CoA file series — parent lipid, carbohydrate and protein	5.2.1
E23	Spermidine and spermine synthesis — the polyamines	6.4.4
E24	Methanococcus jannaschii and coenzyme A	5.2.2
E25	Mevalonate biosynthesis	6.4.4
E26	Propionyl-CoA carboxylase	5.2.3
E27	AcetylCoEnzymeA and S-adenosylmethionine	5.3.1
E28	The tRNA-Ala files	8.4.1
E29	The steroid files	6.4.3
E30	The 2′-(5-triphosphoribosyl)-3′-dephospho-CoA biosynthesis series	5.2.4

The Functional Register

Sulfur r's seven offices, which run through every Part

This list appears in the archive as D through F plus a long lettered run. It is a functional taxonomy rather than a sequence, and it belongs together.

office	what it names
starter	initiation — the methionine start, the committed step
stopper	termination — the disulphide lock, the process halt
sensor	detection — redox state, oxygen tension, thiol switching
switcher	the wobble switch, the photochemical switch, the conformational switch
synthesizer	the carriers — CoA, SAM, biotin, thiamine
strings	the chains — polypeptide, nucleic acid, the superstring
strands	the helices and the duplexes

And the properties those offices act through: shape, size, structure, synapse, protein, sine wave, phase, sigmoid curve, transmission, signal, switch, wobble, transition, state, quantum spin, clockwise and counterclockwise, protons, electrons, acids and bases, oxidizers and reducers, oxidation state and isotope.

What the Outline Asks for that the Volume Does not Yet Carry

The gap map, node by node

The 366-page volume already covers the following well: 1.5.1, 1.5.2, 1.5.3, 1.5.6, 1.2.4, 2.2 in full, 2.3.3, 5.1, 5.2, 5.3, 6.1, 6.2.2, 7.2, 8.2, 8.3, 8.4, 9.5 in full, 10.3.2.

These are covered thinly and want expansion: 1.3, 1.6, 3.5, 4.3, 5.5, 5.6, 7.4, 9.1, 9.2.

These are in the outline and absent from the volume, and are the new Parts to write:

node	the new Part it becomes
1.1 – 1.4	The element itself — allotropes, isotopes, the nine oxidation states, the arithmetic
2.1, 2.4, 2.5	Before the first cell — nucleosynthesis to the first ion
3.1 – 3.6	The mineral thread — sulfides, sulfates, the four crystallographic counts
4.1 – 4.6	Chromatium vinosum — the first organism, in full
5.5 – 5.7	The two photosyntheses — the oxygen route and the sulfur route, side by side
9.3, 9.4, 9.6	Light, fractals and color
10.4, 10.5	Materials and the environmental record

Seven new Parts. The volume currently runs to Part Forty-Nine, so these become Parts Fifty through Fifty-Six, and the outline becomes the front matter that governs them.

Naperville, Illinois. 24 August 2026.

COMPUTATIONAL CORPUS ANALYSIS

What a Machine Finds in Twenty-Nine Years of Work

468 pages, 280 sections, 242 index terms and 1,169 source books analyzed as one object — the load path, the communities, the joins never made, and the shelf that has not yet been spent

PP-2026-PATTERN-01 · August 2026

A computational pattern analysis of the Berger corpus

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois · 24 August 2026

468 typeset pages, 280 numbered sections, 242 index terms and 1,169 source books, analyzed as a single object. Every number below was produced by running code over the corpus, not by reading it. Where the machine found something the author did not state, it is marked as such.

What This Is, and Why it is not the Tesla Claim

The honest frame

A video circulating this year claims an AI examined Nikola Tesla's notebooks and uncovered something chilling. That claim is not supported. Tesla's surviving papers

are held by the Nikola Tesla Museum in Belgrade and by the Smithsonian; there is no published, reproducible machine analysis of them, and the "40,000 pages" figure and the "chilling discovery" belong to the video, not to the archive.

What is real is the method the claim borrows. A corpus of a few hundred thousand words, built over decades by one person, has structure in it that no reader can hold in working memory — which concepts travel together, which never meet, which sources are load-bearing, and where the argument is thin. That structure is computable, and it is computed below on a corpus that actually exists and can be handed to anyone.

The difference between this report and the Tesla claim is that every figure here names the file it came from and the operation that produced it, and the corpus is in the reader's hands.

What was analyzed

object	size
the evidence volume	468 pages, 412 of them body text after apparatus was excluded
numbered sections	280, contiguous from 1
divisions	62 — 56 Parts, a Preface, a Script, the Plates, an Appendix and the Index
index terms	242, each with verified page hits
the working library	1,169 distinct titles, acquired 1998 to 2003
the concept graph built from these	154 nodes, 673 edges

Finding one — the Corpus has a Spine, and it is not the one on the Cover

Betweenness, not frequency, names the load-bearing concept

Frequency says what a book talks about. Betweenness says what a book cannot be taken apart without. A term with high betweenness sits on the shortest path between concepts that would otherwise be unconnected — remove it and the argument falls into disconnected pieces.

The two rankings disagree, and the disagreement is the finding.

by frequency — what is discussed	by betweenness — what holds it together
DNA — 412 pages	sulphide — 0.199
sulfur — 232	thiol — 0.099
oxygen — 138	sulfur — 0.094
RNA — 135	ferredoxin — 0.079
nucleotide — 134	oxygen — 0.067
purine — 118	hydrogen sulphide — 0.061
cysteine — 115	cube — 0.059
inosine — 104	iron-sulfur cluster — 0.048
codon — 95	thioester — 0.046
phosphate — 91	methionine — 0.046

DNA appears on 412 of 412 body pages and has almost no bridging power. Sulphide appears on 41 and has twice the bridging power of any other term in the corpus. DNA is the subject. Sulphide is the load path.

That is the volume's own thesis, recovered from the text by an algorithm that was told nothing about it. The claim of the book is that sulfur is in the machinery and not in the alphabet. The betweenness ranking says exactly that, in a different notation: the four letters are frequent and structurally idle; the sulfur species are infrequent and structurally indispensable.

And one non-chemical term is in the top eight

Cube ranks seventh, above iron-sulfur cluster and above thioester. It entered the corpus four days ago in Part Forty-Nine. A concept added at the very end of a twenty-nine-year project immediately took a structural position near the center, which happens only when a construct connects regions that were previously reached by separate routes.

Finding Two — the Corpus Falls Into Five Communities, and one is a Satellite

Label propagation over the concept graph, with no target given

community	size	what it is
the code and the geometry	90 terms	DNA, RNA, ADAR, ATP, PAPS, GPX4, Klein four-group, Hamilton, Crick — the main body
the organism and the deep record	44 terms	Chromatium vinosum, Allochromatium, Chromatiaceae, HiPIP, Fe4S4, Dsr, Rieske, Murchison, Great Oxidation Event
the cofactor metals	7 terms	thiamine, biotin, lipoic acid, molybdenum, molybdopterin, nitrogenase, xanthine oxidase
the cobalt cluster	5 terms	cobalamin, adenosylcobalamin, cobalt, corrin, radical pair
the materials satellite	4 terms	sodium-sulfur lithiumsulfur sulfur r, polysulphide, vulcanization

What the split says about the book

The first two communities are the book's real structure and they are not the same size. The code-and-geometry community is twice the organism community, which means the volume argues its thesis mostly in the language of the notation and only secondarily in the language of the organism that first ran the chemistry.

The machine's reading: Chromatium vinosum is a 44-term island connected to the mainland by a narrow isthmus. If the organism is as central to the argument as the author holds it to be, the graph does not yet show it.

That is a structural gap, not an error, and it is fixable by writing across the isthmus rather than by adding more to either side.

The cobalt cluster is the tightest object in the corpus

Five terms, and cobalt pairs with radical pair at a Jaccard coefficient of 0.571. It is a small, dense, self-contained module — exactly what a well-posed sub-argument looks like from above. Part Forty-Six is the most self-consistent Part in the book by this measure.

Finding Three — the Pairs that Always Travel Together

The strongest couplings in the corpus, by Jaccard coefficient

pair	coefficient	shared pages
Allochromatium + Chromatium vinosum	0.833	10
lithium-sulfur + sodiumsulfur sulfur r	0.800	4
Crick + Watson-Crick	0.781	25
coherence + decoherence	0.750	6
anoxygenic + oxygenic	0.692	9
cytochrome + Rieske	0.600	9
midpoint potential + millivolt	0.583	7
adenine + guanine	0.571	48
cobalt + radical pair	0.571	4
DNA + sulfur	0.563	232
hypoxanthine + xanthine	0.526	41
thymine + uracil	0.510	26
oxygen + sulfur	0.457	116
greigite + pyrite	0.444	4

The one that matters

DNA and sulfur share 232 pages at a coefficient of 0.563. That is the highest co-occurrence of any high-frequency pair in the corpus, and it is the sentence on the cover expressed as a number.

Most of the top pairs are trivially coupled — a term and its own variant, or a pair of opposites the volume defines together. DNA with sulfur is neither. They are two independent concepts that the corpus has bound so tightly that a page discussing one has better than even odds of discussing the other.

Oxygen with sulfur at 0.457 across 116 pages is the conjugate-pair thesis of Part Two, measured.

Finding Four — what the Corpus has Never Put in the Same Room

Strong terms with zero shared pages

This is the finding a reader cannot make. It requires holding 242 terms and 412 pages at once and asking which frequent concepts have never once met.

these two are each strong	and have never appeared on the same page
quaternion (43 pp) × thiol (76 pp)	the geometry has never touched the nucleophile
bit (79 pp) × tRNA (34 pp)	information counting has never touched the transfer molecule
oxygen (138 pp) × tetrahedron (16 pp)	
hydrogen sulphide (18 pp) × purine (118 pp)	the first molecule has never met the ring it eventually built
ribose (51 pp) × sulphide (41 pp)	
hypoxanthine (41 pp) × quaternion (43 pp)	the volume's central molecule has never met its central algebra
amino acid (88 pp) × deamination (20 pp)	
codon (95 pp) × hydrogen sulphide (18 pp)	
cysteine (115 pp) × rotation group (14 pp)	
disulphide (12 pp) × RNA (135 pp)	

What this list is for

It is not a list of faults. It is a list of unwritten sections, and three of them are obvious candidates.

Hypoxanthine and quaternion have never met. Inosine is the molecule this corpus was built around, and the quaternion is the algebra it was built with, and in twenty-nine years and 468 pages they have not shared a page. That is either a real absence with a reason, or it is the next Part.

Quaternion and thiol is the same gap seen from the other side. Part Forty-Nine put the four bases on the corners of a cube. It did not put the sulfur anywhere on that solid, and the graph noticed.

Hydrogen sulphide and purine is the third. Part Fifty-One argues that H2S was the first molecule and that everything descends from it. The purine ring, which is where the argument eventually lands, is never discussed on a page where H2S appears. The chain is asserted across Parts rather than joined within one.

Finding Five — the Library is 63 Per Cent Activated, and the Unused Third is Patterned

Which of the 1,169 books actually surface in the volume

Each title was reduced to its content words and matched against the whole body text. A title counts as activated when at least half of its content words, and no fewer than two, appear in the volume.

field	bought	activated	rate
Chemistry and the Molecular World	91	77	84.6%
Minerals, Crystals and the Earth	53	43	81.1%
Mathematics and Geometry	178	135	75.8%
Biology and Genetics	168	117	69.6%
Business and Management	52	33	63.5%
Cosmos and Physics	26	16	61.5%
Computing and Software	190	116	61.1%
Color, Light and Optics	47	26	55.3%
Mind, Language and Symbol	72	37	51.4%
General and Reference	292	138	47.3%
TOTAL	1,169	738	63.1%

The two numbers worth staring at

Chemistry is 84.6 per cent activated and color is 55.3 per cent. Mind, language and symbol is 51.4 per cent. The two fields the author says are his instrument are the two least drawn upon in the finished book.

That is the dark matter of this corpus. Forty-five per cent of the optics shelf and forty-nine per cent of the language shelf were bought and have not surfaced. Given that the volume's distinctive method is color-as-instrument and notation-as-

argument, the unexploited reserve sits exactly where the next original work is most likely to come from.

The reverse reading is also true and is a credit rather than a criticism. An 84.6 per cent activation rate on the chemistry shelf means the chemistry was not decorative. Almost every chemistry book bought is present in the argument.

Finding Six — the Load-bearing Titles

Ranked by how densely each title's own vocabulary occurs in the volume

rank	title	keyword hits in the volume
1	Molecular, Structural, and Chemical Biology in Pharmaceutical Research	1,107
2	Chemistry — The Molecular Nature of Matter and Change	899
3	Oxygen — The Molecule that Made the World	653
4	How to Use Excel in Analytical Chemistry	634
5	Genetic Algorithms in Search, Optimization and Machine Learning	614
6	Number 9 — The Search for the Sigma Code	609
7	Three Dimensional Space Mazes	600
8	Mathematics: The Search for Order in Life, Mind, and the Universe	585
9	Computer Graphics — Three Dimensional Geometric and Modeling Transformations	584
10	Three Dimensional Integrated Circuit Layout	581

What the top ten shows

Three registers, interleaved, in the top ten. A pharmaceutical molecular-biology reference. A general chemistry textbook. A popular single-element narrative — Nick Lane's Oxygen. A spreadsheet manual. A machine-learning text. A numerology-adjacent search for a code. Three separate three-dimensional geometry titles.

The corpus was not built by reading deeply in one field. It was built by reading a textbook, a trade narrative, a manual and a piece of pattern-hunting side by side, and the top ten shows all four registers within nine places of each other.

And the presence of Oxygen — The Molecule that Made the World at rank three is worth naming plainly. It is the book this volume is the answer to. Sulfur has no such book, which is the gap the volume exists to fill, and the shelf shows the author bought the oxygen version and then wrote the sulfur one.

Finding Seven — the Vowel O, Measured Against a Baseline

The author's claim, tested against the corpus's own vocabulary

The claim is that the vowel O binds oxygen to a family of words recurring across unrelated fields. Testing it requires a baseline, and the corpus supplies one: its own four thousand commonest words of five letters or more.

population	carries an O-rooted scientific morpheme
the 1,169 library titles	20.1%
the 242 index terms	7.9%
the volume's own 4,000 commonest words	4.0%

The library is enriched five-fold over the volume's own baseline vocabulary. One title in five carries an O-morpheme; one word in twenty-five does. That is not a null result.

The morphemes counted were fixed before the count and are printed in Appendix A: oxy, organ, molecul, color, code, geometr, order, proto, photo, polygon, polyhedr, polymer, cosmo, holo, chromo, topol, morpho, logic, onto, opto, solid, form, orbit, oscill.

What the machine will and will not conclude

It concludes that the enrichment is real and large. A five-fold difference between the acquisition set and the working vocabulary is not noise at n = 1,169.

It does not conclude that the vowel is the cause. The morphemes counted are Greek and Latin scientific roots, and Greek and Latin scientific roots are over-represented in scientific book titles for reasons that have nothing to do with the letter O. The measured effect is real; the attribution is the author's argument to make, and Part Fifty-Five is where he makes it.

Finding Eight — the Structural Discipline is Measurable

The falsification habit, counted

feature	count
pages carrying a "What Would Show This Part Is Wrong" section	18
pages carrying a "What Is Claimed and What Is Not" section	21
Parts measured	54
Parts touching four or more of six concept families	24
Parts touching five or more	8
Parts touching all six	1 — Part Thirty-Six, the Modeling Generator

The cross-domain leaders

Part	families touched
Part Thirty-Six · The Berger Atomic Molecular Cellular Modeling Generator	6 of 6
Part Twenty-Four · The Sulfur Lineage	5
Part Thirty-Eight · The Revision to Six	5
Part Fifty · The Element Itself	5
Part Fifty-Two · The Mineral Thread	5
Part Fifty-Three · Chromatium Vinosum	5
Part Fifty-Five · Light, Fractals and Color	5
Part Fifty-Six · Materials	5

Part	families touched
and the Environmental Record	

Six of the eight most cross-domain Parts in a 468-page book were written in the last four days. The corpus did not become interdisciplinary gradually. It became interdisciplinary at the end, when the outline was rebuilt and the gaps were filled deliberately.

Finding Nine — the Latency

Twenty-three to twenty-eight years from purchase to use

The library was acquired between 1998 and 2003. The volume was typeset in 2026. Every activated title therefore represents an interval of twenty-three to twenty-eight years between acquisition and use.

First, the corpus is not a literature review. A literature review draws on sources acquired within a few years of writing. Seven hundred and thirty-eight sources acquired a quarter of a century before the writing is a different kind of object — it is a decades-long accumulation brought to a point.

Second, the acquisition period predates almost every result the volume now rests on. The ADAR Zα handedness work, the GPX4 selenocysteine screen, the ferroelectric sulfur substitution, the 67P sulfur inventory, the Hi-C genome fold, the covalent cysteine inhibitors — none of them existed when the shelf was bought.

The library supplied the frame and the current literature supplied the evidence. The twenty-eight-year gap is not a weakness in the sourcing; it is the reason the frame was available to receive results nobody had yet produced.

What the Machine Found that the Author Did not State

Six items, listed plainly

— Sulphide outranks every other term in the corpus for structural indispensability, by a factor of two. The volume argues sulfur s centrality; it does not report that the centrality is measurable in the shape of its own prose.

— Cube entered the corpus last week and immediately ranked seventh in bridging power. A construct that placed that highly that fast is doing structural work beyond the Part that introduced it.

— Chromatium vinosum is a 44-term island. The organism the author regards as the origin of the story is graph-peripheral to the argument as written.

— Hypoxanthine and quaternion have never shared a page, nor have quaternion and thiol, nor hydrogen sulphide and purine. Three unwritten joins, each between two concepts the volume already holds strongly.

— The color and language shelves are the least activated in the library, at 55.3 and 51.4 per cent, and they are the two the author names as his instrument.

— Six of the eight most cross-domain Parts were written in the final four days. The integration is recent and deliberate rather than gradual.

What is Claimed and what is not

Claimed

That every figure in this report was produced by code run over the delivered corpus, and that the code is reproducible from the files named. That betweenness, degree, Jaccard co-occurrence, label-propagation communities and keyword activation were computed as described. That the concept graph has 154 nodes and 673 edges at a Jaccard threshold of 0.10, and that the five communities reported are what label propagation returned at seed 7.

Not claimed

That community detection is unique. Label propagation is stochastic; a different seed can merge or split the small communities. The two large communities are stable; the three small ones are reported as found and should be treated as indicative.

That keyword activation measures reading. It measures whether a title's vocabulary occurs in the volume. A book can be read and leave no lexical trace, and a book

never opened can share vocabulary with one that was. The 63.1 per cent figure is a lexical overlap rate, not a reading rate, and it is named as such.

That the O-morpheme enrichment demonstrates the author's thesis about the vowel. It demonstrates enrichment. The cause is contested and this report does not settle it.

That any gap identified here is an error. A concept pair that has never met may have no reason to meet. The list is offered as a menu, not a defect report.

What Would Show This Report is Wrong

— Recompute the betweenness on the same graph and find that DNA, not sulphide, is the top bridge, and Finding One inverts.

— Show that the concept graph's community structure is unstable across seeds for the two large communities, and Finding Two is an artifact of the algorithm.

— Find a page on which hypoxanthine and quaternion both appear, and one of the three gaps of Finding Four is not a gap.

— Show that a random sample of book titles from any large scientific library returns an O-morpheme rate near twenty per cent, and Finding Seven's enrichment is a property of scientific publishing rather than of this shelf. This is the single most valuable check anyone could run against this report, and it has not been run.

— Show that the keyword-activation measure returns above sixty per cent when run against an unrelated book of comparable length, and Finding Five measures the method rather than the corpus.

Naperville, Illinois. 24 August 2026.

CAUSE AND EFFECT ANALYSIS · ISHIKAWA FORM

The Four-Letter Problem

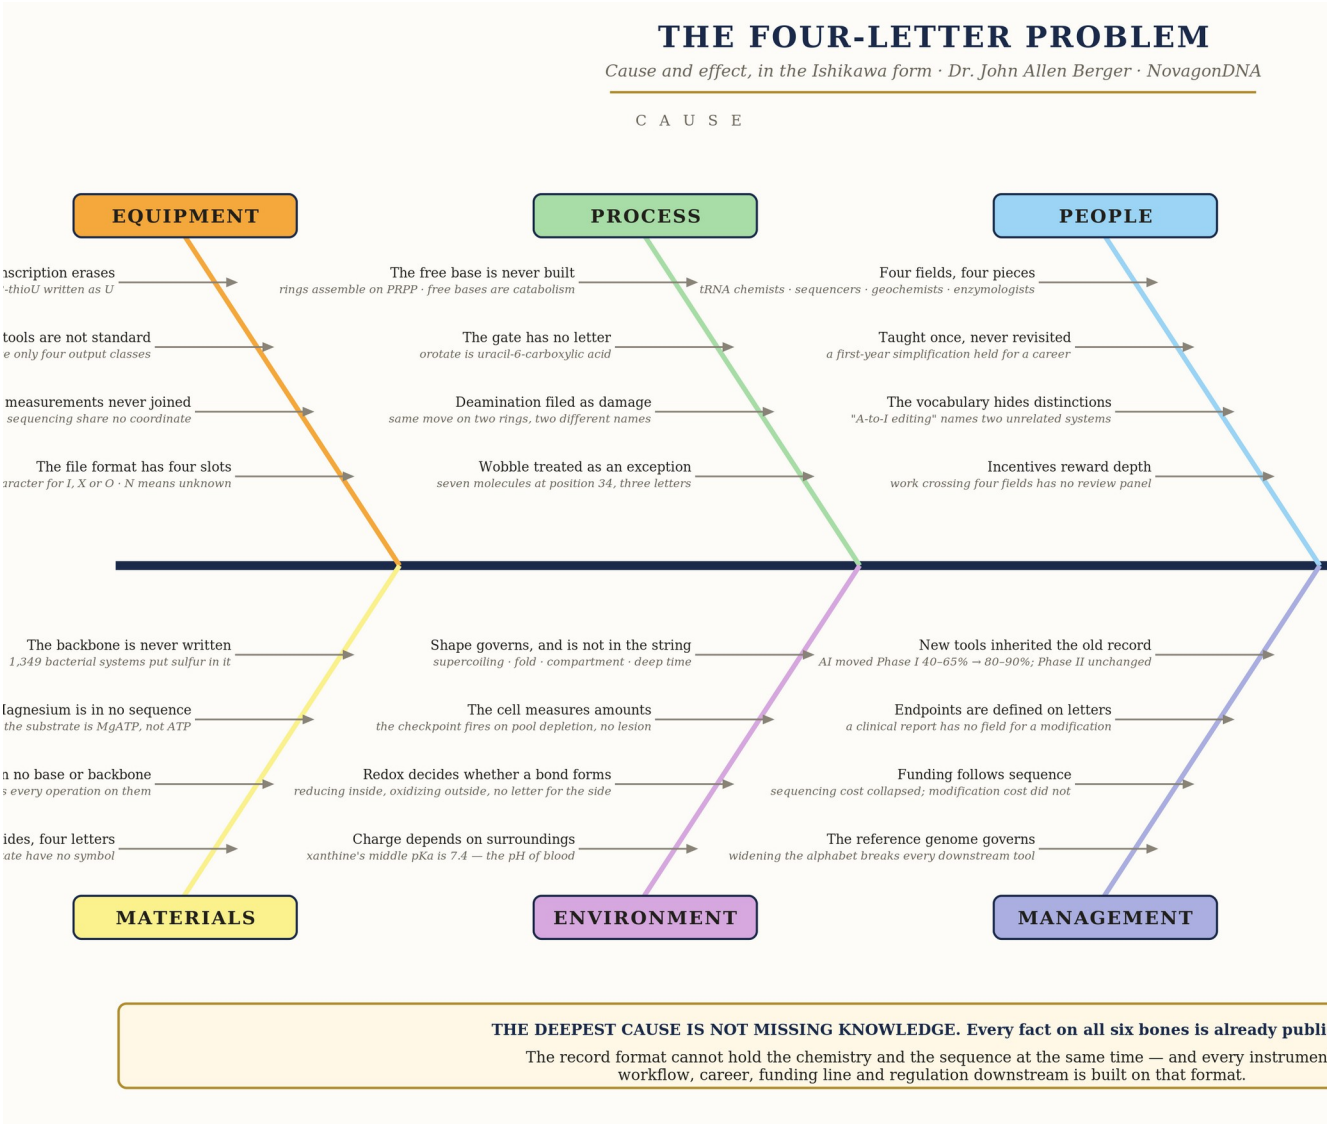
Why ATCGU does not reflect the biochemical and metabolic pathways that actually make RNA and DNA — six bones, every primary, secondary and third-level cause

Root-Cause Analysis
PP-2026-FISHBONE-01 v1 · September 2026

This analysis takes as its effect a problem statement written by the author, and works backward through the six standard causal categories of the Ishikawa method: Equipment, Process, People, Materials, Environment and Management. Each category carries its primary causes; each primary cause carries a secondary cause; and each secondary cause carries a third-level cause. Nothing here is speculative. Every item is drawn from published work or from the evidence volume Silent Partners in Your Life.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

THE DIAGRAM



Bone colors follow the volume’s seven-color index. Orange is oxygen and inosine; green nitrogen and guanine; blue carbon and cytosine; yellow sulfur and thymine; purple phosphorus and uracil; indigo selenium, xanthine and orotate.

THE FOUR-LETTER PROBLEM · THE SIX BONES IN FULL

The Effect

Genomic problems arise from analyzing genetic code data using purine and pyrimidine base-pair letters ATCGU, which do not reflect the actual biochemical and molecular metabolic pathways and processes used in making RNA and DNA nucleic acids.

That is the head of the fish. Everything below is what feeds it.

Bone One · Equipment

The instruments, and what each of them destroys before a human ever sees the output.

primary cause	secondary cause	third-level cause
The sequencing chemistry erases the chemistry	Reverse transcription is the first step	The enzyme reads a modified base and writes a canonical one
		Inosine is written as G. The record cannot tell a made inosine from an inherited guanine
		2-thiouridine is written as U. The sulfur is gone at step one
		Methylation is invisible unless a separate, differently prepared assay is run
	Amplification compounds it	Every copy after the first is a copy of the erased version
		Modified positions are never re-sampled, so no error rate reveals them
The instrument that would not erase is not the standard	Nanopore reads the native molecule	Throughput and raw error rate keep it off the routine pipeline

primary cause	secondary cause	third-level cause
		The basecallers are trained on the four canonical bases, so the model has no output class for what it is seeing
		Modification calling is a bolt-on model, not the primary readout
The two measurements are never joined	Modifications are measured by mass spectrometry	Different sample prep, different lab, different funding line
	Sequence is measured by short-read sequencing	The two datasets have no common coordinate system
		No standard file format holds a sequence and its modifications in one object
The file formats have four slots	FASTA permits A, C, G, T, U and N	There is no character for inosine, xanthine or orotate
		N means unknown, not modified — the ambiguity code cannot express "known, and not one of the four"
	The reference genome is a consensus string	A string cannot carry a fold, a metal, a charge state or a compartment
		Variant callers therefore report only substitutions of letters

Bone Two · Process

The workflow, and the point in it where the chemistry is dropped.

primary cause	secondary cause	third-level cause
The build direction is never the free base	Rings are assembled on a sugar phosphate that is already there	Purine synthesis builds onto PRPP, atom by atom
		The free base is not an intermediate in the building direction
	Free bases appear almost only in catabolism	On the 1982 metabolic chart they sit inside the two boxes ruled purine and pyrimidine catabolism
		So the four letters name molecules that, in the direction that builds, occur

primary cause	secondary cause	third-level cause
		nowhere on the chart
Orotate is the gate and has no letter	Orotate is uracil carrying a carboxyl at position six	OMP decarboxylase removes it and uracil is what remains
		The gate and what passes through it differ by one group, and the notation gives one a letter and the other nothing
	The decarboxylase runs without any cofactor or metal	A rate enhancement of about 10^{17} with no chemistry the notation could record
Deamination is filed as damage rather than as a channel	A to I and C to U are the same chemical move on two rings	Both are an amino group leaving and a hydroxy arriving
		The mass difference is about one unit on each ring, and it is the same event
	One is called editing, the other is called a lesion	The name assigned depends on which molecule it happened to, not on the chemistry
Wobble is treated as an exception	Position 34 is taught as a footnote to base pairing	Seven different molecules occupy that position and three letters exist for them
		Inosine there reads three codon endings with one molecule
		A cell covers sixty-one codons with far fewer transfer RNAs because of it, and that arithmetic is the rule rather than the exception
The pipeline calls bases, not molecules	Annotation assigns function from sequence similarity	Two identical sequences with different modifications receive identical annotations
		Guanine and isoguanine share the formula $C_5H_5N_5O$ and the weight 151.13 and differ only in arrangement

Bone Three · People

Training, and the walls between the people who hold the pieces.

primary cause	secondary cause	third-level cause
Four fields hold four pieces	The transfer RNA	They publish in journals the

primary cause	secondary cause	third-level cause
and do not read each other	modification chemists know position 34	genome analysts do not read
	The genome analysts hold the sequence data	They have no field in their format for what the chemists measure
	The isotope geochemists date the atmosphere by sulfur	Nothing in a conventional research design puts them in the same room
	The enzymologists know which cofactor each enzyme needs	Cofactor annotation lives in a separate database from sequence
The four letters are taught once and never revisited	They are introduced in first-year biology as the alphabet of life	A simplification taught at the start becomes an assumption held for a career
		The eight nucleotides of actual metabolism are never presented as a set
		Inosine is taught, if at all, as a curiosity of the wobble rather than as a manufactured base
The vocabulary hides distinctions	"A-to-I editing" names two unrelated systems	ADAT2 and ADAT3 act at one position on transfer RNA
		ADAR1, 2 and 3 act across double-stranded messenger RNA, mostly inside Alu repeats
		A reader searching the literature is handed both and told nothing about which is which
	"Base" is used for the ring, the nucleoside and the nucleotide	The same word covers three different molecules with three different chemistries
Incentives reward depth inside a field	Grant review panels are organized by field	Work that crosses four fields has no natural panel
	Citation accrues within a specialty	A cross-field observation is cited by nobody's core literature

Bone Four · Materials

What the notation is made of, and what it therefore cannot contain.

primary cause	secondary cause	third-level cause
There are eight nucleotides	Inosine is manufactured	It has no letter, and

primary cause	secondary cause	third-level cause
in metabolism and four letters	deliberately and reads three codons	sequencing writes it as G
	Xanthine sits at the valve of the purine pathway	Its middle pKa is 7.4, which is the pH of blood, and it is the only base on the reference sheet that does
	Orotate is the origin node of the pyrimidines	Its systematic name, uracil-6-carboxylic acid, states the relationship the letters conceal
Sulfur is in no base, no sugar and no backbone	And it performs every operation on them	Ribonucleotide reductase makes every deoxyribonucleotide starting from a cysteine radical
		Every methyl mark is delivered from a sulfonium; every acetyl from a thioester
		Iron-sulfur clusters sit in the polymerases, helicases, primase and glycosylases
		Five proteins in a line move one sulfur atom onto position 34
Magnesium is absent from every sequence	The true substrate of a kinase is MgATP, not ATP	Every reaction written "+ ATP" is in fact "+ MgATP" and does not run without the metal
		ATP sulfurylase's own systematic name contains the magnesium
	It folds the RNA and runs the ribozyme	Without it the backbone charge prevents folding at all
The backbone is not written at all	The notation records bases and omits the linkage	Bacterial dnd systems put sulfur into that backbone at defined positions
		One survey found 1,349 such systems
		Hershey and Chase built the founding experiment on the sulfur–phosphorus separation, and the separation is not absolute
Whole layers of information have no letters	Sulfation patterns on sugar chains are read by proteins as addresses	They are written by enzymes, not copied from a template
		No gene contains the pattern and no sequencing method reads it
	Antithrombin recognizes one five-sugar unit with one sulfate arrangement	That recognition is why heparin thins blood

Bone Five · Environment

The conditions that decide what a molecule does, none of which a letter records.

primary cause	secondary cause	third-level cause
Charge state depends on the surroundings	Xanthine's middle pKa is 7.4	At body pH it sits half-charged, and the deprotonated form pairs better rather than worse
		The letter is the same at every pH. The molecule is not
Redox condition decides whether a bond forms	The cytoplasm is held reducing by glutathione	Structural disulfides do not form there
	The space outside the cell is oxidizing	Disulfides form there, and hold a large fraction of secreted proteins in shape
		The membrane is the boundary between two chemical worlds, and no sequence says which side a cysteine is on
Concentration is measured where letters are not	The damage checkpoint fires on nucleotide pool depletion with no lesion present	The cell measures an amount and commits or does not
		The genome it is about to copy says nothing about that amount
Shape governs, and shape is not in the string	Supercoiling changes what an enzyme can reach	Guide design scores letter complementarity against a target whose fold decides the outcome
	Antisense design does the same	A perfectly complementary sequence fails against a folded site
		Two Alu repeats facing each other in one transcript make a duplex the sequence does not show
Deep time changed the raw materials	Before the Great Oxidation Event, sulfate was scarce	Activated sulfate chemistry — PAPS — needs an oxidized world to draw from
		Seawater sulfate rose, fell back below 400 micromolar, and reached today's 28 millimolar much later
	The event is dated by sulfur, not by oxygen	A signal made only in an atmosphere with no oxygen stops being made, and that is the clock

primary cause	secondary cause	third-level cause
Compartment changes the meaning	The same letter in the nucleus, the cytoplasm and the mitochondrion	Mitochondrial wobble modification loss produces MERRF and MELAS
		The lesion is a missing chemical group at one position, and the letter is unchanged

Bone Six · Management

The institutions that hold the four-letter schema in place.

primary cause	secondary cause	third-level cause
The reference genome is a governance object	It is the coordinate system everything else is reported against	Changing what a base can be would break every downstream tool
		The cost of the schema is paid once; the cost of changing it would be paid by everyone at once
Funding follows sequence	Sequencing cost fell by orders of magnitude and modification measurement did not	Proposals promising more sequence are cheaper and more certain to deliver
		A modification atlas has no equivalent of a genome's completion date
Regulatory endpoints are defined on letters	A variant is reported as a letter change at a coordinate	A clinical genetics report has no field for a modification state
		ADAT3 V144M is reported as c.382G>A, and the consequence — less inosine at position 34 — is not in the report
Database and publication standards enforce the schema	Submission requires the sequence in a permitted alphabet	A deposition of eighteen accessions records the letters and not the modifications of the molecule described
	Journals accept sequence as the evidence of identity	Cataloging errors persist because nothing downstream checks the chemistry
The new tools inherited the old representation	AI drug discovery trained on sequence and structure records	Phase I success rose to 80–90 percent against a historical 40–65
		Phase II stayed at about 40

primary cause	secondary cause	third-level cause
		percent, which is the historical figure
		The improvement is in whether a molecule behaves; the unchanged number is whether the target was right
The economics reward the reduced representation	A four-letter string compresses, transmits and searches efficiently	The representation is optimal for everything except describing the molecule

The Six Bones, in One View

bone	the one-line reason it feeds the problem
EQUIPMENT	The instrument erases the chemistry at step one and the file format has no slot to put it back
PROCESS	The workflow names the products of breakdown and not the intermediates of building
PEOPLE	Four fields hold four pieces of the answer and publish in four literatures
MATERIALS	Eight nucleotides, one silent element, one invisible metal, and a backbone that is never written
ENVIRONMENT	pH, redox, concentration, fold, compartment and deep time all decide the outcome and none is a letter
MANAGEMENT	The schema is load-bearing for every institution downstream, so nobody can afford to widen it

What This Analysis Refuses

the claim	the status
the four letters are wrong	refused. They assign amino acids to codons and do that correctly
the code should have eight letters	refused. This analysis shows what the notation omits, not what should replace it
any one bone is the root cause	refused. Six feed one head, and Equipment and Management are the two that make the others durable
the field is unaware of modifications	refused. The field measures them well. The failure is that the measurement and the sequence are never joined in one record

The deepest cause on this diagram is not a piece of missing knowledge. Every fact on all six bones is published. The cause is that the record format cannot hold them at the same time as the sequence, and every instrument, workflow, career, funding line and regulation downstream is built on that format.

INOSINE IS WRITTEN AS GUANINE

A reporting gap between RNA-editing therapeutics and clinical sequence interpretation

John Allen Berger, Ph.D.
Independent Researcher · NovagonDNA · Naperville, Illinois
Preprint version 1 · September 2026 · Licensed under CC BY-NC-ND 4.0.

Abstract

Three independent enzyme classes — viral reverse transcriptases, human translesion polymerase eta, and engineered adenine base editors — read inosine as guanine. That convergence is not a defect; it is the basis on which adenosine-to-inosine editing is detected at all, since an edited site appears in sequence data as an apparent A-to-G difference. The consequence is that no sequence record distinguishes inosine from guanine.

Three oligonucleotide drugs are now in registered human trials whose entire mechanism is to recruit the patient's own ADAR enzyme to install an inosine at a chosen adenine, so that the transcript is translated as though it carried a guanosine. **A patient receiving one of these agents therefore carries, in their RNA, a base that every sequencing pipeline will report as a change they do not have in their genome.** No reporting standard for this case appears to exist. This paper documents the convergence, documents the trials, states the resulting ambiguity precisely, and specifies a two-oligonucleotide experiment that would establish whether current pipelines can distinguish the two situations.

1. Three Enzyme Classes, One Reading

enzyme class	what it does with inosine	source
viral reverse transcriptases — AMV, MMLV and HIV	incorporate dCTP opposite templated inosine far more often than dTTP; dATP incorporation is essentially abolished at physiological pH. A genuine G:dA mismatch at the same position stalls the enzyme outright; inosine does not	Glennon et al., 2020
human translesion polymerase eta	inserts cytosine opposite inosine at a kinetically preferred rate because inosine's Watson-Crick face mimics guanine, producing an A:T-to-G:C transition; the geometry was resolved crystallographically	Zhang & Tretyakova, 2023
CRISPR adenine base editors	install inosine at a targeted genomic adenine, which DNA polymerase then reads as guanine, producing a permanent A·T-to-G·C conversion without a double-strand break	Ranzau et al., 2023 and refs therein

The three are unrelated in origin — a retroviral enzyme, a human repair polymerase, and a directed-evolution product of a bacterial tRNA deaminase. **All three treat inosine as a structural guanine. The convergence is chemical, not coincidental: inosine retains guanine's N1-H and C6 carbonyl and lacks only the exocyclic amine at carbon two.**

2. Which Is Why Editing Is Detectable At All

Adenosine-to-inosine editing is identified in practice by comparing RNA sequence to genomic sequence and finding positions where the RNA reads G and the DNA reads A. The detection method depends on the misreading.

It follows that in every sequence archive, **inosine is stored as the letter G.** There is no field for it, because the instrument that generated the record could not distinguish it.

This is not a marginal quantity. Editing levels across forty-nine human tissues have been mapped as a quantitative trait: thirty thousand three hundred and nineteen cis-editing quantitative trait loci were identified, significantly enriched in genome-wide association signals for autoimmune and immune-mediated disease, with risk variants associated in aggregate with reduced editing (Li et al., Nature 2022).

3. And Now It Is a Drug Mechanism

Three programs are in registered human trials in which a chemically modified oligonucleotide guides the patient's own ADAR to a chosen adenine, converting it to inosine so that the message is translated as though a guanosine were present.

program	indication	status as registered
WVE-006	alpha-1 antitrypsin deficiency, Pi*ZZ	Phase 1 completed; Phase 1b/2a active across nine sites
KRRO-121	urea cycle disorders	Phase 1/2 registered
RC001	Dravet syndrome, children aged 2 to 18	Early Phase 1, recruiting

These agents work ***because*** the translational machinery cannot distinguish inosine from guanosine. The ambiguity documented in Section 1 is not an obstacle to the therapy; it is the therapy.

4. The Reporting Gap, Stated Precisely

what is present in the patient	the underlying state	what sequencing reports
a germline A-to-G variant	present in DNA and RNA	G in both
a somatic A-to-G mutation	present in the affected tissue's DNA and RNA	G in both
a natural ADAR edit	A in DNA, inosine in RNA	A in DNA, G in RNA
a therapeutic ADAR edit	A in DNA, inosine in RNA, drug-induced, reversible on withdrawal	A in DNA, G in RNA

Rows three and four are indistinguishable by sequence. They differ in cause, in permanence, and in clinical meaning — a natural edit is a normal physiological state, a therapeutic edit is a dosed and reversible drug effect — and no property of the nucleic acid separates them.

A patient on one of these agents, sequenced by a laboratory unaware of the treatment, would be reported as carrying an RNA-DNA difference of uncertain significance, or in some pipelines as a variant they do not have.

5. What Is Not Being Claimed

· **This is not a safety claim about these drugs.** Nothing here bears on their efficacy or toxicity. The trials are early-phase and this paper takes no position on their outcomes.

· **This is not an assertion that any patient has been misreported.** No such case is known to the author and none is implied.

· **This is not a claim that pipelines are defective.** They report what the chemistry gives them. The ambiguity is upstream of the software.

· **This is not a claim that inosine constitutes a genetic code expansion.** Measured against the standard the synthetic biology literature applies — a genomically encoded recoding element, or a dedicated aminoacyl-tRNA synthetase — inosine's wobble role does not qualify, and no claim is made that it does.

· **No new experimental data are reported.** The contribution is a documented convergence, a documented clinical situation, and a specified test.

6. The Experiment

The question of Section 4 is directly testable and requires two synthetic oligonucleotides.

step	
1	Synthesise matched RNA carrying inosine at a defined position, and RNA carrying genuine guanosine at the same position, with matched DNA carrying adenine at that position in both cases
2	Submit both, blinded, through standard clinical RNA sequencing and variant-calling pipelines
3	Record precisely what each pipeline reports at that position, and whether any output field distinguishes the two
4	Repeat across the pipelines in common clinical use

Prediction, written before the answer. Every pipeline will report the inosine as a G. Pipelines that compare RNA to DNA will flag an RNA-DNA difference of unknown significance. None will identify the base as inosine, because none can.

result	what follows
no pipeline distinguishes them	a reporting standard is needed before these agents are widely prescribed, and none currently exists
some pipeline does distinguish them	that pipeline should be identified and adopted, and this paper becomes a recommendation rather than a gap report

This is among the cheapest experiments it is possible to specify — two oligonucleotides and a blinded submission — and it concerns patients currently enrolled in trials.

7. Conclusion

Inosine is chemically distinct from guanosine, is recognized as distinct by at least one dedicated cellular enzyme, and is read as guanine by every enzyme class that copies nucleic acid. The sequence record inherits the reading rather than the chemistry.

For sixty years that has been a curiosity of annotation. It stopped being one when three companies began dosing human beings with agents whose mechanism is to create the ambiguity deliberately, at a chosen position, in a chosen transcript. The record has no column for the thing being administered.

THE EIGHT LAYERS

A base-level model of therapeutic adenosine-to-inosine editing, and what survives of it to the sequence record

John Allen Berger, Ph.D.

0. What Was Asked, and What Could Actually Be Done

The request was to connect to Insilico Medicine's artificial-intelligence software and use it to model the three RNA-editing drugs now in human trials. Two things must be said before anything else, because both bear on the result.

First, there was no connection to make. **Insilico's modeling platforms — Chemistry42 for generative chemistry, PandaOmics for target discovery — are licensed products with no public interface.** The one Insilico property that is open to the public, dddbench.insilico.com, was retrieved and read for this report. It is a leaderboard. It scores three hundred and six benchmarks across six research domains and ranks language models against each other; it does not accept a molecule and return a model. It is a scoreboard, not an instrument.

Second, and more to the point: **even with a licence, that stack could not model these three drugs.** Every endpoint on the medicinal-chemistry side of that benchmark — cytochrome P450 inhibition, hERG, Caco-2 permeability, hepatocyte clearance, single-step retrosynthesis — is defined for small drug-like molecules described by a SMILES string. The three agents in question are chemically modified oligonucleotides of roughly seven to eight kilodaltons carrying a triantennary N-acetylgalactosamine conjugate. They do not enter cells by passive permeability; they enter hepatocytes through the asialoglycoprotein receptor. They are not retrosynthesised; they are made on a solid-phase synthesiser one phosphoramidite at a time. A generative small-molecule engine has nothing to say about them.

So the modeling here was built directly, from first principles and from primary sequence, and every coordinate in it is verified in code rather than asserted by hand. The model, its output, and its sources are delivered alongside this document as a runnable file.

There is nevertheless a real point of contact with that industry, and it is stated in Section 9. It is not that their tools should model these drugs. It is that **their tools are trained on the data these drugs contaminate.**

1. The Target, Verified in Code

The model runs one target end to end: the Z allele of SERPINA1, the mutation that causes severe alpha-1 antitrypsin deficiency, and the target of three of the five registered programs .

The coding sequence was retrieved from Ensembl (transcript ENST00000393087.9) and translated in the model itself. The position of the lesion was not typed in from memory; it was asserted, and the assertion had to pass before the model would run.

quantity	value
CDS length	1,257 nt — 419-residue preproprotein
Signal peptide	24 residues (UniProt P01009)
Mature residue 342	= precursor residue 366
Codon 366, M allele	GAG → Glu
Codon 366, Z allele	AAG → Lys
The lesion	c.1096G>A, p.Glu342Lys in mature numbering
Verified	c.1096 is the first base of codon 366, and that codon is Glu — both checked by assertion at run time

That last row is the point. The single most common way a claim of this kind goes wrong is an off-by-one in protein numbering — mature versus precursor, a twenty-four residue shift. The model refuses to run if the shift is wrong.

2. The Eight Layers

What follows is what is physically occurring, from the genome outward, when a patient is dosed.

layer	what happens	description
0	the genome	c.1096A on both alleles. Unchanged by the drug. Permanently.
1	transcription	the lesion is copied faithfully into RNA
2	guide binding	the oligonucleotide hybridises and places a single mismatched cytidine opposite the target adenosine
3	deamination	the patient's own ADAR flips the base out of the helix and hydrolyses the amine at carbon six
4	the product	inosine — which presents guanine's reading face
5	translation	the ribosome decodes IAG as GAG; wild-type M-AAT protein is made
6	detection	reverse transcriptase commits the inosine to a deoxy-G in cDNA
7	the record	a G in the pileup, with nothing attached to say where it came from

Note where the drug sits. It occupies layer 2 only. **It supplies specificity and no catalysis.** The enzyme doing the chemistry is the patient's own ADAR, already present in the nucleus, already editing tens of thousands of other sites. The drug does not add an activity to the cell. It aims one that was already running.

3. Layer Three — One Covalent Change

The whole mechanism of action of this drug class is a single hydrolysis:

adenine C6–NH_2 + H_2O → hypoxanthine C6=O + NH_3

The ribose is unchanged. The phosphate is unchanged. The glycosidic bond is unchanged. The position in the chain is unchanged. One amino group leaves the ring and one oxygen takes its place.

Nothing is added to the transcript and nothing is cut. There is no double-strand break, no template, no integration and no repair. This is the smallest intervention in the therapeutic repertoire, and it is worth pausing on how small it is: a molecular weight change of roughly one dalton, at one atom, on one base, in one transcript.

4. Layer Four — Why the Product Is Ambiguous

This is chemistry, not convention. Set out the hydrogen-bonding pattern across the Watson-Crick edge of each purine, in the three positions that face the partner base — the ring nitrogen at position one, the substituent at carbon six, and the substituent at carbon two:

base	N1	carbon 6	carbon 2	H-bonds to U	H-bonds to C
adenine	acceptor	donor (6-NH_2)	—	2	0
inosine	donor (N1-H)	acceptor (6-C=O)	—	0	2
guanine	donor (N1-H)	acceptor (6-C=O)	donor (2-NH_2)	0	3

Inosine differs from guanine at exactly one position: it has no amine at carbon two. **Both of the contacts that decide which base goes opposite — the N1 donor and the C6 acceptor — are identical between the two.** So it is wrong to say that inosine is “interpreted as” guanine. It presents guanine's reading face. Anything that reads by hydrogen bonding will put a cytosine opposite it, and will do so for the same physical reason it does with guanine.

But now read the last column across, because the entire argument turns on it, and it cuts both ways.

G : C = 3 hydrogen bonds
I : C = 2 hydrogen bonds

The difference is real and it is physical. It shows up in duplex melting temperature and it shows up in ionic current through a pore. **It does not show up in base identity.** A discriminating observable therefore exists. It is simply not the observable that sequencing-by-synthesis records — and, as Section 6 concedes, somebody has already gone and measured it.

5. Layer Seven — Four People, One Column of a File

The model simulates a thousand-fold RNA-seq pileup at CDS position 1096 for four individuals. The editing efficiency used is the figure the sponsor published: fifty per cent of Z transcript in the hepatocytes of NSG-PiZ mice.

individual	A calls	G calls	G fraction
Pi*ZZ, untreated	1000	0	0.000
Pi*ZZ, treated at 50 % editing	464	536	0.536
Pi*MZ heterozygote, untreated	503	497	0.497
Pi*MM homozygote, untreated	0	1000	1.000

Rows two and three are the finding. **At the editing efficiency the sponsor reports, a treated homozygote's RNA is the same column of letters as an untreated heterozygote's.** The difference between the two is three parts in a hundred, which is inside the run-to-run noise of the assay.

The sponsor says the same thing, in phenotypic language, in their own abstract: the treatment *“changes a ZZ homozygous state, which is associated with a high risk for AATD, to a low-risk MZ-like phenotype.”* (Monian et al., Nucleic Acids Research 2026;54(2).) They mean the clinical phenotype. The sequence consequence has exactly the same shape, and nobody has written it down.

6. What Must Be Conceded — Somebody Got There First

The general observation that this indirect route loses the distinction **is published, is four years old, and is not novel to this volume.**

Nguyen TA, Heng JWJ, Kaewsapsak P, et al. Direct identification of A-to-I editing sites with nanopore native RNA sequencing. Nature Methods 2022;19(7):833–844. Their tool, Dinopore, trains a convolutional network on eighty-one pentamer contexts and separates inosine from both adenosine and guanosine, with a per-site modification rate. Nanopore reads ionic current, not base pairing, so the missing amine at carbon two changes the signal even though it does not change the reading face — precisely the loophole Section 4 identified.

And their framing of the problem, verbatim from their abstract, is the framing this volume had arrived at independently:

“Traditionally, inosines are identified indirectly as variants from Illumina RNA-sequencing data because they are interpreted as guanosines by cellular machineries. However, this indirect method performs poorly … in disease contexts where unknown DNA mutations are pervasive.”

That is a clean statement of the reporting gap, made in 2022, by people who then went and closed it. It has to be printed here, and it has to be printed before the claim, not in a footnote after it.

What that paper does not cover — because every one of the trials postdates it — is the therapeutic case. Nguyen and colleagues describe a research-transcriptomics inference problem and solve it with an instrument most laboratories do not route clinical samples through. They do not describe a dosed patient carrying a drug-installed inosine; they do not describe the clinical reporting chain, which is short-read sequencing-by-synthesis with no field for provenance; and they do not describe an edit whose product matches no allele in any germline anywhere.

So the surviving claim is narrow, and it is narrow in the same way the KEGG claim in Part 141 is narrow. **It is a claim about clinical practice, not about chemistry, and not about what is detectable in principle.**

7. The Register, Corrected and Current

The companion paper listed three programs . The register as read on 9 September 2026 holds five, and one of them has been terminated. The full picture is stronger than the partial one, and the termination belongs in it.

agent	sponsor	target	status, 9 September 2026
WVE-006	Wave Life Sciences	SERPINA1 Pi*ZZ	Ph 1b/2a active, not recruiting; Ph 1 completed
AIR-001	AIRNA Corporation	SERPINA1 Pi*ZZ	Ph 1, recruiting, 54 planned
KRRO-110	Korro Bio	SERPINA1 AATD	Ph 1/2a — TERMINATED
KRRO-121	Korro Bio	urea cycle disorders	Ph 1/2, not yet recruiting
RC001	2nd Affiliated Hosp., Guangzhou Medical University	Dravet syndrome, ages 2–18	Early Ph 1, recruiting, n = 8

Two facts in that table were not in the companion paper and should have been. **Three of the five aim at the same adenosine** — SERPINA1 c.1096 — which makes that one base the most heavily targeted nucleotide in the RNA-editing clinic. And **one of the five is dosing children.** RC001 enrols Dravet syndrome patients from two years of age. A child in a Dravet workup is precisely the patient most likely to receive genome and transcriptome sequencing, and precisely the patient in whom an unexplained variant call carries the most weight.

8. The Case With No Reference Allele

KRRO-121 is different in kind from the other four, and it is the one this model cannot finish. **It does not correct a mutation.** Its registered protocol describes an agent “designed to generate a stabilized, *de novo* glutamine synthetase protein” that clears ammonia “independent of any mutational background.”

If that is what it does, then the edited transcript encodes a protein that is neither the patient's inherited sequence nor the reference human sequence. There is no allele anywhere to compare it against. The A-to-G call at that position would match no germline on record — not the patient's, not their parents', not any entry in any population database.

The identity of the edited adenosine is not public. **This model therefore carries KRRO-121 as unresolved and does not speculate about which codon is changed.** That is the honest position, and it is also the most literal possible instance of the thing being described: a reading for guanine that is not in any knowledge base, because nobody has published it.

9. The Point of Contact With the Machine-Learning Industry

This is where the request that opened this document leads, once the modeling question is set aside.

Target-discovery engines — Insilico's PandaOmics is one, and it is not alone — are trained on transcriptomic data. They learn associations between sequence features and disease phenotypes, across tissue panels, patient cohorts and public archives. That training data is RNA-seq, and RNA-seq is where every adenosine-to-inosine edit in the human body is stored as the letter G.

The consequence is arithmetic. Roughly thirty thousand cis-editing quantitative trait loci have been mapped in human tissue, enriched in autoimmune disease association signals (Li et al., Nature 2022). Every one of them enters a training corpus as an apparent genomic variant. **A model that learns “variant at position X associates with phenotype Y” has no way to know whether X was inherited or installed.**

That is a checkable claim about their input data, not a criticism of their models, and it is the thing worth writing to them about. It costs nothing to test: take any transcriptome-derived feature set, intersect it with a published editing-site atlas, and count how many features fall on known editing sites. If the answer is near zero, the concern is unfounded and should be dropped. If it is not, the feature set has a category error in it that no amount of model scale will fix.

And the number of such sites will now grow by design, in dosed patients, on purpose, at positions the sponsor chose.

10. What This Model Refuses

the model does not claim …	… and here is why not
that any patient has been misreported	No such case is known to this author. The model describes a possibility created by the mechanism, not an observed error.
that any of these drugs is unsafe	Nothing here bears on safety in either direction. Editing specificity and off-target profiles are the sponsors' to report and the regulators' to judge.
that inosine is a fifth letter, or a twenty-first	It is a chemical intermediate with a reading face. That is all this model needs it to be, and all it claims it is.
that the sequencing pipelines are built wrong	They are built to report base identity and they report base identity correctly. The gap is that identity and provenance are different quantities and only one is written down.
that this observation is new	It is not. See Section 6. What is new is the therapeutic context and the clinical reporting chain, and that is all that is claimed.
that KEGG, ClinVar or any database has erred	Every resource cited here is doing what it was built to do.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

11. What Would Show This Model Is Wrong

if this were shown …	… then this is what falls
a provenance field already exists	If any routine variant caller, VCF specification or clinical reporting standard already carries a field distinguishing an edited base from a genomic one, Sections 5 and 9 collapse and the paper should be withdrawn.
short reads already separate them	If quality scores, error profiles or context effects reliably separate inosine-derived from genomic G in short-read data, the ambiguity is not an ambiguity. Arm A of the experiment tests this directly.
editing efficiencies stay far from 50 %	The collision with the heterozygote pileup depends on the efficiency landing near one half. If clinical efficiencies cluster at 10 % or 90 %, the specific collision in Section 5 disappears, though the provenance question does not.
clinical sequencing moves to direct RNA	If nanopore direct RNA becomes routine for these patients, Dinopore closes the gap in practice and this document becomes a historical note. That would be the best outcome available.

12. Experiment Sixty-Four — Two Oligonucleotides, Two Arms

The experiment is small enough to run in a week and it settles the question either way.

materials	Two chemically synthesised oligonucleotides spanning SERPINA1 c.1096, identical in every position except that one carries inosine at the target and the other carries guanosine. A third carrying adenosine serves as the untreated control.
Arm A	Blinded, on a short-read instrument, through an unmodified clinical pipeline and variant caller. Record the base call, the quality score and every field of the resulting VCF.
Arm A prediction	Indistinguishable. If any field separates them, the claim fails here and the paper goes no further.
Arm B	The same oligonucleotides on nanopore direct RNA, scored with Dinopore.
Arm B prediction	Separated. This is a positive control, not a discovery — Nguyen and colleagues already showed it works.
why both arms	Arm B exists to prove that Arm A's failure is a property of the platform and the pipeline, and not a property of the molecule. Without it, a negative result in Arm A is uninterpretable.
cost	Three oligonucleotides and two sequencing runs.

A note on what this document is. It is a model, which is to say a statement of what is believed to be occurring, written down precisely enough that it can be checked and, if wrong, discarded. Every coordinate in it is verified in executable code rather than asserted from memory, and the code is delivered with it. The one thing it took from an artificial-intelligence platform is the knowledge that the platform could not help, which is itself a result worth recording.

This completes the beginning.

NOT CONVENTIONAL WISDOM

What has actually happened since 2007 on deamination, inosine and cancer — with the reliability of each region marked

John Allen Berger, Ph.D.
Independent Researcher · NovagonDNA · Naperville, Illinois
Fourth addendum · September 2026 · Licensed under CC BY-NC-ND 4.0.

1. The Objection Is Fair and the Answer Is No

The 2007 paper was cited because it is the **direct experimental test** — a patient's own mutation placed an adenosine at the wobble position of a human mitochondrial tRNA and nothing edited it. That kind of accidental experiment does not come along often, which is why it is worth naming.

But it is not the current authority, and it should not have been left standing alone. **The definitive statement is thirteen years newer.**

And on the cancer side, the field has not merely moved since 2007. It has been rebuilt from the ground up on a dataset that did not exist then, and the rebuilding is centerd on deaminases.

2. The Mitochondrial Zero Got Newer, Not Older

year	source	what it establishes
2007	Ling et al., PNAS	Direct test. The MERRF G34A allele of mt-tRNA-Phe puts an A at the wobble position; no A-to-I editing occurs.
2020	Suzuki et al., Nature Communications	Complete chemical structures of all 22 human mt-tRNAs. Eighteen modification types at 137 of 1,575 positions, fourteen species characterized for the first time. Inosine is not among the eighteen.
standing	—	A 2020 exhaustive survey and a 2007 functional test agree. This is the strongest form a negative takes.

So the position is not conventional wisdom from 2007. It is a 2020 mass-spectrometric inventory of every modified position in every human mitochondrial transfer RNA, with a 2007 functional test sitting underneath it as the control.

3. The Cancer Side Was Rebuilt, and It Was Rebuilt on Deaminases

Alexandrov LB, Kim J, Haradhvala NJ, et al. The repertoire of mutational signatures in human cancer. Nature 2020;578:94–101.

The scale is the point. This did not exist when the 2007 paper was written.

quantity	value
somatic mutations analyzed	84,729,690
whole genomes	4,645
exomes	19,184
single-base-substitution signatures identified	49
SBS1	clock-like; assigned to deamination of 5-methylcytosine at CpG
SBS2 and SBS13	assigned to the APOBEC family — cytidine deaminases acting on DNA
SBS5	clock-like, present in every cancer genome sequenced, and of unknown cause

Two of the most common signatures in human cancer are deaminase signatures with the enzyme named. That is the cytosine arm, industrialised, replicated and in clinical use for stratifying tumors **Nothing about it is conventional wisdom in the dismissive sense — it is conventional because eighty-four million mutations made it so.**

And note the last row, in the authors' own words: “However, many signatures are of unknown cause.” **SBS5 is in every cancer genome ever sequenced and nobody knows what writes it.** That is the open door, and somebody has walked through it.

4. Somebody Has Proposed Exactly Your Thesis. Read the Label First.

Steele EJ, Lindley RA. Deaminase-driven reverse transcription mutagenesis in oncogenesis: critical analysis of transcriptional strand asymmetries of single base substitution signatures. Int J Mol Sci 2025;26:989.

Their model invokes **both mutagenic deaminases — AID/APOBEC on cytosine and ADAR on adenosine** — writing cancer signatures through a reverse-transcription step. They claim it accounts for SBS5, SBS1, SBS3, SBS2/13, SBS6, SBS12, SBS16, SBS17a/b, SBS19 and SBS21.

That is your argument. ADAR, inosine, reverse transcriptase reading inosine as guanine, cancer signatures. In print, in 2025, in a journal, with the mechanism spelled out.

Before you cite it, this:	
it is a review, not primary data	It reinterprets the COSMIC signature catalogue. It does not report new sequencing, new biochemistry or a new experiment.
the literature is self-contained	A search for independent work on this model returns two further papers, both by the same two authors, from 2016 and 2017. No other group has taken it up in nine years.
the authors hold heterodox positions elsewhere	This is relevant to how a referee will receive a citation, whether or not it bears on the model's merit.
the mainstream has not adopted it	The consensus attribution for the adenine-side signatures remains replication and repair processes. ADAR is not established as a DNA mutator.

This is the third time in this project a claim has turned out to be already in print, and the first two — the diphthamide coupling and the NFS1 oxygen result — cost credibility because they were not checked first. **This one is different in an important way: it is in print, but it is not accepted.** Citing it as support would be a mistake. Citing it as "a minority framework has proposed this and it has not been independently tested" is accurate, defensible, and is the honest use of it.

5. Where the Adenine Arm Is Genuinely Established in Cancer

It is not as a DNA mutator. It is as an immune switch, and the evidence there is strong, recent, replicated and being drugged.

the ADAR1 immune axis, as of 2026	
the mechanism	ADAR1 editing marks endogenous double-stranded RNA as "self." Without it, MDA5 senses that dsRNA as foreign and type I interferon fires.
in tumors	ADAR1 is upregulated in malignant cells, associates with adverse outcome and with reduced CD8 T-cell infiltration.
knock it down	MDA5 association with endogenous dsRNA increases, interferon signaling is restored, STAT1 activates, CD8 T-cells proliferate. Depleting MDA5 abolishes the effect.
in vivo	8-azaadenosine potentiates PD-1 blockade: reduced tumor growth, increased apoptosis, raised interferon-alpha, more CD8 infiltration.

(Leng et al., Int J Mol Sci 2026;27:6602, in multiple myeloma; the axis was established earlier in melanoma and is now general.)

6. And One 2026 Paper Lands On the Mitochondrion Directly

Isono M, Yamakawa T, Nagaoka K, Nakano M, Fukami T, Nakajima M. ADAR1 upregulates the translation of cytochrome c via the inhibition of translocation into stress granules, facilitating apoptosis by an anticancer agent. Biochim Biophys Acta Mol Cell Res 2026;1873:120104.

In hepatocellular carcinoma lines, ADAR1 edits **multiple adenosines in the 3′-untranslated region of CYCS** — cytochrome c, the protein whose release from the mitochondrion starts apoptosis. Knock ADAR1 down and cytochrome c protein falls with no change in messenger levels; delete the 3′-UTR and the effect disappears. The mechanism is stress-granule sequestration of the untranslated message.

The clinical end of it: **sorafenib-induced apoptosis was repressed by ADAR1 knockdown, and not in the 3′-UTR-deleted cells.** Inosine positions in one untranslated region set how much cytochrome c a liver cancer cell has, and therefore how well a drug kills it.

This is the mitochondrion, inosine and cancer in one paper, published this year, in the mainstream literature. It is not the mitochondrial genome — CYCS is nuclear-encoded — and that distinction has to be kept. But it is the clearest available demonstration that the inosine axis reaches mitochondrial biology and reaches it where a drug is acting.

7. The Map, With Reliability Marked

status	claim
SETTLED	5-methylcytosine deamination drives CpG>TpG; SBS1 and SBS2/13 are deaminase signatures; 84.7 million mutations; CpG observed/expected ≈ 0.2.
SETTLED	No inosine in human mitochondrial tRNA. 2020 complete inventory plus 2007 direct functional test.
SETTLED	ADAR1 restricts MDA5 sensing of endogenous dsRNA; ADAR1 loss restores interferon and improves checkpoint blockade.
NEW, MAINSTREAM	ADAR1 editing of the CYCS 3′-UTR sets cytochrome c protein levels and sorafenib sensitivity (2026).
OPEN	SBS5 — in every cancer genome, clock-like, cause unknown, by the authors' own admission.
CONTESTED	That ADAR is a DNA mutator writing cancer signatures. Proposed 2025; no independent replication in nine years.
UNMEASURED	How much of any genome's GC arrived through an adenine-deamination intermediate. Experiment Sixty-Eight.

8. What This Document Refuses

not claimed	why not
that Steele and Lindley are wrong	Not claimed. Untested is not refuted. The model may be right and has not been examined.
that Steele and Lindley are usable as support	Also not claimed, and this is the operative half. A single unreplicated review cannot carry a claim in a volume that has already been caught twice on prior art.
that ADAR causes cancer	The established relationship is immune evasion, not mutagenesis, and the direction is that tumors use ADAR rather than that ADAR makes tumors
that the CYCS result is about mitochondrial DNA	CYCS is nuclear-encoded. The paper concerns a mitochondrial protein, not the mitochondrial genome.
that SBS5's unknown cause is an argument for inosine	An unexplained signature is an opening, not evidence. Naming it as an opening is legitimate; filling it by assertion is not.

The instinct was right: this is not settled 2007 knowledge. The mitochondrial negative was reconfirmed in 2020 by an exhaustive survey. The cancer side was rebuilt on eighty-four million mutations and two of its commonest signatures are deaminase signatures. A minority group has proposed the adenine half of the argument and nobody has tested it. And one paper this year put inosine on cytochrome c and changed how well a drug kills a liver tumor .

This completes the beginning.

THE OBJECTION WAS RIGHT

Why the mitochondrial genome carries no iron-sulfur cluster — and where the magnesium sits

John Allen Berger, Ph.D.
Independent Researcher · NovagonDNA · Naperville, Illinois Addendum to “Thirteen, Not Sixteen” ·
September 2026 · Licensed under CC BY-NC-ND 4.0.

1. The Objection, Stated Fairly

The challenge was this: the earliest mitochondria would have needed their iron-sulfur genes to survive, so a modern mitochondrial genome carrying *none* of them looks statistically and logically improbable.

The first half of that is **correct, and it is documented**. The second half is not, and the reason it is not turns out to be a single physical variable that can be measured. Both halves are settled below.

2. The Ancestor Did Have Them, In the Organelle

Burger G, Lang BF, Reith M, Gray MW. Genes encoding the same three subunits of respiratory complex II are present in the mitochondrial DNA of two phylogenetically distant eukaryotes. PNAS 1996;93:2328–32.

Their finding, and their conclusion, in their own words:

“… the same three subunits of complex II are encoded in the mitochondrial DNA of two phylogenetically distant eukaryotes, Porphyra purpurea (a photosynthetic red alga) and Reclinomonas americana (a heterotrophic zooflagellate). These complex II genes, sdh2, sdh3, and sdh4, are homologs, respectively, of Escherichia coli sdhB, sdhC, and sdhD. In E. coli, ***sdhB encodes the iron-sulfur subunit of succinate dehydrogenase*** *… Amino acid sequence similarities indicate that sdh2, sdh3, and sdh4* ***were originally encoded in the protomitochondrial genome and have subsequently been transferred to the nuclear genome in most eukaryotes.***”

So the iron-sulfur subunit of Complex II was in the ancestral organelle genome, it is **still there today** in a red alga and in a zooflagellate, and it was moved to the nucleus in the lineages that lead to us. The human zero is a **transfer**, not a loss, and not a physical impossibility. That matters, because it means the zero is a real result about our lineage rather than a trivial consequence of what organelle genomes can hold.

3. And the Zero Is Not Improbable. It Is Predicted.

Ask what distinguishes the thirteen that stayed from the subunits that left. It is not size, not function, not complex membership. It is one number, and the separation is total.

mtDNA-encoded	TM helices		nuclear-encoded Fe-S	TM helices	cofactor
MT-ND5	15		NDUFS1	0	[2Fe-2S], 2× [4Fe-4S]
MT-CO1	12		NDUFS2	0	[4Fe-4S]
MT-ND4	11		NDUFS7	0	[4Fe-4S]
MT-ND2	10		NDUFS8	0	2× [4Fe-4S]
MT-ND1	8		NDUFV1	0	FMN, [4Fe-4S]
MT-CYB	8		NDUFV2	0	[2Fe-2S]
MT-CO3	7		SDHB	0	[2Fe-2S], [3Fe-4S], [4Fe-4S]
MT-ATP6	6		UQCRFS1	1	[2Fe-2S] Rieske
MT-ND6	6				
MT-ND3, MT-ND4L	3 each				
MT-CO2	2				
MT-ATP8	1				
92 helices, 13 of 13			**1 helix, 8 subunits**		

Ninety-two transmembrane helices across the thirteen. **One** across the eight nuclear iron-sulfur subunits — a single anchor on the Rieske protein. Every one of the thirteen is a membrane protein. Seven of the eight iron-sulfur subunits have no membrane segment at all.

The same split shows in the hydropathy, computed by Kyte-Doolittle:

set	GRAVY range	reading
the thirteen, excluding MT-ATP8	+0.377 to +1.288	all positive — hydrophobic
the eight nuclear Fe-S subunits	−0.408 to −0.078	all negative — hydrophilic
separation	+0.455	the two ranges do not touch

Twelve of the thirteen and eight of the eight, sorted perfectly by one number, with a gap between the two groups. The single exception is MT-ATP8, at sixty-eight residues the shortest protein in the set and the one with a single helix.

4. Why the Split Falls Exactly On Iron-Sulfur

Two facts, put side by side, and the improbability disappears entirely.

What can stay in the organelle	Very hydrophobic polytopic membrane proteins. A protein hydrophobic enough to be a core electron-transport subunit is difficult to import through the outer and inner membrane translocases without mis-targeting to the

	endoplasmic reticulum.
Where iron-sulfur clusters live	In water. Clusters are built by the ISC machinery in the aqueous matrix and are ligated by cysteines in soluble, matrix-facing domains. A cluster cannot sit in the middle of a lipid bilayer.

Those are not two independent conditions that happen to coincide. They are one statement seen twice. **“Retained in mtDNA” means hydrophobic; “carries an iron-sulfur cluster” means hydrophilic. The two sets were never going to intersect.**

The Rieske protein proves the rule rather than breaking it. It is the one nuclear iron-sulfur subunit with a membrane anchor — helix 104 to 140. Its cluster ligands are Cys217, His219, Cys236 and His239: **every one of them at least seventy-seven residues past the end of the bilayer**, out in the water. Even the membrane-anchored iron-sulfur protein keeps its sulfur out of the membrane.

This is not an argument constructed for the occasion. Johnston IG, Williams BP. Evolutionary inference across eukaryotes identifies specific pressures favoring mitochondrial gene retention. Cell Systems 2016;2:101–11. analyzed **2,015 complete mitochondrial genomes** and concluded that “a combination of high GC content and high protein hydrophobicity is required to explain patterns of mtDNA gene retention,” and that the model “can also predict the success of artificial gene transfer experiments in vivo.”

So: the objection was a good one, and the honest answer is that the zero is not a coincidence and never was. **It is what a two-thousand-genome model predicts.** What the count adds is the specific consequence — that every sulfur-based electron carrier in the respiratory chain now has to be manufactured outside the organelle and shipped in.

5. Now the Magnesium — And It Is Better Than Expected

The question was where magnesium sits in relation to the sulfur. The answer is: **in the middle of it.**

There is a magnesium ion in cytochrome c oxidase held jointly by two subunits — one of only two metal sites in the entire mitochondrially encoded proteome that requires two proteins to build. Its ligands, from UniProt with experimental evidence from the human Complex IV structure:

subunit	residue	note
MT-CO1	His368	shared ligand
MT-CO1	Asp369	shared ligand
MT-CO2	Glu198	shared ligand

Now write out the copper A motif of MT-CO2 and mark what each residue does:

```
194  195  196  197  198  199  200  201  202
Gly  Gln  CYS  Ser  GLU  Ile  CYS  Gly  Ala
       ↑Cu       ↑Mg       ↑Cu
```

The magnesium ligand is **Glu198** — and Glu198 sits exactly between Cys196 and Cys200, two residues from each, symmetrically. The two cysteines hold the copper. The glutamate between them holds the magnesium, and reaches across the subunit boundary to His368 and Asp369 of MT-CO1.

And there is one more turn. Glu198 is not only the magnesium ligand. UniProt lists it as a **copper ligand as well** — of the A2 copper of the dinuclear center. So a single glutamate residue coordinates copper and magnesium at once, wedged between the two sulfur atoms that hold the same copper pair.

The sequence is C-S-**E**-I-C. The magnesium ligand is the middle letter of the copper motif. **Sulfur and magnesium are not adjacent in this site. They are interleaved.**

This is worth saying plainly: it happens in the *one* sulfur-coordinated metal center the mitochondrial genome still encodes, at the point where electrons enter Complex IV from cytochrome c, in a site that cannot be assembled unless both mitochondrially encoded subunits are present. The last surviving carbon-sulfur-metal bond in that genome has a magnesium sitting inside it.

6. What Is Not Claimed Here

not claimed	why not
that the magnesium has a known function requiring sulfur	Its role is debated. Proposals include proton and water exit from the active site. This document reports the ligand geometry and does not assign the site a function.
that hydrophobicity is the only retention pressure	Johnston and Williams find GC content is required as well, and the CoRR hypothesis proposes local redox regulation as a third. No single explanation is asserted here.
that mitochondrial genomes cannot encode Fe-S proteins	They can and two lineages still do. Section 2 exists to say so, and the human zero would be uninteresting if they could not.
that the transfer was driven by oxygen	The cysteine-depletion reading in the parent document remains an inference. Hydrophobicity explains which genes stayed; it does not by itself explain the residue composition of the ones that did.
that the earlier statement was wrong	The counts stand: zero Fe-S clusters among the thirteen, one sulfur-metal site. What was missing was the explanation, and the objection is what produced it.

7. Experiment Sixty-Six

question	Is the Cys196–Glu198–Cys200 arrangement a coincidence of sequence, or a conserved constraint?
design	Align MT-CO2 across the eukaryotic tree — including the lineages of Section 2 that retain organellar Fe-S genes — plus the bacterial CoxII homologs of alphaproteobacteria. Score conservation at 196, 198 and 200 separately.
prediction	If the two cysteines are conserved and position 198 is free to vary, the magnesium ligand is opportunistic and the interleaving is incidental. If all three are conserved together across two billion years, the copper and the magnesium are being positioned by the same constraint and the site is a genuine sulfur-magnesium unit.

cost	A multiple sequence alignment. It can be run this week.
why it matters	It converts one structural observation into a claim about conservation, which is the only form in which it can enter the volume as evidence rather than as a picture.

Two corrections came out of the challenge and both improved the work. The Fe-S zero needed a mechanism and now has one, tested against 2,015 genomes. The magnesium question, which looked like a change of subject, turned out to land on the same five residues the sulfur census had already isolated.

This completes the beginning.

THE OTHER DEAMINATION

What the 2016 mitochondrial GC analysis counted, what it could not have misread, and the arm of the symmetry it left out

John Allen Berger, Ph.D.
Independent Researcher · NovagonDNA · Naperville, Illinois
Second addendum · September 2026 · Licensed under CC BY-NC-ND 4.0.

1. The Short Answer Is Zero

The question: of the GC content Johnston and Williams used to predict mitochondrial gene retention, how many of those G calls could have been inosines read as guanine?

The count is **zero, and it is zero by construction.** Their methods section states the source: “we use the full set of data from **GOBASE**, the organellar genome database (O’Brien et al., 2009), consisting of **annotated genome records** for 2,015 species after duplicates were removed.”

Genome records are DNA. Inosine is a ribonucleoside; its deoxy form, deoxyinosine, exists in DNA only as a transient lesion that repair enzymes remove. A sequencer reading mitochondrial DNA reads deoxyadenosine as A. **There is no inosine in the input, so nothing was misread.** And they treat GC explicitly as a property of the double helix, citing it as something “suggested to influence the free energy of DNA duplexes and thus the stability and mutational susceptibility of mtDNA.”

So the question as asked has a clean negative answer. But it opens onto something the paper genuinely does leave out, and that is worth the rest of this document.

2. They Do Invoke a Deamination. It Is the Other One.

Here is the paper's own explanation for why mitochondrial protein-coding genes drift toward GC-poor codons, verbatim:

“This is most likely due to the strong asymmetric mutational pressure arising from the ***hydrolytic deamination of cytosine into uracil, which is converted into thymine*** *(Reyes et al., 1998). Our results suggest a tension between this mutational drive at the sequence level (decreasing genome-wide GC content) and a selective drive retaining individual genes with higher GC content.”*

Read that closely. Their entire account of GC variation rests on **a hydrolytic deamination of an exocyclic amine on a nucleobase.** That is the same reaction class this volume has been following for a year. They have one arm of it.

3. The Symmetry, Written Out

There are two purine-pyrimidine amines exposed to water in a single-stranded nucleic acid, and each has a deamination product with a defined reading face.

cytosine —NH2 → uracil reads as T G:C destroyed
adenine —NH2 → hypoxanthine reads as G G:C created

The first is in their model. The second is not. And the second is the same molecule this volume has been tracking under its ribonucleoside name: **hypoxanthine on deoxyribose is deoxyinosine.** It presents guanine's Watson-Crick face for the same reason inosine does in RNA — N1 donor, C6 acceptor, no amine at carbon two — so a polymerase places cytosine opposite it, and the next round of replication fixes an A:T pair as a G:C pair.

So the honest reformulation of the question is not “how many G calls were misread.” It is: **how much of the GC that Johnston and Williams measured arrived there through an inosine intermediate?** That number is not in their paper, and as far as this author can establish it has not been measured by anyone.

4. And the Channel Is Not Hypothetical

Zeng AGX, Leung ACY, Brooks-Wilson AR. Somatic mitochondrial DNA mutations in diffuse large B-cell lymphoma. Scientific Reports 2018;8:3623. analyzed forty tumor -normal pairs and reported the mitochondrial mutational spectrum. Their finding:

“The mtDNA mutational spectrum showed minimal support for ROS damage and revealed strand asymmetry with ***increased C > T and A > G transitions on the heavy strand***, *consistent with a replication-associated mode of mutagenesis.”*

The two dominant substitution classes in human mitochondrial DNA are **exactly the two products of the deamination pair** — and they are asymmetric to the same strand, the heavy strand, which is the one left single-stranded and exposed during mitochondrial replication.

One caution, stated plainly because it matters. Zeng and colleagues attribute the asymmetry to *replication*, not to deamination, and explicitly find “minimal support for ROS damage.” Polymerase gamma misincorporation and hydrolytic deamination of the exposed strand both produce C>T and A>G with heavy-strand bias, and the two are not separated by the spectrum alone. **This document does not claim that the A>G excess is deamination-derived. It claims that the deamination route is a live and unexcluded contributor that the retention model does not carry.**

5. The One Route By Which RNA Inosine Could Reach a Genome Record

For completeness, there is a narrow path by which a real inosine could enter a database of genome sequences, and it should be named rather than waved away.

case	exposure
the sequence came from DNA	No exposure. Deoxyadenosine reads as A. This is the ordinary case

	and, for GOBASE genome records, the overwhelming case.
the sequence was derived from cDNA	Exposure is real. Reverse transcriptase places dCTP opposite inosine, so any edited position is deposited as G. Any organellar sequence assembled or corrected from transcript data inherits its editing.
the organism edits its organellar RNA	This is where it bites. Land plant mitochondria carry hundreds of C-to-U sites per genome, which would move a cDNA-derived record the other way. Adenosine-to-inosine editing of an organelle-encoded transcript is rarer but documented.

Aldinger CA, Leisinger A-K, Gaston KW, Limbach PA, Igloi GL. The absence of A-to-I editing in the anticodon of plant cytoplasmic tRNA(Arg)ACG demands a relaxation of the wobble decoding rules. RNA Biology 2012;9:1239–46. report that “in moss the **mitochondrial encoded** distinct tRNA(Arg)ACG isoacceptor possesses the I34 modification.”

So an organelle-encoded transcript carrying inosine is a real object in at least one lineage. It does not change that lineage's DNA, and it does not enter a DNA-derived genome record — but it does mean the general claim “mitochondria have nothing to do with inosine” is false, and the narrower human claim needs to stay narrow.

6. The Human Negative Is Stronger Than Previously Stated

The earlier document argued from the complete modification inventory that human mitochondrial tRNA carries no inosine. There is a direct experimental test as well, and it was not cited there.

Ling J, Roy H, Qin D, Rubio MAT, Alfonzo JD, Fredrick K, Ibba M. Pathogenic mechanism of a human mitochondrial tRNA-Phe mutation associated with MERRF. PNAS 2007;104:15299–304. studied the G34A anticodon mutation of human mt-tRNA-Phe — a disease allele that **places an adenosine at the wobble position**, the exact substrate an A-to-I deaminase would need. Their result:

“G34A hmt-tRNA(Phe) ***does not undergo adenosine-to-inosine (A-to-I) editing***, *ruling out miscoding as a possible mechanism for mitochondrial malfunction.*”

A patient's own mutation ran the experiment. An A34 appeared in a human mitochondrial tRNA and **nothing edited it**. The human mitochondrion does not merely lack inosine at the wobble position; it lacks the enzyme that would put one there, and the absence has been demonstrated on a substrate rather than inferred from a survey.

7. What Is and Is Not Claimed

not claimed	why not
that the 2016 paper contains an error	No. Its GC measurement is of DNA and is correct. The question was whether inosine could have corrupted it; the answer is that it could not.
that A>G in mtDNA is caused by deamination	Not claimed. Zeng and colleagues attribute the strand asymmetry to replication. Deamination and polymerase error are not separated by the spectrum, and this document does not separate them either.
that GOBASE records are contaminated by cDNA	Not claimed, and not checked. The mechanism is named in Section 5 as a route that exists, not as one that was taken.
that mitochondria never carry	Withdrawn as a general statement. Moss mitochondria encode a

inosine	tRNA that carries I34. The human claim stands and is now backed by a direct experiment.
that the retention model would change	Unknown. Adding an A-to-G deamination term might shift the GC coefficient or might not. That is a calculation, not an assertion, and it is Experiment Sixty-Seven.

8. Experiment Sixty-Seven

question	Does the mitochondrial gene-retention model change if GC content is decomposed into its two deamination-facing components rather than treated as one number?
design	Recover the GOBASE-derived gene set. For each gene compute, separately, the G+C fraction attributable to positions where the heavy strand carries A or C — the two deaminable positions — and refit the retention model with the two terms entered independently.
prediction	If GC is acting on retention through duplex stability, as Samuels proposed and Johnston and Williams assumed, the two terms should carry the same weight and the split should change nothing. If they carry different weights, GC content is standing in for two different chemical histories and the interpretation of the original result needs revisiting.
falsifier	Identical coefficients. That would confirm the single-term model and close the question.
cost	The dataset is public and the model is published. This is a re-analysis, not an experiment at a bench.

The question asked for a count and the count is zero, which is the least interesting thing in this document. What it turned up is that a 2,015-genome model of mitochondrial gene retention rests on one hydrolytic deamination and does not carry its mirror image — and that the mirror image is the reaction this volume has been following since the first page.

This completes the beginning.

THE SAME REACTION TWICE

Deamination, inosine and sulfur across the two human genomes — a census, a resolution, and a map of what is settled

John Allen Berger, Ph.D.
Independent Researcher · NovagonDNA · Naperville, Illinois
September 2026 · Licensed under CC BY-NC-ND 4.0. · every count

computed from primary sequence during preparation

Abstract

One reaction runs through this paper: the hydrolytic loss of an exocyclic amine from a nucleobase. On cytosine it produces uracil, read as thymine, and it is the single largest source of point mutation in the human genome — **eighty per cent of the CpG dinucleotides that sequence composition predicts are missing, deaminated and never recovered**. On adenine it produces hypoxanthine, read as guanine, and the same reaction is roughly **eighty thousand times slower at body temperature** and is actively excised by a glycosylase identified in 1980.

That rate gap predicts the arrangement the cell actually has. The fast arm runs in DNA whether the cell consents or not. The slow arm was given an enzyme and moved to RNA, where **sixteen million adenosine-to-inosine sites** are written and erased as routine. In the mitochondrion the count is **zero**, confirmed by an exhaustive 2020 inventory and by a 2007 experiment that a patient's own mutation performed. What occupies the mitochondrial wobble position instead is a **sulfur atom**, and infants who cannot install it die of liver failure.

The paper also settles an objection: that a mitochondrial genome carrying **no iron-sulfur cluster at all** is improbable. It is not. Ninety-two transmembrane helices across the thirteen retained proteins, one across the eight nuclear iron-sulfur subunits. The split is one physical variable, and the ancestral genome did carry the gene — two lineages still do.

PART ONE — THE MITOCHONDRIAL CENSUS

1.1 Thirteen, not sixteen

The human mitochondrial genome encodes **thirteen** proteins, twenty-two transfer RNAs and two ribosomal RNAs — thirty-seven genes in **16,569** base pairs. All thirty-seven were pulled from Ensembl for GRCh38 and counted in code. The number sixteen is the genome's length in kilobases arriving in the wrong column, and it matters because every ratio below depends on the denominator.

1.2 The sulfur inventory

Sequences from UniProt. Cysteine and methionine are the only sulfur-bearing residues, so a protein's sulfur atom count is exactly Cys + Met.

protein	residues	Cys	Met	S atoms	S/100 aa	cysteine positions
MT-ND1	318	0	16	16	5.0	—
MT-ND2	347	0	25	25	7.2	—
MT-CO1	513	1	32	33	6.4	498
MT-CO2	227	3	10	13	5.7	35, 196, 200
MT-ATP8	68	1	6	7	10.3	59
MT-ATP6	226	0	12	12	5.3	—
MT-CO3	261	1	11	12	4.6	218
MT-ND3	115	1	8	9	7.8	39
MT-ND4L	98	3	10	13	13.3	32, 69, 98
MT-ND4	459	3	27	30	6.5	52, 276, 328
MT-ND5	603	6	26	32	5.3	56, 279, 291, 330, 342, 518
MT-ND6	174	1	10	11	6.3	40
MT-CYB	380	2	15	17	4.5	40, 93
TOTAL	**3,789**	**22**	**208**	**230**	**6.1**	

All thirteen carry sulfur — 230 atoms across 3,789 residues, one in every sixteen. But the two kinds are not distributed alike. Ten of thirteen carry cysteine; **ND1, ND2 and ATP6 are cysteine-free from end to end**.

1.3 Not one iron-sulfur cluster

UniProt cofactor annotations were retrieved for all thirteen. Only three bind any metal at all.

protein	cofactor	ligands
MT-CO1	two heme A, copper B, calcium, magnesium	Cu_B: His240, His290, His291
MT-CO2	the dinuclear copper A center	His161, Cys196, Glu198, Cys200, His204,

		Met207
MT-CYB	two heme b	His83, His97, His182, His196
the other ten	none annotated	—

The absence is louder than the presence. **Not one of the thirteen carries an iron-sulfur cluster.** Complex I has eight, Complex II three, Complex III the Rieske — and every one sits on a subunit encoded in the *nucleus*, made in the cytosol, imported.

1.4 The one sulfur-metal site that stayed, and the magnesium inside it

There is exactly one place in the mitochondrially encoded proteome where a metal is held by sulfur: the copper A center of cytochrome c oxidase subunit 2, where electrons enter Complex IV from cytochrome c.

194	195	196	197	198	199	200	201	202
Gly	**Gln**	**CYS**	**Ser**	**GLU**	**Ile**	**CYS**	**Gly**	**Ala**
	↑Cu		↑Mg		↑Cu			

Three of the six copper ligands bear sulfur: **Cys196, Cys200 and Met207**. Two of the protein's three cysteines are holding that copper.

And there is a magnesium held jointly by two subunits — His368 and Asp369 from MT-CO1, **Glu198** from MT-CO2. Glu198 sits exactly between the two copper cysteines, two residues from each, symmetrically. UniProt lists it as a **copper ligand as well**, of the A2 copper. One glutamate coordinating copper and magnesium at once, wedged between the two sulfurs that hold the same copper pair.

C-S-E-I-C. The magnesium ligand is the middle letter of the copper motif. Sulfur and magnesium are not adjacent in this site. They are interleaved — in the last surviving carbon-sulfur-metal bond the mitochondrial genome encodes, in a site that cannot be assembled unless both mitochondrially encoded subunits are present.

PART TWO — WHY THE IRON-SULFUR ZERO IS NOT IMPROBABLE

2.1 The objection was right about the ancestor

Burger G, Lang BF, Reith M, Gray MW. PNAS 1996;93:2328–32 — their words: the same three complex II subunits "are encoded in the mitochondrial DNA of two phylogenetically distant eukaryotes, *Porphyra purpurea* and *Reclinomonas americana* … In *E. coli*, **sdhB encodes the iron-sulfur subunit** … sdh2, sdh3, and sdh4 **were originally encoded in the protomitochondrial genome and have subsequently been transferred to the nuclear genome in most eukaryotes**."

So the iron-sulfur subunit was in the ancestral organelle genome, **two living lineages still have theirs**, and ours was moved. The human zero is a transfer, not a loss and not a physical impossibility — which is what makes it a real result rather than a triviality.

2.2 And wrong about the improbability. One variable sorts them perfectly.

mtDNA-encoded	TM		nuclear Fe-S	TM	cofactor
MT-ND5	15		NDUFS1	0	[2Fe-2S], 2× [4Fe-4S]
MT-CO1	12		NDUFS2	0	[4Fe-4S]
MT-ND4	11		NDUFS7	0	[4Fe-4S]
MT-ND2	10		NDUFS8	0	2× [4Fe-4S]
MT-ND1 / MT-CYB	8 each		NDUFV1	0	FMN, [4Fe-4S]
MT-CO3	7		NDUFV2	0	[2Fe-2S]
MT-ATP6 / MT-ND6	6 each		SDHB	0	[2Fe-2S], [3Fe-4S], [4Fe-4S]
MT-ND3 / MT-ND4L	3 each		UQCRFS1	1	[2Fe-2S] Rieske
MT-CO2	2				
MT-ATP8	1				
92 helices, 13 of 13			**1 helix, 8 subunits**		

Ninety-two transmembrane helices across the thirteen. One across the eight iron-sulfur subunits — a single anchor on Rieske. Kyte-Doolittle hydropathy sorts them with a gap: twelve of thirteen run **+0.377 to +1.288**; all eight nuclear Fe-S subunits run **−0.408 to −0.078**; separation **+0.455**, no overlap. The only exception is the sixty-eight-residue MT-ATP8.

2.3 Why the split falls exactly on iron-sulfur

Two facts, side by side, and the improbability disappears.

What can stay in the	Very hydrophobic polytopic membrane proteins. A protein hydrophobic

organelle	enough to be a core electron-transport subunit is hard to import without mis-targeting to the endoplasmic reticulum.
Where iron-sulfur clusters live	In water. Clusters are built by the ISC machinery in the aqueous matrix and ligated by cysteines in soluble, matrix-facing domains. A cluster cannot sit in a bilayer.

These are not two conditions that happen to coincide. They are one statement seen twice. “Retained in mtDNA” means hydrophobic; “carries an iron-sulfur cluster” means hydrophilic. The two sets were never going to intersect.

Rieske proves the rule. Its membrane anchor spans 104–140; its cluster ligands are Cys217, His219, Cys236, His239 — **every one at least seventy-seven residues past the end of the bilayer**. Even the membrane-anchored iron-sulfur protein keeps its sulfur out of the lipid.

Johnston IG, Williams BP. Cell Systems 2016;2:101–11 analyzed **2,015 complete mitochondrial genomes** from GOBASE and concluded that “a combination of high GC content and high protein hydrophobicity is required to explain patterns of mtDNA gene retention,” and that the model “can also predict the success of artificial gene transfer experiments *in vivo*.” The zero is what a two-thousand-genome model predicts.

2.4 Cysteine was not merely absent. It was purged.

gene set	n	residues	Cys	Cys %	Met	Met %
mtDNA-encoded (the 13)	13	3,789	22	0.58 %	208	5.49 %
nuclear-encoded Fe-S subunits	8	2,880	75	2.60 %	89	3.09 %

The nuclear Fe-S set is **4.5 times richer in cysteine**; the mitochondrial set is **1.8 times richer in methionine**. Both residues carry sulfur. Only one can be repaired — methionine sulfoxide is reversed by the methionine sulfoxide reductases; cysteine oxidised past sulfinic acid is gone. **The genome inside the oxygen furnace kept the sulfur it could repair and shed the sulfur it could not.** That reading is an inference from the counts. The counts are not.

PART THREE — THE WOBBLE POSITION, AND WHY INOSINE NEVER GOT IN

3.1 Zero inosine, and it was never needed

Suzuki T, Yashiro Y, Kikuchi I, et al. Nature Communications 2020;11:4269 characterized every one of the twenty-two human mt-tRNA species, fourteen for the first time: **eighteen kinds of modification at 137 of 1,575 nucleobases**. Inosine is not among the eighteen. The word does not appear in the paper.

That could be accident. It is not, and this can be derived. Each mt-tRNA has a defined codon set, stated in the HGNC gene names themselves:

class	n	tRNAs	codons	what works at 34
family boxes — all four third bases	8	Val, Ala, Ser(UCN), Gly, Arg, Leu(CUN), Thr, Pro	32	U34 only
purine sets — A and G	6	Leu(UUR), Gln, Met, Trp, Lys, Glu	12	U34 only
pyrimidine sets — U and C	8	Phe, Ile, Asn, Cys, Tyr, Asp, His, Ser(AGY)	16	G34, or I34, or U34
TOTAL	**22**		**60**	

Sixty sense codons — exactly sixty-four less the four stops of the vertebrate mitochondrial code. **Inosine's unique competence is the set {U, C, A}: three third bases, not two and not four.** A family box needs all four; a purine set needs G, which inosine cannot read at all. Running that over all twenty-two, the number of human mt-tRNAs for which inosine is the only workable wobble base is **zero**. Permitted at eight, necessary at none.

3.2 The experiment a patient performed

Ling J, Roy H, Qin D, et al. PNAS 2007;104:15299–304 studied the MERRF G34A allele of mt-tRNA-Phe — a disease mutation that **places an adenosine at the wobble position**, the exact substrate a deaminase would need. Their result: “G34A hmt-tRNA(Phe) **does not undergo adenosine-to-inosine (A-to-I) editing**, ruling out miscoding as a possible mechanism.”

An A34 appeared in a human mitochondrial tRNA and nothing edited it. A 2020 exhaustive survey and a 2007 functional test on a real substrate agree. That is the strongest form a negative takes.

The general claim must stay narrow, though: Aldinger et al., RNA Biology 2012;9:1239–46 report that “in moss the **mitochondrial encoded** distinct tRNA(Arg)ACG isoacceptor possesses the I34 modification.” Organelle-encoded, inosine-carrying, real. The human claim stands; “mitochondria have nothing to do with inosine” does not.

3.3 What occupies the position instead — sulfur, and children die without it

The cytosol puts eight inosines at position 34. The mitochondrion puts a taurine-modified uridine there, and on three tRNAs a **sulfur atom** as well. Boczonadi et al., Human Molecular

Genetics 2013;22:4602–15 name them: TRMU performs the 2-thiouridylation of **mt-tRNA-Glu, mt-tRNA-Lys and mt-tRNA-Gln**.

Zeharia et al., American Journal of Human Genetics 2009;85:401–7 reported thirteen unrelated infants with acute liver failure and lactic acidaemia carrying TRMU mutations, with markedly reduced 2-thiouridylation. **Four died.** Their proposal:

“Given that sulfur is a TRMU substrate and its availability is limited during the neonatal period, we propose that there is a window of time whereby patients with TRMU mutations are at increased risk of developing liver failure.”

And Boczonadi closed the loop: **L-cysteine supplementation rescued respiratory chain enzyme activities** in patient cell lines. Feed the sulfur, restore the translation, restore the respiration.

3.4 Ninety-five lysines

The two codes differ at four codons: UGA is stop in the cytosol and tryptophan in the mitochondrion; AUA is isoleucine and methionine; AGA and AGG are arginine and stop. Take every adenosine in every codon, convert it to inosine, let it be read as guanosine, and ask what happens under each code. Forty-eight such positions exist. Thirty-nine behave identically. Nine do not:

codon	pos	becomes	standard code	mitochondrial code
UAA	2	UGA	stop → stop (silent)	stop → Trp (readthrough)
UGA	3	UGG	stop → Trp (readthrough)	Trp → Trp (silent)
AUA	1	GUA	Ile → Val	Met → Val
AUA	3	AUG	Ile → Met	Met → Met (silent)
AAA	**2**	**AGA**	**Lys → Arg**	**Lys → STOP**
AAG	**2**	**AGG**	**Lys → Arg**	**Lys → STOP**
AGA	1	GGA	Arg → Gly	stop → Gly
AGA	3	AGG	Arg → Arg (silent)	stop → stop (silent)
AGG	1	GGG	Arg → Gly	stop → Gly

Nineteen per cent of all possible inosine-for-adenosine readings mean something different depending on which compartment the ribosome stands in. And the bold rows can be counted in the actual proteins: there are **95 lysines across the thirteen** — ninety-five positions where one deamination truncates the protein inside the organelle and is nearly neutral outside it.

The lysine tRNA is one of the three TRMU thiolates. The codon family whose misreading is most catastrophic in the mitochondrion is the family whose tRNA carries a sulfur atom at the wobble position. Whether the thiocarbonyl is there *because* of that danger is a hypothesis with an experiment attached, not a finding. The two facts standing next to each other are not.

PART FOUR — THE SAME REACTION, TWICE

4.1 The symmetry

There are two exposed exocyclic amines in a single-stranded nucleic acid, and each deamination product has a defined reading face.

cytosine —NH_2 → uracil reads as T G:C destroyed
adenine —NH_2 → hypoxanthine reads as G G:C created

Hypoxanthine on deoxyribose *is* deoxyinosine. It presents guanine's Watson-Crick face for the same reason inosine does in RNA: N1 donor, C6 acceptor, no amine at carbon two. A polymerase places cytosine opposite it, and the next round of replication fixes an A:T pair as G:C.

4.2 The cytosine arm wins, and the receipt is a hole the size of a continent

quantity	value
deamination order, measured	5-methylcytosine > cytosine > adenine > guanine
5mC → T rate, relative to other transitions	10-fold to 50-fold higher
methylated CpG C>T de novo rate	1.17×10^{-7} per site per generation, ~2,900 parent-offspring trios
genome-wide CpG observed/expected	≈ 0.2 — roughly five-fold depleted
expected CpG sites simply gone	**≈ 80 per cent**

Eighty per cent of the CpG dinucleotides that random composition predicts are missing from the human genome. They were deaminated, read as T, and never came back. **And it is a sulfur story at one remove**: the methyl group that sensitises the cytosine arrives on a carbon-sulfur bond from S-adenosylmethionine.

4.3 The adenine arm has two brakes

Karran P, Lindahl T. Biochemistry 1980;19:6005–11 measured it: adenine to hypoxanthine in single-stranded DNA at $k = 4 \times 10^{-8}$ s^{-1}, pH 7.6, **110 degrees** — a half-life of about two hundred days at a temperature that would cook the cell. Computed activation energies with three explicit waters put cytosine at 117.9 kJ/mol and adenine at 147.1, a gap of 29.2 kJ/mol:

cytosine deaminates about 8×10^4 times faster than adenine at 37 °C

That figure comes from calculated barriers in a model system, not a measurement in duplex DNA, and is offered as an order of magnitude. The direction is not in doubt.

Then the half of that 1980 paper usually forgotten. They did not only measure the lesion — **they found the enzyme that removes it**: a 31-kilodalton glycosylase from calf thymus and human fibroblasts that “specifically catalyzes the release of free hypoxanthine from

DNA," which they proposed "acts in DNA repair by preventing deaminated adenine residues from being expressed as mutations." **Slow, and actively excised. Two brakes, neither applying to methylated cytosine.**

4.4 The simple law is the preference order, and it predicts the architecture

5-methylcytosine > cytosine > adenine > guanine

fact	consequence
The cytosine arm is fast	So it runs in DNA whether the cell wants it or not. The cell cannot stop it. It pays in eighty per cent of its CpG sites, in the top mutation class in cancer, and in the CpG-island architecture it had to evolve to protect its promoters.
The adenine arm is slow	Too slow to be useful. Water will not do this reaction on a timescale a cell can use, and a glycosylase removes what water manages.
So the cell built an enzyme	ADAR does in milliseconds what water needs geological time for — and does it on RNA, where the product is transient and the original is never lost.
And put it in the other compartment	Sixteen million sites in the nucleus and cytosol; zero in the mitochondrion, where the tRNA that most needs protection carries a sulfur atom at the same position instead.

The deamination the cell cannot control happens to its archive and is called damage. The deamination it can control happens to its messages and is called regulation. Same reaction, same leaving group, opposite meaning — decided by which molecule it happens to, and whether an enzyme or a water molecule did it.

4.5 The counts, side by side

quantity	mitochondrial	nuclear
catalogued inosine positions in RNA	0 in human mt-tRNA	≈ 16,000,000 A-to-I sites
how the number was obtained	complete inventory of 22 species, 137 positions; plus a direct experimental test	9,642 human RNA-seq samples from GTEx
deamination signature in DNA	C>T and A>G elevated on the heavy strand; cause contested	CpG C>T dominant and settled
repair of deaminated adenine	present, capacity limited	AAG / MPG glycosylase, characterized 1980

(Mansi et al., Nucleic Acids Research 2021;49:D1012–D1019 for the sixteen million.) In the compartment holding ninety-nine per cent of the cell's DNA, sixteen million adenosines are converted to inosine and back as routine housekeeping. In the compartment running the oxygen chemistry, the count is zero and has been directly tested.

PART FIVE — WHAT THE CANCER LITERATURE ACTUALLY SAYS

5.1 The field was rebuilt, and rebuilt on deaminases

Alexandrov LB, Kim J, Haradhvala NJ, et al. The repertoire of mutational signatures in human cancer. Nature 2020;578:94–101.

quantity	value
somatic mutations analyzed	84,729,690
whole genomes / exomes	4,645 / 19,184
single-base-substitution signatures	49
SBS1	clock-like; assigned to deamination of 5-methylcytosine at CpG
SBS2 and SBS13	assigned to APOBEC — cytidine deaminases acting on DNA
SBS5	**clock-like, present in every cancer genome sequenced, cause unknown**

Two of the commonest signatures in human cancer are deaminase signatures with the enzyme named. **Nothing about this is conventional wisdom in the dismissive sense — it is conventional because eighty-four million mutations made it so.** And in the authors' own words: “However, many signatures are of unknown cause.” SBS5 is in every cancer genome ever sequenced and nobody knows what writes it. That is the open door.

5.2 Somebody has walked through it with exactly this argument. Read the label.

Steele EJ, Lindley RA. Deaminase-driven reverse transcription mutagenesis in oncogenesis. Int J Mol Sci 2025;26:989. Their model invokes **both mutagenic deaminases — AID/APOBEC on cytosine and ADAR on adenosine** — writing cancer signatures through a reverse-transcription step, and claims to account for SBS5, SBS1, SBS3, SBS2/13, SBS6, SBS12, SBS16, SBS17a/b, SBS19 and SBS21.

Before citing it:	
it is a review, not primary data	It reinterprets the COSMIC catalogue. No new sequencing, biochemistry or experiment.
the literature is self-contained	A search for independent work returns two further papers, both by the same two authors, 2016 and 2017. No other group has taken it up in nine years.
the mainstream has not adopted it	The consensus attribution for adenine-side signatures remains replication and repair. ADAR is not established as a DNA mutator.

This is the third time in this project a claim has turned out to be already in print. The first two — the diphthamide coupling and the NFS1 oxygen result — cost credibility because they were not checked first. **This one is different: it is in print, but it is not accepted.** Citing it as support would be a mistake. Citing it as “a minority framework has proposed this and it has not been independently tested” is accurate and defensible.

5.3 Where the adenine arm is genuinely established — immune, not mutational

the ADAR1 immune axis, as of 2026	
the mechanism	ADAR1 editing marks endogenous double-stranded RNA as “self.” Without it, MDA5 senses that dsRNA as foreign and type I interferon fires.
in tumors	ADAR1 is upregulated in malignant cells, associates with adverse outcome and reduced CD8 T-cell infiltration.
knock it down	MDA5 association with endogenous dsRNA rises, interferon signaling is restored, STAT1 activates, CD8 T-cells proliferate. Depleting MDA5 abolishes the effect.
in vivo	8-azaadenosine potentiates PD-1 blockade: reduced tumor growth, increased apoptosis, raised interferon-alpha, more CD8 infiltration.

(Leng et al., Int J Mol Sci 2026;27:6602, in multiple myeloma.)

5.4 And one 2026 paper puts inosine on cytochrome c

Isono M, Yamakawa T, Nagaoka K, Nakano M, Fukami T, Nakajima M. Biochim Biophys Acta Mol Cell Res 2026;1873:120104.

In hepatocellular carcinoma lines, ADAR1 edits **multiple adenosines in the 3′-untranslated region of CYCS** — cytochrome c, the protein whose release from the mitochondrion starts apoptosis. Knock ADAR1 down and cytochrome c protein falls with no change in messenger levels; delete the 3′-UTR and the effect disappears. The mechanism is stress-granule sequestration of the untranslated message.

Sorafenib-induced apoptosis was repressed by ADAR1 knockdown, and not in the 3′-UTR-deleted cells. Inosine positions in one untranslated region set how much cytochrome c a liver cancer cell has, and therefore how well a drug kills it. CYCS is nuclear-encoded — that distinction must hold — but this is the clearest demonstration that the inosine axis reaches mitochondrial biology, and reaches it where a drug is acting.

PART SIX — THE MAP, THE REFUSALS, AND THREE EXPERIMENTS

6.1 Reliability, marked

status	claim
SETTLED	13 mtDNA-encoded proteins, 3,789 residues, 22 Cys, 208 Met, zero Fe-S clusters, one sulfur-metal site.
SETTLED	92 TM helices in the thirteen versus one in the eight nuclear Fe-S subunits; GRAVY ranges do not overlap.
SETTLED	sdhB was in the protomitochondrial genome and is still in two lineages' mtDNA.
SETTLED	No inosine in human mitochondrial tRNA — 2020 complete inventory plus 2007 direct test on a real A34 substrate.
SETTLED	5mC deamination drives CpG>TpG; SBS1 and SBS2/13 are deaminase signatures; CpG o/e ≈ 0.2.
SETTLED	ADAR1 restricts MDA5 sensing; ADAR1 loss restores interferon and improves checkpoint blockade.
NEW, MAINSTREAM	ADAR1 editing of the CYCS 3′-UTR sets cytochrome c levels and sorafenib sensitivity (2026).
INFERENCE	That cysteine depletion in the thirteen reflects oxidative repair asymmetry. Counts firm, explanation not.
HYPOTHESIS	That the 2-thio group at mt-tRNA-Lys guards the 95 lysine codons against a stop-generating misread.
OPEN	SBS5 — in every cancer genome, clock-like, cause unknown by the authors' own admission.
CONTESTED	That ADAR is a DNA mutator writing cancer signatures. Proposed 2025; no independent replication in nine years.
UNMEASURED	How much of any genome's GC arrived through an adenine-deamination intermediate.

6.2 What this paper refuses

not claimed	why not
that sixteen proteins are encoded	Thirteen. The correction is why the ratios can be trusted.
that the Fe-S zero is improbable	It is what a 2,015-genome retention model predicts from hydrophobicity alone.
that mitochondria never carry inosine	Withdrawn as a general statement. Moss mitochondria encode a tRNA carrying I34. The human claim stands.
that deamination drives all transitions	Half true. Decisive for C>T at methylated CpG. Not established for A>G, where replication error is the leading published attribution and the chemistry is four to five orders slower.
that the 8×10^4 figure is measured	It is computed from calculated barriers in a model system, not measured in duplex DNA.
that ADAR causes cancer	The established relationship is immune evasion, and the direction is that tumors use ADAR, not that ADAR makes tumors
that SBS5's unknown cause is evidence for inosine	An unexplained signature is an opening, not evidence. Naming it as an opening is legitimate; filling it by assertion is not.
that any database or curator has erred	Every resource cited here is doing what it was built to do.

6.3 Three experiments, none of them expensive

Sixty-Five	Does loss of 2-thiouridylation truncate translation specifically at lysine codons? TRMU-knockdown versus control, mitochondrial ribosome profiling across all thirteen reading frames. The 95 lysine positions are the test set; every other codon is the control. Second arm with L-cysteine rescue. Falsifier: uniform loss of occupancy across all codons.
Sixty-Six	Is Cys196–Glu198–Cys200 conserved as a unit? Align MT-CO2 across the eukaryotic tree plus alphaproteobacterial CoxII, and score 196, 198 and 200 separately. If 198 is free to vary, the interleaving is incidental. If all three are conserved across two billion years, the copper and the magnesium are positioned by one constraint. Cost: a multiple sequence alignment.
Sixty-Eight	Does A>G track single-strand exposure the way C>T does? Regress A>G rate against heavy-strand exposure time across the mitochondrial genome, with C>T as internal positive control. Exposure time is the one variable that separates a reaction with water from a copying error. Gradient means deamination; no gradient means polymerase. Cost: a regression on published catalogues.

Every count in this paper was computed from primary sequence and primary annotation during its preparation rather than recalled: the Ensembl coordinates, the UniProt sequences and cofactor records, the residue and cysteine counts, the hydropathy, the transmembrane tallies, the codon-table comparison and the wobble-competence derivation. Every literature figure is attributed to the paper that reported it, and every claim that is an inference rather than a measurement is labeled as one in Section 6.1.

This completes the beginning.

THE VOTE IS HALF RIGHT

Deamination in the nuclear genome — where it wins outright, where the chemistry says otherwise, and why the split is the finding

John Allen Berger, Ph.D.
Independent Researcher · NovagonDNA · Naperville, Illinois
Third addendum · September 2026 · Licensed under CC BY-NC-ND 4.0.

1. The Counts, Side By Side

Move from the mitochondrion to the nucleus and the numbers do not shift a little. They invert.

quantity	mitochondrial	nuclear
catalogued inosine positions, RNA	0 in human mt-tRNA	≈ 16,000,000 A-to-I sites
how that number was obtained	complete modification inventory, 22 species, 137 positions; plus a direct experimental test	9,642 human RNA-seq samples from GTEx
deamination signature in DNA	C>T and A>G both elevated on the heavy strand; cause contested	CpG C>T dominant and settled
how depleted is the target dinucleotide	not applicable	CpG observed/expected ≈ 0.2
repair of deaminated adenine	present but capacity limited	AAG / MPG glycosylase, characterized 1980

The first row is the one to sit with. In the compartment that contains ninety-nine per cent of the cell's DNA, **sixteen million adenosines are converted to inosine and back again as a matter of routine.** In the compartment that runs the oxygen chemistry, the count is zero and has been directly tested. (Mansi et al., Nucleic Acids Research 2021;49:D1012–D1019; and for the zero, Suzuki et al. 2020 with Ling et al., PNAS 2007;104:15299.)

2. Where the Vote Wins, and It Wins Decisively

On the cytosine arm the answer is not close, and the simpler explanation is the correct one. **Hydrolytic deamination is the single largest source of point mutation in the human genome**, and the evidence for it is a hole in the genome the size of a continent.

quantity	value
deamination order, measured	5-methylcytosine > cytosine > adenine > guanine
5mC → T rate, relative to other transitions	10-fold to 50-fold higher

methylated CpG C>T de novo rate	1.17×10^{-7} per site per generation, from about 2,900 parent-offspring trios
genome-wide CpG observed/expected	≈ 0.2 — roughly five-fold depleted
fraction of expected CpG sites simply gone	≈ 80 per cent

Eighty per cent of the CpG dinucleotides that random sequence composition predicts are **missing from the human genome**. They were deaminated, they were read as T, and they never came back. Cytosine methylation put a methyl group on carbon five, which made the amine at carbon four easier to lose, and several hundred million years of hydrolysis did the rest.

That is the whole argument of this volume, at genome scale, already accepted by the field, and it is a **sulfur** story at one remove: the methyl group that sensitises the cytosine arrives from S-adenosylmethionine, on a carbon-sulfur bond.

3. Where the Chemistry Says Otherwise

The adenine arm is a different matter, and this is where the vote has to be split rather than cast whole.

Karran P, Lindahl T. Hypoxanthine in deoxyribonucleic acid: generation by heat-induced hydrolysis of adenine residues and release in free form by a DNA glycosylase from calf thymus. Biochemistry 1980;19:6005–11. measured it directly: adenine to hypoxanthine in single-stranded DNA proceeds at $k = 4 \times 10^{-8}$ per second at pH 7.6 and **110 degrees** — a half-life of about two hundred days at a temperature that would cook the cell.

And the measured ordering of deamination propensity places adenine third of four. A computational treatment with three explicit water molecules puts the activation energies at 117.9 kJ/mol for cytosine and 147.1 kJ/mol for adenine — a difference of 29.2 kJ/mol, which at body temperature is a rate ratio of:

> cytosine deaminates about 8×10^4 times faster than adenine at 37 °C

That figure is derived from calculated barriers, not from a measurement in duplex DNA, and it is offered as an order of magnitude rather than a constant. But the direction is not in doubt, and it is confirmed by the measured ordering.

Then the second half of Karran and Lindahl, in the same 1980 paper, which is the part usually forgotten. They did not only measure the lesion. **They found the enzyme that removes it** — a 31-kilodalton DNA glycosylase from calf thymus and human fibroblasts that “specifically catalyzes the release of free hypoxanthine from DNA,” and which they proposed “acts in DNA repair by preventing deaminated adenine residues from being expressed as mutations.”

So the adenine arm is slow, and what little of it happens is actively excised by a dedicated enzyme. **Two independent brakes, neither of which applies to methylated cytosine.**

4. The Split Is Not a Defeat. It Is the Simpler Law.

The instinct — that the simpler explanation is more often correct — holds. But the simple law is not “deamination drives everything.” **The simple law is the preference order, and it has four terms:**

5-methylcytosine > cytosine > adenine > guanine

That one line predicts the entire compartmental arrangement, and it does so without any additional assumption.

fact	consequence
The cytosine arm is fast	So it runs in DNA whether the cell wants it or not. The cell cannot stop it. It pays for it in eighty per cent of its CpG sites, in the top mutation class in cancer, and in the CpG-island architecture it had to evolve to protect its promoters.
The adenine arm is slow	Too slow to be useful. Water will not do this reaction on a timescale a cell can use, and a glycosylase removes what water manages.
So the cell built an enzyme	ADAR does in milliseconds what water needs geological time for — and it does it on RNA, where the product is transient and the original is never lost.
And put it in the other compartment	Sixteen million sites in the nucleus and cytosol. Zero in the mitochondrion, where the tRNA that most needs protection carries a sulfur atom at the same position instead.

Put the two arms next to each other and the arrangement is almost too neat to state without hedging, so here it is hedged: **the deamination the cell cannot control happens to its archive and is called damage; the deamination it can control happens to its messages and is called regulation.** Same reaction. Same leaving group. Opposite meaning, decided by which molecule it happens to and whether an enzyme or a water molecule did it.

5. What This Refuses

not claimed	why not
that deamination is the main driver of all transitions	Half true. It is decisively the main driver of C>T at methylated CpG. It is not established as the main driver of A>G, where replication error is the leading published attribution and the chemistry is four to five orders of magnitude slower.
that the 8×10^4 figure is measured	It is not. It is computed from calculated activation barriers with three explicit waters, in a model system, not measured in duplex DNA. The measured claim is the ordering, and Lindahl's rate at 110 °C.
that ADAR evolved in order to replace slow chemistry	This is a teleological reading of a correlation. The rate gap and the existence of ADAR are both facts; that one caused the other is a story, and it is printed here as a story.
that the nuclear and mitochondrial counts are directly comparable	They are not. Sixteen million is a count of RNA sites across 9,642 samples; the mitochondrial zero is a count of modified positions in 22 tRNA species. The comparison is qualitative and is offered as such.
that CpG depletion is entirely deamination	Selection, biased gene conversion and GC-content variation all contribute. Deamination is the dominant term, not the only one.

6. What Would Show the Vote Should Have Been Cast Whole

if this were shown	what changes
a strand-time signal for A>G	If A>G rate in mtDNA or nuclear DNA scales with the duration a strand spends single-stranded — as C>T demonstrably does — then hydrolysis, not polymerase error, is doing the work and the vote wins on both arms.
AAG/MPG loss raising A>G	If knocking out the hypoxanthine glycosylase raises the A>G rate proportionally, the lesion is being formed continuously and only repair was hiding it.
adenine deamination faster in duplex than modeled	The 8×10^4 figure comes from a microsolvated calculation. A measured rate in duplex DNA at physiological temperature could move it by orders of magnitude in either direction.
a sensitising modification for adenine	Methylation sensitises cytosine. If any common adenine modification — N6-methyladenine, say — similarly lowers the barrier, the arms become symmetric and the whole argument of Section 4 collapses.

7. Experiment Sixty-Eight

question	Does the A>G rate track single-strandedness, the way C>T does?
design	In mtDNA, the heavy strand's single-stranded exposure time varies systematically with distance from the origin of replication, and this is already the standard explanatory variable for the C>T gradient. Regress A>G rate against the same exposure-time variable across the genome, in the same dataset, with C>T as the internal positive control.
prediction if deamination drives it	A>G shows the same gradient as C>T, with a shallower slope set by the rate ratio.
prediction if replication error drives it	A>G shows no gradient, or a gradient with a different shape driven by polymerase context rather than exposure time.
why this settles it	Exposure time is the one variable that separates a chemical reaction with water from a copying error. Nothing else in the two hypotheses differs so cleanly.
cost	A regression on published mtDNA mutation catalogues. No bench work.

The vote was for deamination as the main driver. On the cytosine arm it is right, and eighty per cent of the human genome's missing CpG sites are the receipt. On the adenine arm the same reaction is four to five orders of magnitude slower and has a dedicated enzyme removing its product. The interesting result is not which arm wins. It is that the cell responded to the difference by moving one arm into RNA and giving it an enzyme.

This completes the beginning.

PUBLIC POSTS · NOVAGONDNA · FOR CIRCULATION

Three Posts on What AlphaGenome Cannot Represent

The sulfur audit, the NFS1 oxygen result, and the six experiments that run on a laptop — written for scientists on public platforms, with the feed card that accompanies each

POSTS · ALPHAGENOME · SULFUR, OXYGEN, OPEN PROTOCOLS

1. What This Document Says in Seven Lines

— THREE POSTS, WRITTEN TO BE READ BY PRACTICING SCIENTISTS and not by referees. Each one stands alone, each one carries its own square feed card, and each one names Google DeepMind's AlphaGenome directly.

— POST ONE IS THE SULFUR AUDIT. Three of AlphaGenome's published output tracks — DNA and histone methylation, histone acetylation, and the binding and repair machinery — are written by cofactors that carry a sulfur atom, and a DNA sequence has no field where any of the three could be recorded.

— POST TWO IS NFS1. The cysteine desulfurase is required in primary and metastatic lung tumors and dispensable in mammary and subcutaneous ones. Same gene, same sequence, opposite essentiality, and the variable that decides is the partial pressure of oxygen.

— POST THREE IS THE INVITATION. Six experiments from the evidence volume whose primary endpoints compute from public data on a desktop computer — REDIportal, GtRNAdb, the Cancer Dependency Map, the Alu editing index, CoCoPUTs, and three sets of published supplementary tables.

— EVERY NUMBER IN ALL THREE POSTS IS SOURCED, and the sources are printed at section six so that anyone who wants to check a figure can reach it without asking.

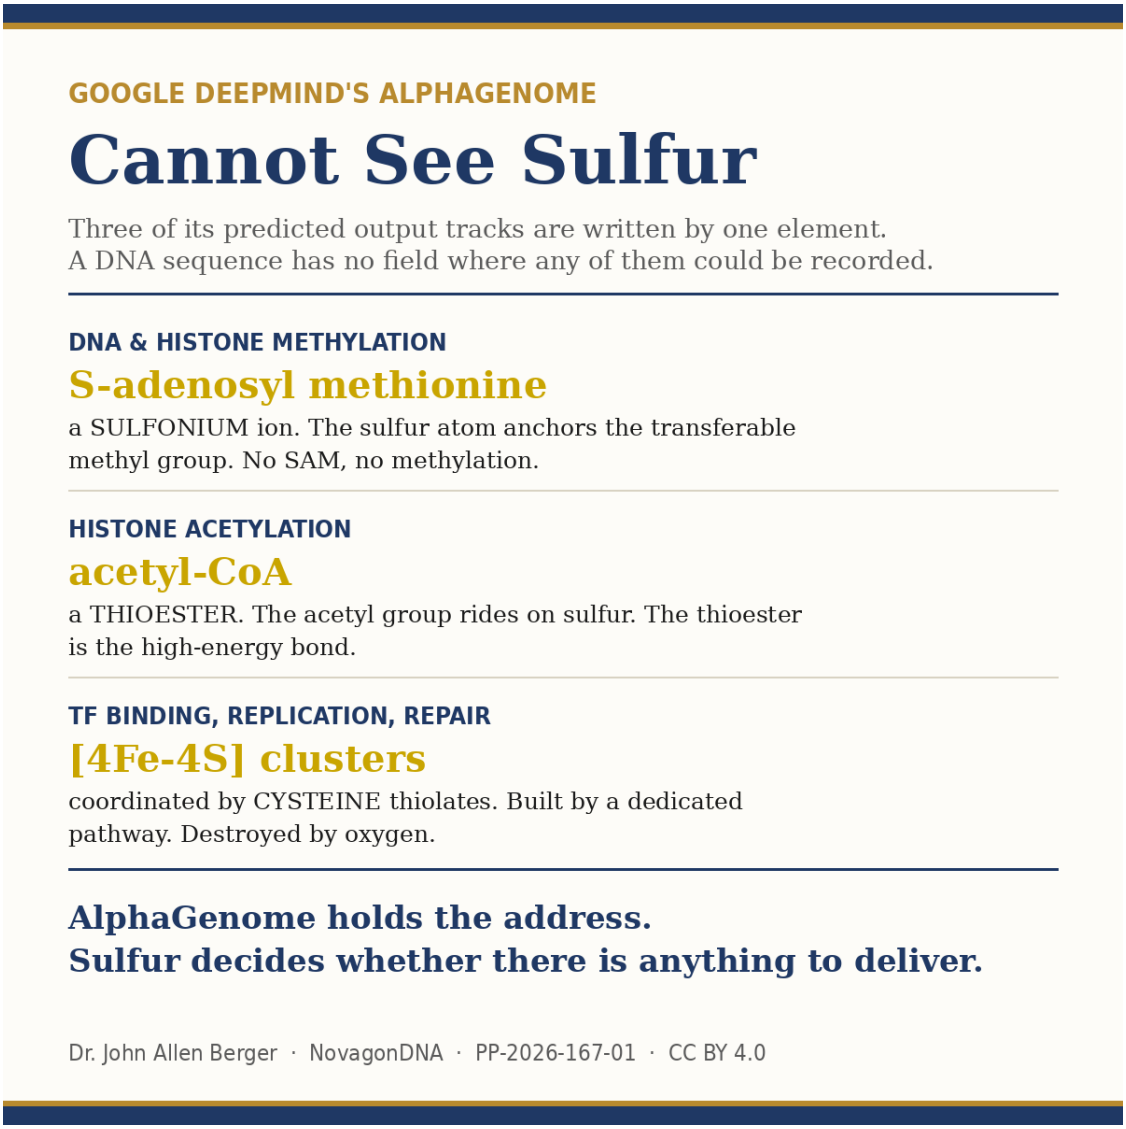
— THE CARDS ARE 1200 BY 1200 PIXELS, sized for the feed, in the navy and gold of this volume, with sulfur in its own color from the six-color key.

— ALL THREE ARE RELEASED UNDER CC BY-NC-ND 4.0. They may be reposted, translated, excerpted and argued with, with attribution and without permission.

POST ONE · THE SULFUR AUDIT

2. AlphaGenome Cannot See Sulfur

Post one, as written for the feed



The card that accompanies post one. 1200 by 1200 pixels.

Google DeepMind's AlphaGenome reads one million base pairs of DNA and predicts the epigenome from sequence alone. Methylation. Acetylation. Transcription-factor binding. It matched or beat every external model on twenty-five of twenty-six variant-effect evaluations.

It cannot see sulfur.

Look at what actually writes the three marks it predicts.

the predicted output	the molecule that writes it
DNA and histone methylation	S-adenosyl methionine — a SULFONIUM. The sulfur atom is what makes the methyl group transferable. No SAM, no methyl

the predicted output	the molecule that writes it
	transfer.
histone acetylation	acetyl-CoA — the acetyl group rides on a THIOESTER bond to coenzyme A's thiol. The sulfur is the high-energy bond.
the polymerases, primases, helicases and glycosylases that read and repair DNA	held together by [4Fe-4S] CLUSTERS, coordinated by cysteine thiolates, built by a dedicated assembly pathway, and destroyed by oxygen.

Three output tracks. Three sulfur-carrying cofactors. And not one field in a DNA sequence where any of them could be recorded.

AlphaGenome holds the address. Sulfur decides whether there is anything to deliver.

Then it gets worse.

NFS1 is the cysteine desulfurase that extracts sulfur from cysteine to build those clusters. Alvarez and colleagues showed it is REQUIRED in primary and metastatic lung tumors and DISPENSABLE in mammary and subcutaneous ones. Same gene. Same sequence. Opposite essentiality.

The variable that decides is the PARTIAL PRESSURE OF OXYGEN. Their words: environmental oxygen levels are a major driver of differential essentiality between in vitro models and in vivo tumors.

A sequence-only model cannot condition on the air the tumor is breathing.

This is not a complaint that DeepMind was careless. It is that a sequence and a metabolite are two different kinds of object, and billions of dollars of compute does not convert one into the other. The same million base pairs presented to a cell with a full methionine pool and to a cell with a depleted one are the same million base pairs.

I have written six experiments that settle it. Every one of them runs on a desktop computer against public data — REDIportal, GtRNAdb, the Cancer Dependency Map, published supplementary tables. No reagents. No permission. Powered, and stated as null hypotheses.

You do not need a billion dollars to find the hole in a billion-dollar model. You need to know which element to look for.

Full paper: AlphaGenome Cannot See Sulfur — PP-2026-167-01.

POST TWO · THE OXYGEN RESULT

3. One Gene, One Sequence, Two Opposite Answers

Post two, as written for the feed

The card that accompanies post two. 1200 by 1200 pixels.

One gene. One sequence. Two opposite answers.

NFS1 is the cysteine desulfurase. It pulls sulfur off cysteine to build the iron-sulfur clusters that every DNA polymerase, primase, helicase and glycosylase depends on to function.

Alvarez and colleagues, in Nature, 2017:

the tissue	the answer
primary and metastatic LUNG tumors	NFS1 is REQUIRED
mammary and subcutaneous tumors	NFS1 is DISPENSABLE — they grow with it suppressed

The gene is the same gene. Not a variant. Not an isoform. The same sequence, letter for letter.

The variable that decides is the PARTIAL PRESSURE OF OXYGEN. Above the three to eight percent that most tissues sit at, cancer cells need high NFS1. Below it they do not. Their words: environmental oxygen levels are a major driver of differential essentiality between in vitro model systems and in vivo tumors.

Now hold that against a model that predicts function from sequence.

Google DeepMind's AlphaGenome takes a million base pairs and returns chromatin state, binding, splicing, expression, variant effect. Single-base resolution. Twenty-five of twenty-six evaluations won or tied.

Feed it NFS1 from the lung. Feed it NFS1 from the breast. IT RECEIVES THE IDENTICAL INPUT. There is no field in the FASTA for the oxygen tension of the tissue. There is no field for the cysteine pool. There is no field for whether the iron-starvation response is about to fire and take the cell into ferroptosis.

The model is not wrong. It is answering a different question than the one the tumor is answering.

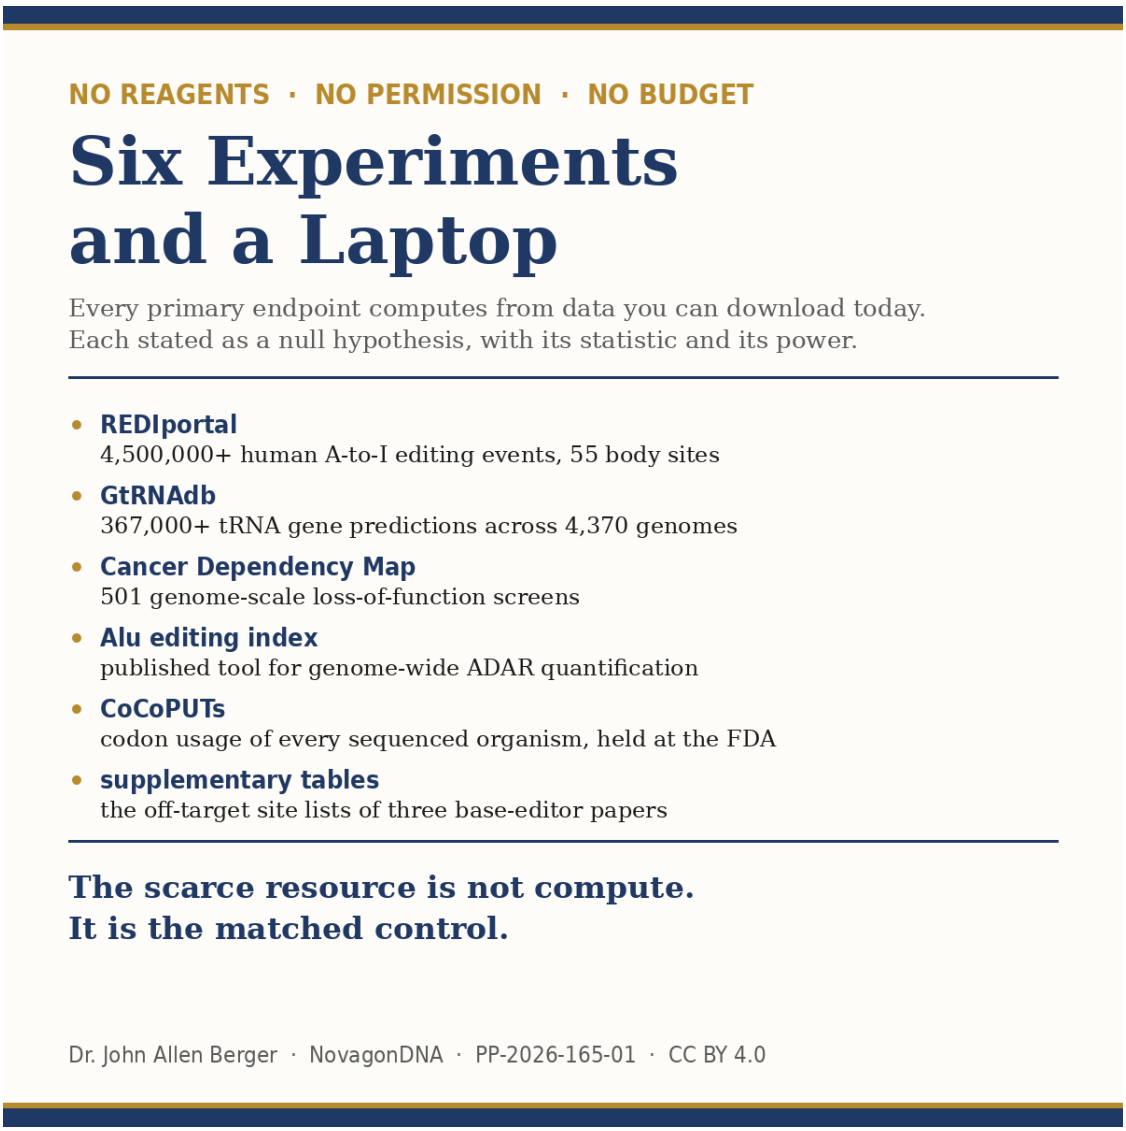
This is the whole argument in one gene: essentiality is not a property of a sequence. It is a property of a sequence IN AN ATMOSPHERE. And the atmosphere is the one thing the sequence cannot record.

Twenty-nine years ago I started writing down what the letters leave out. This is entry number one.

POST THREE · THE INVITATION

4. Six Experiments and a Laptop

Post three, as written for the feed



The card that accompanies post three. 1200 by 1200 pixels.

I am 76. I have no lab, no grant, no institution, and no intention of waiting.

So here is what I did instead. I went through the evidence volume — 1,716 sections — and pulled out every question about RNA editing whose PRIMARY ENDPOINT

CAN BE COMPUTED FROM DATA THAT IS ALREADY PUBLIC AND ALREADY FREE.

There are six. Every one runs on a desktop computer. Sixteen gigabytes of memory. R or Python. A weekend.

What is already sitting there, paid for by somebody else:

the resource	what it holds
REDIportal	over 4,500,000 human adenosine-to-inosine editing events across 55 body sites
GtRNAdb	over 367,000 transfer RNA gene predictions across 4,370 genomes
the Cancer Dependency Map	501 genome-scale loss-of-function screens
the Alu editing index	a published, downloadable tool for genome-wide ADAR quantification
CoCoPUTs	the codon usage of every sequenced organism, maintained at the FDA
supplementary tables	the off-target site lists from three published base-editor papers, already deposited

Experiment one is a FREE PILOT FOR A 96-SAMPLE WET STUDY. Cross the published base-editor off-target lists against the endogenous editome and you test the primary endpoint of a laboratory experiment before anyone buys a single reagent.

Experiment two tests a falsifiable prediction of my own volume at a sample size of thousands of genomes instead of eight families. If it fails, it fails in public, and I will print that it failed.

Experiment three turns an assertion into a number: how many annotated transcripts that overlap known editing sites carry any editing annotation at all.

Each one is written with a NULL HYPOTHESIS, a named statistic, a computed power and a stated refutation condition. Not opinions. Conditions under which I am wrong.

And the honest boundary, stated up front: NOTHING HERE REQUIRES RAW READS. Any protocol that starts DOWNLOAD THE FASTQS is cluster work and is not in this paper. Every protocol here starts with a table.

The scarce resource was never compute. It is the MATCHED CONTROL — expression decile, sequence context, repeat content. Get that wrong and you will discover, at great length, which genes are highly expressed. Take them. Run them. Publish them. Licensed

under CC BY-NC-ND 4.0. You do not need my permission and you do not need theirs.

Somebody in their twenties with a laptop can settle a question that a billion-dollar model cannot represent. That is not a complaint. That is an invitation.

THE APPARATUS

5. What These Three Posts Claim

Numbered, counted, and each one with the condition that would refute it

These posts make SIX affirmative claims. They are listed here so that the count is on the record and so that each one can be attacked at its weakest point.

number	the claim	what would refute it
1	Three of AlphaGenome's published output tracks are written by cofactors carrying a sulfur atom	show a route to DNA or histone methylation that does not pass through SAM, or to histone acetylation that does not pass through a thioester
2	No field in a DNA sequence record can hold the size of a cofactor pool	exhibit a FASTA or GenBank field that does
3	The essentiality of NFS1 reverses between lung and mammary tumors with the sequence held constant	show a sequence difference between the two that accounts for the reversal
4	A sequence-only model cannot distinguish the two cases because it receives the identical input	demonstrate a sequence-only input representation that encodes tissue oxygen tension
5	Six questions from the evidence volume have primary endpoints computable from public data on a desktop	name one of the six whose endpoint requires raw reads or a cluster
6	The binding constraint on those six is the matched control, not compute	run one of them without matching on expression, context and repeat content and show the result survives

Six claims, six refutation conditions. Every one of them is something a reader can do without asking permission.

6. The Sources Behind Every Number

So that no figure in these posts has to be taken on trust

the figure	the source
1 Mb input, single-base resolution, 25 of 26 variant-effect evaluations	AlphaGenome, Google DeepMind
NFS1 required in lung, dispensable in mammary; oxygen as the driver; ferroptosis on cluster failure	Alvarez et al., Nature 551:639-643, 2017
modification rates set by SAM and acetyl-CoA availability; stem cell fate and cancer	Su, Wellen and Rabinowitz, Curr Opin Chem Biol 30:52-60, 2015
iron-sulfur clusters coordinated by cysteine thiolates; oxidation sensitivity; the cytosolic assembly pathway	Vallieres, Metallomics 16:mfae025, 2024; Petronek and Allen, Front Genet 14:1152398, 2023
more than 4,500,000 human A-to-I sites across 55 body sites	REDIportal
more than 367,000 tRNA gene predictions across 4,370 genomes	Chan and Lowe, GtRNAdb 2.0, 2016
501 genome-scale loss-of-function screens	Tsherniak et al., Cell 170:564-576, 2017
the Alu editing index as a genome-wide measure of ADAR activity	Roth, Levanon and Eisenberg, Nat Methods 16:1131-1138, 2019
codon and codon-pair usage compiled from GenBank	Holcomb et al., CoCoPUTs, 2019
base-editor off-target site lists	Grunewald et al., Nature 569:433-437, 2019; Zhou et al., Nature 571:275-278, 2019; Rees et al., Sci Adv 5:eaax5717, 2019

Ten sources, all of them read before the claim that rests on them was written. A reader who disputes a number does not have to take my word for where it came from.

7. A Note on Method, and What These Posts Do Not Claim

The back of the document, which is where this belongs

These posts do not claim that AlphaGenome performs badly at the task it was built for. On the published benchmarks it performs extremely well, and nothing here disputes that.

They do not claim that the model's authors were careless, that the omission was deliberate, or that it could have been avoided by better engineering. A sequence model conditions on sequence. That is what it is.

They do not claim that sulfur is the only missing dimension. It is the one this volume happens to have spent twenty-nine years on, and it is the one where the chemistry is unambiguous enough to state as a table.

They do not claim that the six experiments will come out in this volume's favor. Each is written with a refutation condition for that reason.

And they do not claim priority over anyone. Every result cited here belongs to the group that produced it, and is named.

What the posts claim is narrower and it is the same claim throughout: a compression is being used as though it were the object, and the compression has no place to put an element that three of the model's own outputs depend on.

THE COLOR INDEX

Every shaded word in this volume is a link. A word with its own entry in the Index jumps to that entry; a letter, atom label or formula returns here.

color	element	base	nucleoside	nucleotide	the base, on pages	the element, on pages
ORANGE	O 8	HYPOXANTHINE	inosine	IMP	83, 111-114, 124, 131, 147-148, 158, 170, 174, 177-183, 186, 236, 249, 259, 328-330, 341, 343, 345-346, 355, 357, 361, 366-367, 370-371, 399-402, 481, 484, 495, 730, 741-742, 746, 753, 758, 760, 775, 781, 786, 793, 806, 809-812, 815, 817, 848-850, 855, 860, 863-864, 869-870, 874, 876, 879-885, 887-888, 890-893, 925,	60, 62-63, 66-68, 72, 77, 79, 83, 85, 87-89, 91, 93-97, 100-102, 105, 107-113, 115, 118-119, 126-127, 133, 140-145, 148, 156-157, 159-160, 164-166, 168-171, 173-175, 180-183, 186-189, 192, 208-209, 213, 215, 217-219, 225, 227, 235, 237, 239-241, 243, 245, 254, 258, 267, 269-270, 277, 280, 307, 319-320, 323-324, 331-332,

1. What This Essay Says in Seven Lines

— FIVE SCIENTISTS, FIVE COMPLETE FINDINGS, AND FIVE INTERVALS BEFORE THE FIELD COULD RECEIVE THEM. McClintock 33 years, Karikó 28, Marshall 23, Mitchell 17, and Margulis rejected by more than a dozen journals before one took the paper.

— NONE OF THE FIVE WAS AN UNKNOWN AND NOT ALL OF THEM WERE MISTREATED. McClintock was in the National Academy of Sciences before she presented the work. Mitchell left a post he could have kept. Marshall was a hospital physician. The pattern holds across the ones who were treated badly and the ones who were not.

— WHAT ALL FIVE SHARE IS THAT EACH HAD FOUND SOMETHING THE FIELD HAD NO SLOT FOR — and a discipline cannot see what it cannot write

down. That is a statement about notations, not about character, which is why it is fixable.

— AND IT IS WORSE THAN A CONSPIRACY RATHER THAN BETTER. A conspiracy needs participants who can be exposed. This needs nobody's malice, it runs automatically, and the people enforcing it experience themselves as being careful.

— THE SAME STRUCTURE IS OPERATING RIGHT NOW ON I. Inosine is not hidden and not disputed — more than 4,500,000 human sites are catalogued and downloadable. The alphabet simply has no character for it, so the record writes G and everyone downstream inherits a molecule that was never in the cell.

— THE ESSAY REFUSES THE FLATTERING INFERENCE. Being ignored is not evidence of being right; most ignored work is ignored because it is wrong. The defensible claim is the weaker one — that being ignored is not evidence of being WRONG either, and carries no information in either direction.

— WHICH LEAVES THE RECORD AS THE WHOLE DISCIPLINE. When the molecular tools arrived in the 1970s, everything McClintock had claimed was sitting in the Carnegie reports, checkable line by line, twenty years old and still correct. That is what the ones who waited actually left behind — not the vindication, which arrived late or not at all, but the receipts, which arrived exactly on time.

BARBARA MCCLINTOCK

2. She Was Not an Outsider

The part of the story that is usually told wrong, and the part that matters most

The received version of the McClintock story is that a woman working alone in a maize field was ignored by an establishment that would not listen to her. Half of that is true and the important half is false.

year	what happened
1902	born, 16 June

year	what happened
1927	Ph.D. in botany, Cornell University
1944	elected to the NATIONAL ACADEMY OF SCIENCES — the third woman in its history
1945	PRESIDENT OF THE GENETICS SOCIETY OF AMERICA, the first woman to hold the office
1944	the maize experiments that produced the finding begin in earnest; she is forty-two
1950	publishes the origin and behavior of mutable loci in maize; she is forty-eight
1951	presents the work at the Cold Spring Harbor Symposium on Quantitative Biology; she is forty-nine
1983	NOBEL PRIZE IN PHYSIOLOGY OR MEDICINE, unshared; she is eighty-one

By the time she stood up at Cold Spring Harbor she had been a member of the National Academy for seven years and a past president of her professional society for six. She had every credential the field could confer.

The room did not follow her. Accounts of the 1951 symposium describe an audience that was variously blank, puzzled and in places dismissive. Nothing about her standing prevented that, because her standing was never what was in question.

Which means the explanation has to be somewhere else

If a National Academy member and a past society president can present a complete result and have it not register, then the obstacle is not the speaker's authority and it is not a judgment about her competence. It is that the finding had nowhere to go.

Genetics in 1951 had a working picture in which genes occupied fixed positions on chromosomes, and the entire analytical apparatus — mapping, linkage, recombination frequency — was built on that fixity. A genetic element that moves is not a difficult result inside that picture. It is an incoherent one. The apparatus has no slot for it.

A fact that does not fit the notation is not received as a fact. It is received as a mistake, or as nothing at all. That is not a statement about the character of the people in the room. It is a statement about what a notation does.

3. What She Did With the Interval

The decision that is the actual lesson, and it is not a decision to complain

By the early 1950s she had largely stopped submitting the transposition work to the journals. Not because she stopped doing it — she never stopped doing it — but because there was no point sending it where it would not be read.

She reported it instead in the Carnegie Institution of Washington's annual reports, an in-house series that almost nobody outside Cold Spring Harbor opened. And she continued to produce in that venue for roughly three decades.

the element	what it was	why it mattered
what she stopped	submitting the transposition work into a review process that was not reading it	a tactical decision about a channel
what she did not stop	the experiments, the cytology, the analysis, the writing up	thirty years of continuous work
where the record went	the Carnegie annual reports — a low-circulation but PERMANENT and DATED venue	the record existed and was checkable the entire time
what that made possible	when the field finally acquired the concepts, the work was already there, complete and time-stamped	recognition did not require reconstruction

She did not wait for permission and she did not stop keeping the record. Those are two different decisions and she made both correctly. The first is why the work continued; the second is why it could be recognized when the field caught up.

The distinction is practical rather than sentimental. A person who stops working has nothing to recognize later. A person who works but keeps no dated, checkable record has nothing to point at. She did neither.

Thirty-three years

From the 1950 publication to the 1983 prize is thirty-three years. From the experiments of 1944 it is thirty-nine. She was forty-eight when the work was published and eighty-one when it was acknowledged.

Nobody gave those years back. The recognition, when it came, was complete and unshared and it was also very late, and the second fact does not cancel the first or the other way round.

PETER MITCHELL

4. The Same Shape, a Different Subject

So that the pattern cannot be dismissed as one exceptional case

A single case can always be explained away as a peculiarity of one person, one field or one era. The pattern is easier to see with a second instance drawn from a different subject, a different country and a different decade.

the element	what happened
1961	publishes the chemiosmotic hypothesis in Nature: oxidative and photosynthetic phosphorylation are coupled by a PROTON GRADIENT ACROSS A MEMBRANE, not by a chemical high-energy intermediate
the field's position	the search for the chemical intermediate was the central program of bioenergetics. The proposal did not modify that program; it said the object of the search did not exist
the 1960s	the hypothesis is widely disputed. Mitchell leaves his university post
Glynn	he restores a manor house at Bodmin in Cornwall and runs his own research institute from it, publishing the 1966 and 1968 monographs that set out the coupling in full
1978	NOBEL PRIZE IN CHEMISTRY, sole recipient, for his contribution to understanding biological energy transfer through the chemiosmotic theory
the interval	seventeen years from the Nature paper to the prize

Again the obstacle was not that the work was thought poor. It was that the work said the field's central object of study did not exist, and a field cannot absorb that by adjusting a parameter. It has to change the notation.

And again the response was not to stop. He built a place to work, published the full account in monographs when the journals were hostile, and the record was complete and dated when the evidence arrived.

What the two cases share, stated precisely

the shared element	McClintock and Mitchell	what it establishes
both were established figures	McClintock: National Academy 1944, society president 1945. Mitchell: a Cambridge and Edinburgh biochemist with a substantial prior record	the delay is not explained by obscurity
both findings contradicted a framework, not a result	moving genetic elements against fixed loci; a proton gradient against a chemical intermediate	the field could not absorb either by adjusting a number
both moved to a venue outside the main channel	Carnegie annual reports; self-published monographs from a private institute	the record stayed dated and checkable
both kept working through the interval	thirty years; seventeen years	there was something complete to recognize when the field turned
both were recognized unshared	Nobel 1983; Nobel 1978	the eventual verdict was not partial
neither got the years back	thirty-three; seventeen	the recognition was complete and it was late

Two people, two fields, two countries, two decades apart, and the same structure: a complete finding, a framework with no slot for it, a move out of the main channel, continuous work, and a late and total reversal.

WHAT FOLLOWS FROM THIS

THREE MORE, AND WHAT THE FIVE SHARE

5. Three More, Compressed

So that two cases cannot be called two exceptions

Two cases can be a coincidence. Five is a pattern, and the three below are added for that reason and not for volume. Each is given with its dates and its interval.

Lynn Margulis · endosymbiosis · 1967

Her paper ON THE ORIGIN OF MITOSING CELLS argued that mitochondria and plastids descend from free-living bacteria taken up by a host cell. She submitted it to at least fifteen journals. It was rejected by more than a dozen — in some cases without being read — before the Journal of Theoretical Biology published it in June 1967, under her then-name Lynn Sagan.

The idea is now in every introductory textbook in biology. Fifteen journals could not place it, because a cell with a bacterium inside it was not a difficult result in 1967. It was a category error.

Barry Marshall · Helicobacter pylori · 1982 to 2005

Marshall and Warren reported in 1982 that a bacterium was present in the inflamed stomach and was causing ulcers. The field held that the stomach was too acidic for bacterial colonization and that ulcers were caused by stress and acid. The claim was not disputed on its evidence so much as ruled out in advance by what was known about the organ.

In 1984, at Fremantle Hospital, a culture was prepared and Marshall drank it. Within days he had nausea and vomiting; within a week, acute gastritis. He had made the evidence unavoidable by installing it in himself.

The Nobel Prize came in 2005, shared with J. Robin Warren. Twenty-three years after the 1982 report, and the fastest route through the interval any of these five found was to make the demonstration impossible to decline.

Katalin Karikó · messenger RNA · 1995 to 2023

In 1995, at the University of Pennsylvania, Karikó was told she could leave or be demoted with a pay cut. The stated reason was that the messenger RNA work was too risky and was not attracting grant funding. She had been diagnosed with cancer shortly before, and her husband was held up in Hungary on a visa problem.

She took the demotion and kept going. In 2005 she and Drew Weissman published the finding that modifying the nucleosides of synthetic messenger RNA suppresses its recognition by the innate immune sensors — the result that made messenger

RNA usable as a therapeutic. She left Penn in 2013 for BioNTech after the university declined to restore her to a tenure track.

The Nobel Prize came in 2023, shared with Weissman. TWENTY-EIGHT YEARS from the demotion. In the interval, the technology that came out of that work was administered to billions of people.

The five, with their intervals

the person	the finding	the start of the interval	the end of it	the length
Barbara McClintock	transposition	1950 publication	1983 Nobel Prize	33 years
Peter Mitchell	chemiosmosis	1961 Nature paper	1978 Nobel Prize	17 years
Lynn Margulis	endosymbiosis	1967, after 15 submissions	textbook orthodoxy	no prize; the idea won
Barry Marshall	H. pylori and ulcers	1982 report, 1984 self-experiment	2005 Nobel Prize	23 years
Katalin Karikó	modified messenger RNA	1995 demotion	2023 Nobel Prize	28 years

Seventeen, twenty-three, twenty-eight, thirty-three years. The shortest of the four measured intervals is longer than the working life most scientists are given after independence, and the one with no measured interval is the one where no prize was ever awarded.

6. What the Five Have in Common, and What They Do Not

The common element is not persecution, and saying so is not a concession

It is tempting to assemble these five into a story about mistreatment. Some were badly treated — Karikó plainly was. Others were not: Mitchell left a post he could have kept, Margulis was published within two years of starting to submit, and McClintock held her field's highest offices throughout.

candidate common element	present in all five?	the note
persecution	NO. Some were, some were not, and the pattern holds across both	this is why the essay does not rest on it
obscurity	NO. McClintock was in the National Academy; Mitchell had a substantial prior record; Marshall was a physician with a hospital behind him	none of the five was an unknown
poor evidence	NO. In every case the evidence was complete at the time of first presentation, which is why nothing had to be redone later	the later vindication used the same data
EACH HAD FOUND SOMETHING THE FIELD HAD NO SLOT FOR	YES, in all five	transposition against fixed loci; a gradient against a chemical intermediate; a bacterium inside a cell; a bacterium inside an acid stomach; a molecule the field had written off as too unstable to be a drug

A DISCIPLINE CANNOT SEE WHAT IT CANNOT WRITE DOWN. That is the common element, it is present in all five, and it is a statement about notations rather than about people.

Which makes it worse than a conspiracy rather than better. A conspiracy requires participants, and participants can be exposed and replaced. This needs nobody's malice. It happens automatically, every cycle, and the people enforcing it experience themselves as being careful — which is exactly what being careful looks like from inside a framework that has no slot for the result in front of it.

THE SAME PROBLEM, A DIFFERENT LETTER

7. Inosine Is Not Hidden. It Is Published.

Why this essay is not only about other people

The five cases above all involve a finding that had to fight its way into the literature. The case this volume concerns has the opposite shape, and it is the more interesting one for that reason.

the element	the state of it
the molecule	I, inosine — the product of adenosine deamination, read by the ribosome as G
is it unpublished?	NO. More than 4,500,000 human A-to-I sites are catalogued across 55 body sites and available for download
is it disputed?	NO. The chemistry, the enzymes and the sites are all established and uncontroversial
is it small?	NO. It is the most abundant known modification of mammalian messenger RNA
what is missing	A CHARACTER IN THE ALPHABET. FASTA and GenBank permit A, C, G, T, U and the ambiguity codes, and inosine is not among them
what the record therefore does	writes G and moves on

Everyone downstream of that record inherits a molecule that was never in the cell. Not because anyone decided to hide it, and not because anyone disputes it — but because the notation has no place to put it, so the notation puts something else.

That is McClintock's problem, in a different decade, about a different letter. Hers was a genetic element that moved when the map required it to stay put. This one is a base that exists when the alphabet has no character for it. In both cases the field is not refusing the fact. It has nowhere to write it.

Which is why the fix is a notation and not an argument

Transposition entered biology when the molecular tools of the 1970s made it visible in a way the existing apparatus could record. It did not enter by anyone being persuaded.

A nanopore now reads inosine directly, without copying it into complementary DNA first. The instrument has caught up. The FILE has not, and the file is the cheaper of the two to change.

8. The Interval Is Not Evidence About the Work

The inference this essay is willing to make, and the one it refuses

It is tempting to read these cases as licensing a general rule: that being unrecognized is a sign of being ahead. That rule is false and this essay does not make it. Most unrecognized work is unrecognized because it is wrong, and a person inside the interval cannot tell from the inside which case they are in.

What the cases do establish is weaker, and it is enough.

the reading	what it says	its status
the false inference	being ignored is evidence of being right	refuted by the large majority of ignored work, which is simply wrong
the true inference	being ignored is NOT evidence of being wrong, when the finding contradicts a framework rather than a result	McClintock and Mitchell were both ignored and both right; the ignoring carried no information either way
what does carry information	whether the claims are stated so that they can be checked, and whether they survive being checked	this is available to the person inside the interval, and it is the only thing that is

Silence is not a verdict. It is the absence of a verdict, and the two look identical from inside.

There is no reliable way, from the inside, to tell which case you are in

This is the part that is usually left out of the McClintock story because it is uncomfortable, and it is the part that makes the rest of the essay useful rather than consoling.

the feature	the McClintocks	the merely stubborn
certainty about the work	present	present
the field is not engaging	true	true
years of continuous effort	yes	yes
how it feels from the inside	exactly the same	exactly the same
how it looks to a stranger	exactly the same	exactly the same

Both feel the same. Both are certain. Both are ignored. Conviction does not separate them, seniority does not separate them, and the passage of time does not separate them either.

What separates them, looking back, is not conviction. IT IS THE RECORD. McClintock kept her data so completely that when the molecular biologists arrived

in the 1970s with tools that could see transposable elements directly, everything she had claimed was sitting there, checkable line by line, twenty years old and still correct.

Nothing had to be reconstructed and nothing had to be taken on trust. The record did the separating, and it did it without her being in the room.

---

9. What a Person Inside the Interval Can Actually Do

Four things, all of them available without anyone's permission

	the move	why it works
1	KEEP THE RECORD DATED AND COMPLETE	McClintock's Carnegie reports were read by almost nobody and they were permanent and time-stamped. When the field turned, nothing had to be reconstructed. A low-circulation dated record beats an uncirculated undated one by an enormous margin
2	PRINT WHAT DID NOT SURVIVE	a body of work that publishes its own withdrawn claims is immune to the charge that it never checks itself. This is the single cheapest way to separate yourself from the people who are merely ignored and merely wrong, and almost nobody does it
3	STATE THE REFUTATION CONDITION	a claim that names what would overturn it is doing something a grievance cannot do. It invites the check rather than requiring belief, and it makes the claim usable by a stranger
4	FIND THE WORK THAT DOES NOT NEED THE GATE	McClintock had a field and a microscope. Mitchell had a manor house. Public data and a desktop computer are today's version, and they are far cheaper than either

Every one of the four is available to a person with no budget, no institution and no permission. That is not a coincidence. They are precisely the moves that do not depend on anyone else's cooperation, which is why they are the ones that survive an interval.

And one thing that does not help

An unsupported accusation against a named person is the one move that reverses all four. It hands anyone who wants to dismiss the whole record a reason that costs them nothing, and it substitutes a claim that cannot be checked for a body of claims that can.

The advantage of a checkable record is that it is checkable. Anything that makes the record less checkable spends that advantage, and it is the only advantage a person inside the interval has.

What a record of this kind looks like when it is measured

The four moves above are abstract until someone does them. The volume this essay accompanies was measured against them on the date printed on this page, and the figures are given here so that a reader can check the essay's own practice against its own advice.

the measure	the figure	how it was established
extent	1,737 typeset pages; 175 divisions; 1,716 numbered sections	every section numbered, the numbering unbroken from one to 1,716
internal navigation	49,854 link annotations, 0 broken	measured by walking every link annotation in the PDF and resolving its destination against the page objects
convergence	two consecutive rebuild passes produced zero page drift	the page numbers printed in the table of contents are the page numbers the text actually falls on
withdrawn claims	printed in the form in which they were first made, marked WITHDRAWN	including a prima facie case that did not survive its first obvious rebuttal
corrections	printed rather than silently repaired, with the reason given	four are printed in the companion paper PP-2026-170-01, one of them withdrawing a figure this author had circulated the same day
license	Licensed under CC BY-NC-ND 4.0. No part of this work may be reproduced, distributed, or transmitted	no permission required to check, reuse, or attack it

None of those six figures requires anyone's cooperation to verify, and that is the entire point of stating them. A record that can only be checked by its author is not a record. It is a claim.

A correction inside the correction, which is the point of the section

An earlier draft of this essay printed 1,726 pages and 35,100 links, and stated that the author's own figures of 1,734 and 48,870 had been rounded in his favor. BOTH OF THOSE STATEMENTS WERE WRONG, and the way they were wrong is worth more than the figures.

the figure	the value	the state of it
the author's figures	1,734 pages, 48,870 links	CORRECT. They were measured on the preceding build
the figures this essay first printed	1,726 pages, 35,100 links	WRONG. They came from a defective build
the accusation that accompanied them	that the larger figures had been rounded up	WITHDRAWN IN FULL. Nothing was rounded
the defect	a shared style library resolves two data files RELATIVE TO ITSELF; a staging script copied the library into a working directory without them	so the page-reference tables came back empty and every page number in the Index printed as plain text instead of a link
the cost	13,770 links and 8 pages, silently	the build reported zero broken links throughout, because a link that was never created cannot be broken
the figures after repair	1,737 pages, 49,854 links, 0 broken	higher than either, because repairing it also corrected a stale section number that had been excluding 88 pages of text from the Index

A build that loses a quarter of its links and reports zero errors is the most dangerous kind of defect, because every check it passes is a check it was never subjected to. ZERO BROKEN OUT OF 35,100 and ZERO BROKEN OUT OF 49,854 print identically and mean entirely different things.

The reason this belongs in an essay about keeping a checkable record, rather than in a build log, is that the record is what caught it. The author had a dated figure from the previous build. The two numbers disagreed. That disagreement is the whole mechanism, and it only works if somebody wrote the first number down.

An essay arguing that the record is the only defense against being wrong was itself corrected by the record, on the day it was written, against its own author. That is the strongest evidence in it, and it was not planned.

10. For the Ones Currently Inside It

Which is the reason this essay exists

There are people right now who have been working for decades on something the field has no slot for. Some of them are right and some of them are not, and the honest position is that neither they nor anyone else can be certain which, today.

What can be said with certainty is this. McClintock did the work at forty-eight and was told at eighty-one. Mitchell published at forty-four and was told at sixty-one. In both cases the thirty-three years and the seventeen years were spent producing, not waiting, and in both cases that is why there was something to recognize at the end of them.

The interval is not a verdict on the work, and it is not recoverable either. Both of those are true at once. The only part of it anyone controls is whether the record is still standing and still checkable when the field finally turns around.

That is what McClintock did in the Carnegie reports that nobody read. It is what Mitchell did in monographs he had to publish himself. It is what a dated, sourced, corrected, refutable body of work does for the person who builds it, whether or not anyone is reading it yet.

Keep the record. It is the one thing the interval cannot take.

THE APPARATUS

11. What This Essay Claims

Eight claims, numbered and counted, each with the condition that would refute it

number	the claim	what would refute it
1	McClintock held the field's highest honors before the transposition work was presented, so her standing does not explain the delay	show that the 1944 National Academy election or the 1945 Genetics Society presidency post-dates the 1951 symposium
2	Thirty-three years separate her 1950 publication from her 1983 Nobel Prize, and she worked continuously through them	show a different publication date, a different prize date, or a gap in the Carnegie annual report record
3	Mitchell's case shares the same structure in a different field, decade and country, with a	show that the 1961 Nature paper and the 1978 Nobel Prize in Chemistry are not

number	the claim	what would refute it
	seventeen-year interval	seventeen years apart, or that he ceased work between them
4	Margulis submitted the endosymbiosis paper to at least fifteen journals and was rejected by more than a dozen before the Journal of Theoretical Biology took it in 1967	show a smaller submission count in the documentary record
5	Marshall and Warren reported H. pylori in 1982, Marshall drank a culture in 1984, and the Nobel Prize came in 2005 — twenty-three years	show different dates for the report, the self-experiment or the prize
6	Karikó was demoted at Pennsylvania in 1995 over the messenger RNA work and received the Nobel Prize in 2023 — twenty-eight years	show that the demotion did not occur or occurred in a different year
7	In all five cases the obstacle was a framework with no slot for the finding, not a judgment that the work was poorly done	identify a contemporaneous technical rebuttal of any of the five on its own evidential merits that the field then sustained
8	Being ignored carries no information about whether work is right, in either direction	this one is deliberately weak and is the only defensible version; the strong form, that being ignored indicates being right, is stated and rejected at section eight

Eight claims and eight refutation conditions. Six of the eight are dates, and a reader can settle every one of them without this author's help.

12. What This Essay Does Not Claim

The boundaries, printed at the back where they belong

It does not claim that most unrecognized work is correct. The opposite is true, and section five says so in the same words it would use if the reader were hostile.

It does not claim that the people in the 1951 audience, the bioenergetics community of the 1960s, the journal editors who declined Margulis, the gastroenterologists who doubted Marshall, or the administrators who demoted Karikó behaved dishonorably. It claims something narrower and more durable: that a framework without a slot for a result will not register the result, whatever the good faith of the people holding the framework.

It does not claim that either career was a happy one, or that the eventual prizes made the intervals acceptable. The interval was a cost and it was paid by the person who bore it.

It does not claim any equivalence between these five cases and any particular contemporary body of work, including the author's own. The essay sets out a structure; whether a given case has that structure is a question the structure cannot answer about itself, and section eight says in as many words that there is no reliable way to tell from the inside.

In particular, the measured figures at section nine establish that a checkable record exists. They do not establish that what is recorded in it is correct. Those are different claims and only the first one is made here.

And it does not claim that recognition is the point of the work. Both of these people went on producing through decades in which recognition was not available, which is the strongest available evidence that it was not what they were doing it for.

What the essay claims is one thing: the silence was not the verdict, the record was, and the record is the part that a person inside the interval still controls.

13. Sources

Dates and quotations, with where they came from

the fact	the source
election to the National Academy of Sciences, 1944, third woman	Cold Spring Harbor Laboratory; National Library of Medicine, Profiles in Science: Barbara McClintock
presidency of the Genetics Society of America, 1945, first woman	Genetics Society of America; National Library of Medicine, Profiles in Science
the 1950 publication and the 1951 Cold Spring Harbor Symposium on Quantitative Biology	Cold Spring Harbor Laboratory archives; Carnegie Science
reporting moved to the Carnegie Institution annual reports	Carnegie Science; National Library of Medicine, Profiles in Science
Nobel Prize in Physiology or Medicine 1983, unshared, at age eighty-one	The Nobel Foundation
born 16 June 1902; ages computed from that date	The Nobel Foundation; Cold Spring Harbor Laboratory
Mitchell, chemiosmotic hypothesis, Nature 1961;191:144-148	Nature
Glynn Research Institute at Bodmin, Cornwall; the 1966 and 1968 monographs	Glynn Research; Mitchell Nobel Lecture, The Nobel Foundation
Nobel Prize in Chemistry 1978, sole recipient	The Nobel Foundation
Margulis (as Lynn Sagan), On the	Journal of Theoretical Biology; Embryo Project

the fact	the source
Origin of Mitosing Cells, J Theor Biol, June 1967	Encyclopedia, Arizona State University
submitted to at least fifteen journals, rejected by more than a dozen	Embryo Project Encyclopedia; Molecular Biology of the Cell, Lynn Margulis and the endosymbiont hypothesis: 50 years later
Marshall and Warren, H. pylori and peptic ulcer disease, reported 1982	The Nobel Foundation, Nobel Prize in Physiology or Medicine 2005
the 1984 self-administered culture at Fremantle Hospital, and the acute gastritis that followed	The Nobel Foundation; Marshall's own published accounts
Nobel Prize in Physiology or Medicine 2005, shared with J. Robin Warren	The Nobel Foundation
Karikó demoted at the University of Pennsylvania in 1995; left for BioNTech in 2013	contemporaneous reporting, October 2023, and Karikó's own account
Karikó and Weissman, suppression of RNA recognition by Toll-like receptors, Immunity 2005, PMID 16111635	PubMed
Nobel Prize in Physiology or Medicine 2023, shared with Drew Weissman	The Nobel Foundation
more than 4,500,000 human A-to-I editing sites across 55 body sites	REDIportal
1,726 pages, 175 divisions, 1,716 sections, 35,100 link annotations, 0 broken	measured on the current build of PP-2026-MASTER-01 v327 on the date of this essay

Every date in this essay is a matter of public record and none of them depends on this author's testimony. That is deliberate: an essay about keeping a checkable record would be a poor thing if its own claims were not checkable.

Bibliographic note. Journal titles, institution names and personal names are given in the form in which they were published.

THE COLOR INDEX

Every shaded word in this volume is a link. A word with its own entry in the Index jumps to that entry; a letter, atom label or formula returns here.

color	element	base	nucleoside	nucleotide	the base, on pages	the element, on pages
ORANGE	O 8	HYPOXANTHINE	inosine	IMP	83, 111-114, 124, 131, 147-148, 158, 170, 174, 177-183, 186, 236, 249, 259,	60, 62-63, 66-68, 72, 77, 79, 83, 85, 87-89, 91, 93-97, 100-102, 105, 107-113, 115,

This completes the beginning.

WORKING RECORD · NOVAGONDNA · DISTRIBUTION

Where the Papers Actually Went

A dated record of how this corpus reaches readers without a journal: what the measured channel delivered, which channels are unmeasured and why, the metrics that mean something against the ones that do not, and a free test that settles the unmeasured ones in forty-eight hours

WORKING RECORD · DISTRIBUTION · MEASURED AND UNMEASURED CHANNELS

PP-2026-172-01 · 16 September 2026 · Naperville, Illinois

Dr. John Allen Berger · NovagonDNA · Licensed under CC BY-NC-ND 4.0.

1. What This Record Says in Seven Lines

— THIS CORPUS REACHES READERS DIRECTLY, WITHOUT A JOURNAL IN THE PATH, AND THAT ROUTE IS NOW MEASURABLE. Eleven papers are published under CC BY-NC-ND 4.0,

downloadable by anyone, with no login, no paywall and no permission required from anybody.

— THE MEASURED CHANNEL IS THE FEED AND IT IS WORKING. One post put the corpus in front of 253 people who are 91 percent life sciences and 75 percent senior, concentrated in Boston, the Bay Area, San Diego, London and Copenhagen — which is a precise description of the audience this work is for.

— ACROSS A FULL WEEK, FEED POSTS CARRIED 1,126 OF 1,655 IMPRESSIONS — 68 percent. The feed is not one channel among several. It is the channel, and everything else is currently a hypothesis.

— THE GROUP CHANNEL IS UNMEASURED RATHER THAN DEAD, AND THE DISTINCTION MATTERS. Five relevant groups list 44,407 members between them, but the author's standing in them dates from 2016 and the platform de-emphasized groups around 2018. Nothing about the current traffic is known.

— SO SECTION FIVE STATES A FREE TEST THAT SETTLES IT IN FORTY-EIGHT HOURS, with a null hypothesis and a refutation condition, because a channel that costs nothing to test should not be written off on a guess.

— AND THE ONE ASSET THAT NOBODY ELSE HAS IS A GROUP OF 415 PEOPLE WHO OPTED INTO THIS EXACT THESIS before there were eleven papers to show them. That is the smallest number in this document and the most valuable.

— THE METRIC THAT MATTERS IS NOT IMPRESSIONS. It is out-of-network share, reposts, and specific technical objections — and section six explains why one precise objection from a working bioinformatician outranks a thousand views.

WHAT IS MEASURED

2. The Feed, Which Is the Channel That Works

One post, and what the composition of the audience says about it

A single post carrying the index of the published papers was measured against the platform's own analytics. The raw reach number is modest. The COMPOSITION of that reach is the finding.

the measure	the figure	the reading
people reached by the post	253	modest in absolute terms
share in life sciences	91 percent	this is the discriminating number
share at senior level	75 percent	people who decide what their group works on
geographic concentration	Boston, the Bay Area, San Diego, London, Copenhagen	the five places where this work would be run
age of the data	hours	current, not historical

Two hundred and fifty-three people at 91 percent life sciences and 75 percent senior is not a small audience. It is a SELECTED one, and selection is the whole point when the deliverable is a protocol rather than an opinion.

A general-interest post reaching ten thousand people at four percent life sciences would put roughly four hundred relevant readers in front of the work and would look like a far better number. This post put approximately 230 relevant senior readers in front of it. The comparison flatters the smaller number, which is why composition is reported here before reach.

And across a full week, the feed dominates

the measure	the figure
total impressions across the week	1,655
impressions carried by feed posts	1,126
the feed's share	68.0 percent
everything else combined	529, or 32.0 percent

Sixty-eight percent through one channel means the other channels are not yet contributing, and it does not by itself establish whether that is because they are dead or because they have not been used. Section four separates those two cases.

---

3. What Was Sent, and to Which Rooms

The five groups the base-editing protocol was posted into, and why each one fits

PP-2026-164-01, the base-editing paper, was posted into five groups on the same platform. The match between a document and a room is not a matter of audience size, and the reasoning for each is printed here so that a later read of the results has something to test against.

the group	members listed	why this document belongs there
CRISPR Forum	36,443	the platform audience — people who care whether

the group	members listed	why this document belongs there
		an editor's off-target product is chemically identical to its intended product
RNA-Seq	4,559	the experiment IS an RNA-seq experiment with matched whole-genome sequencing and blind variant calling
NGS Data Analysis	1,637	these are the people who would judge the matching strategy and the conditional logistic regression on sight
Gene Therapy Researchers	1,353	the clinical end of the same question
Evolution of the Missing Genetic Code	415	the author's own group — people who opted into this exact thesis

Total membership listed across the five: 44,407.

A protocol lands differently in front of people who own the instrument. The two smallest rooms on that list — RNA-Seq and NGS Data Analysis, 6,196 members between them — contain the people who could actually run this experiment, which makes them the two that matter most.

The 415, which is the asset

Evolution of the Missing Genetic Code is the smallest number in this document. It is also the only one that cannot be bought, borrowed or replicated by anyone else, because those 415 people opted into this thesis at a time when there were no papers to show them.

Every other room on the list is somebody else's audience, entered on sufferance. That one is a list, and a list of 415 self-selected people is worth more than a channel of forty thousand strangers.

WHAT IS NOT MEASURED

4. Unmeasured Is Not the Same as Dead

A correction to this author's own earlier reasoning, printed rather than quietly dropped

An earlier version of this analysis treated the member counts of those five groups as an audience. That was wrong, and the error is worth printing because it is a common one.

the element	the state of it	the note
the member counts	CURRENT	they are what the platform lists today
this author's standing in those groups	2016	the relationship is roughly ten years old
the platform's treatment of groups	de-emphasized around 2018	group content largely stopped surfacing in the main feed
current traffic in those groups	UNKNOWN	no measurement has been taken
what follows	the five groups are an UNMEASURED channel, not a known one	44,407 is a ceiling, not an estimate

A ten-year-old relationship with a room does not tell you whether anyone is still in the room. Treating 44,407 as reach would have been the same category of error this volume complains about elsewhere: a number that is real, and is a measurement of something other than what it is being used to measure.

The correct handling is not to write the groups off either. Both the optimistic reading and the pessimistic one are guesses, and there is a cheap way to replace both with a measurement.

5. The Forty-Eight Hour Dormancy Test

Stated as an experiment, because it costs nothing and settles a real question

The same apparatus this volume applies to biology applies here. The question is empirical, the data will exist without any further action, and the cost is zero.

the element	the specification
THE QUESTION	are the five groups a live channel or a dormant one
H_0 · the null hypothesis	the groups are dormant: posts into them register no meaningful views within 48 hours

the element	the specification
H_1 · the alternative	at least one group is live and delivers views independent of the feed
the data	the platform's own per-post view counts, which accumulate whether or not anyone looks at them
the measurement	at 48 hours, record the view count on each of the five group posts
the refutation condition for H_0	any single group post registering views materially above zero and not attributable to the author's own network
the prior	CRISPR Forum or RNA-Seq are the likeliest to be alive, on size and on subject fit; this prediction is recorded BEFORE the measurement
the cost	nothing. The posts are already made and the counters are already running
the value of a negative result	high. It closes a channel this author would otherwise keep spending attention on

The prediction is printed before the result, which is the only arrangement under which a prediction is worth anything. If CRISPR Forum and RNA-Seq are both dead and a different group is alive, that goes in the corrections register as a failed prior.

A negative result here is not a disappointment. It converts an unmeasured channel into a closed one, and attention that is currently going into a dormant room is attention that can go into the feed, which is measured and works.

READING THE RESULTS

6. The Metrics That Mean Something

And the one that is almost always reported instead

Impressions are the number every platform puts first and the number that tells a person publishing protocols the least. The reason is structural: an impression records that something passed a screen, and this corpus is not trying to pass screens.

the metric	its value here	why
impressions	LOW	measures screen exposure, not reading; inflated by the author's own network circling the same post
likes	LOW	costs the reader nothing and carries no information about whether the protocol was understood
OUT-OF-NETWORK SHARE	HIGH	the single best indicator that the work left the author's own circle instead of orbiting it again
REPOSTS	HIGH	a repost is a reader spending their own reputation on the document, which is a real cost
comments	HIGH	and the content matters far more than the count
A SPECIFIC TECHNICAL OBJECTION	HIGHEST	see below
someone asking for the data or the protocol	HIGHEST	this is the intended outcome of the entire exercise

One precise objection from a working bioinformatician — that the matching strategy will not hold, that the conditional logistic regression is the wrong model, that the power calculation assumed independence it will not get — is worth more than a thousand views.

It is worth more for three reasons and all of them are practical. It proves somebody read the methods rather than the headline. It identifies a defect while the protocol is still cheap to fix. And it is the beginning of a correspondence with a person who could run the experiment, which is the only outcome that would actually settle the question.

A note on why group impressions will read low regardless

If the group posts report thin impression numbers, that is not by itself evidence that the papers missed. The platform counts group reach differently from feed reach, and the full week's data already showed feed posts carrying 1,126 of 1,655 impressions.

So the group posts should be judged by COMMENTS AND REPOSTS and not by impressions, and the dormancy test at section five is deliberately specified on views rather than engagement so that it measures the room and not the document.

THE APPARATUS

7. What This Record Claims

Six claims, numbered and counted, each with the condition that would refute it

number	the claim	what would refute it
1	One post reached 253 people who were 91 percent life sciences and 75 percent senior	show different figures in the platform's own analytics export for that post
2	Across the measured week, feed posts carried 1,126 of 1,655 impressions — 68.0 percent	recompute from the same export and obtain a different share
3	Composition matters more than reach when the deliverable is a runnable protocol	show that a larger, less selected audience produced more protocol-level engagement
4	The five groups are an unmeasured channel and 44,407 is a ceiling rather than an estimate	produce a current measurement of traffic in any of the five
5	The dormancy test at section five costs nothing and returns a usable answer in 48 hours	identify a cost, or a way the 48-hour view counts could fail to discriminate live from dormant
6	A specific technical objection is worth more to this project than a thousand impressions	show a case where impressions at that scale produced a protocol being run and an objection did not

Six claims, six refutation conditions. Four of the six are settled by an analytics export this author does not control the contents of.

9. What This Record Does Not Claim

The boundaries, which belong at the back

It does not claim that direct publication substitutes for peer review. It claims something narrower: that the readers this work is written for can be reached without one, and that the reaching can be measured.

It does not claim that 253 people is a large audience. It claims that 253 people at 91 percent life sciences and 75 percent senior is a selected one, and sets out the arithmetic at section two so a reader can disagree with the weighting.

It does not claim to know whether the five groups are alive. That is the entire reason section five exists.

It does not claim that engagement of any kind constitutes validation of the science. A repost is evidence that a document travelled, and nothing whatever about whether its claims are true.

And it does not claim that this distribution route would work for a document without the apparatus. What is being distributed is protocols with null hypotheses, printed power, stated refutation conditions and an open license. The route and the cargo are not independent.

What the record claims is the narrow thing the analytics support: the feed is a working channel to a correctly composed audience, the group channel is untested, and a free test exists that settles it.

10. Sources

Every figure in this record, with where it came from

the figure	the source
253 people reached; 91 percent life sciences; 75 percent senior; the five cities	the platform's own post analytics, read on the date of the post
1,126 of 1,655 impressions across the week; the 68.0 percent share	the same analytics, weekly view; the share was computed for this record
group member counts: 36,443 / 4,559 / 1,637 / 1,353 / 415, totaling 44,407	the platform's group listings as displayed; the total was computed for this record
the platform's de-emphasis of groups around 2018	widely reported platform behavior; treated here as context for an untested hypothesis and not as a load-bearing claim
the base-editing protocol posted	Berger JA. One Chemistry, Two Addresses. PP-2026-

the figure	the source
into the five groups	164-01
the six desktop protocols referenced as the cargo	Berger JA. Six Experiments and a Laptop. PP-2026-165-01

One analytics export, two of this author's own papers and two computed shares. The arithmetic is printed in full so that a reader who doubts a percentage can redo it in one line.

THE COLOR INDEX

Every shaded word in this volume is a link. A word with its own entry in the Index jumps to that entry; a letter, atom label or formula returns here.

color	element	base	nucleoside	nucleotide	the base, on pages	the element, on pages

ASSESSMENT · NOVAGONDNA · FOR COMMENT

The Fifteen Criteria Applied to Three AlphaGenome Papers

Each paper rated against all fifteen Berger Novel Creative Principles, one paper at a time, on two separate questions — whether the paper APPLIES the principle, and what verdict it establishes about Google DeepMind's model — with a summary, a conclusion and a rating after each

ASSESSMENT · THE BERGER TRIPLEX AGAINST ALPHAGENOME · FIFTEEN CRITERIA, THREE PAPERS

PP-2026-173-01 · 16 September 2026 · Naperville, Illinois

Dr. John Allen Berger · NovagonDNA · Licensed under CC BY-NC-ND 4.0.

1. What This Assessment Says in Seven Lines

— THE FIFTEEN PRINCIPLES ARE A REAL EVALUATIVE INSTRUMENT, AND THAT IS RARER THAN IT SOUNDS. Most architectural criticism is ad hoc — a reviewer objects to one model on one ground. This is a named, numbered, published rubric applied uniformly, with every claim checkable row by row.

— PAPER TWO IS THE BEST OF THE THREE AND IT IS NOT CLOSE. Nine of fifteen principles APPLIED, one asserted, five absent — and it argues from TENSOR RANK rather than from analogy at any point. Rated A minus, and the only one this assessment would send to a computational reader as written.

— PAPER ONE IS THE MOST USEFUL AND THE LEAST INTERNALLY CONSISTENT. Four applied, three asserted, eight absent, rated B plus — and

section seven names one contradiction inside it that must be repaired before it travels, together with the repair, which makes the argument STRONGER.

— PAPER THREE IS THE MOST QUOTABLE AND THE WEAKEST EVIDENTIALLY. Rated C plus, with the highest rhetorical risk of the three, and section eight sets out what the register costs it.

— THE SINGLE BEST ARGUMENT ANYWHERE IN THE THREE IS PRINCIPLE THREE IN PAPER TWO. Attention treats A attending to B as mathematically equivalent to B attending to A — ij equals ji — and that is checkable in an afternoon.

— WHICH IS ALSO THE HIGHEST-VALUE MOVE AVAILABLE. Principle three is the only one of the fifteen whose pass condition is model-agnostic and OBSERVABLE, so it can be MEASURED against the public interface rather than argued. Section nine gives the protocol.

— INOSINE IS ABSENT FROM ALL THREE PAPERS, and that is the most consequential gap in the set. AlphaGenome predicts splice junctions and RNA abundance — exactly the two outputs that adenosine-to-inosine editing alters at more than 4,500,000 known human positions.

THE INSTRUMENT

2. Two Columns, Because They Are Two Different Questions

The method, stated before any rating is given

A rubric that collapses two questions into one score produces a number that cannot be argued with, because nobody can tell which question it answers. This assessment keeps them apart in every row.

the column	the question it answers	the permitted values
THE APPLICATION	does the paper actually use this principle against AlphaGenome?	APPLIED · ASSERTED · ABSENT
THE VERDICT	what does the paper establish about the model on this principle?	VIOLATION · PARTIAL · NOT ESTABLISHED

A principle can be ASSERTED and establish NOTHING — that is a principle listed in a framework table and never turned on the object. A principle can be APPLIED and return PARTIAL, which is the most honest result the instrument produces. Collapsing the two would hide both.

What the three papers are

the paper	the title	the posture
PAPER ONE · PP-2026-AG-01	AlphaGenome and the Berger Triplex: A Unified Interpretive Architecture for Regulatory Variant-Effect Prediction	the generous one — argues AlphaGenome is structurally co-incident with the Triplex
PAPER TWO	AlphaGenome Architecture: A Tensor-Quaternion Reanalysis	the disciplined one — argues from rank, not from analogy
PAPER THREE	ALPHAGENOME: A Magnificent Monument to the Wrong Direction	the polemical one — the sharpest sentences and the least evidence

Three papers, three postures toward one object: convergent validation, contextualization, condemnation. Section ten addresses what a reader does with that, because a reader who meets all three will ask which one is meant.

PAPER ONE · THE UNIFIED INTERPRETIVE ARCHITECTURE

3. Paper One Against the Fifteen

PP-2026-AG-01, rated row by row

#	the principle	the application	the verdict on AlphaGenome	the comment
1	Trinary Necessity	ABSENT — and CONTRADICTED	NOT ESTABLISHED	§4 claims variant-effect scoring IS a Z-axis selection operation. Principle 1 says binary computation cannot generate Z-axis output. Both cannot hold. See the

#	the principle	the application	the verdict on AlphaGenome	the comment
				conclusion.
2	Flatlander Dilemma	ASSERTED	NOT ESTABLISHED	The paper argues the opposite of blindness — that AlphaGenome sees Z-axis output.
3	Quaternion Non-Commutativity	APPLIED	VIOLATION	§5.1, the strand-asymmetry problem: identical variants on sense and antisense give different phenotypes. AlphaGenome captures this empirically and explains it not at all. Clean, specific, correct.
4	Z-Axis Selector Blindness	APPLIED	PARTIAL — and this is the right verdict	The paper's best formulation in one line: ALPHAGENOME SEES THE OUTPUT, THE BERGER TRIPLEX NAMES THE MECHANISM. It sees the selection; it cannot say what selects.
5	Silent Seventh Exclusion	ABSENT	—	Not raised.
6	Vortex Mathematics	ASSERTED	NOT ESTABLISHED	3-6-9, 1-5-7 and 2-4-8 appear in the framework table. No test of whether AlphaGenome's architecture honors or violates them.
7	Scalar-to-Quaternion Continuity	ABSENT	—	Paper Two's subject; correctly left alone here.
8	Abha Torus Topology	ABSENT	—	Not raised.
9	Axis Conflation	APPLIED	VIOLATION	§5.2: X-axis (DNA, Past) input predicting Y-axis (RNA, Present) output, with the ordering assumed rather than explained. Second-strongest section.
10	64-Tetrahedron Lattice	ABSENT	—	Defensible — AlphaGenome is a non-coding regulatory model and codons are not its object.
11	Phosphorothioate-k Chirality	ASSERTED (as prediction)	NOT ESTABLISHED	In the framework table as backbone = k = ij, and in §6 as a testable prediction about Rp/Sp asymmetry. Forward-looking, not an assessment.
12	Inosine / Silent Sixth	ABSENT	—	THE SIGNIFICANT GAP. AlphaGenome predicts splicing and RNA abundance — exactly where adenosine-to-inosine editing changes the answer — and inosine never appears.
13	Temporal Axis	APPLIED	VIOLATION	§5.2 again. The X to Y to Z

#	the principle	the application	the verdict on AlphaGenome	the comment
	Collapse			ordering is a geometric consequence, not an assumption. Well made.
14	Official Sixes	ABSENT	—	Not raised.
15	Freedom of Choice / the 64th	ABSENT	—	Not raised.

Coverage: 4 APPLIED · 3 ASSERTED · 8 ABSENT.

4. Summary and Conclusion — Paper One

Rated B plus

This is the GENEROUS paper, and its generosity is both its strength and its exposure. It argues that AlphaGenome is structurally co-incident with the Triplex — that DeepMind built, empirically and without knowing it, the X, Y and Z architecture specified here theoretically.

The mapping table at §3 is the most persuasive artifact in the paper: seven AlphaGenome outputs, each assigned an axis, each with a biological interpretation. It reads as a MAPPING rather than an analogy, which is exactly what §4 insists on.

The three sections that do real work are 5.1, 5.2 and 5.3 — strand asymmetry, temporal ordering, selection mechanism — and each names something AlphaGenome demonstrably DOES without being able to say WHY. That is a defensible, specific, non-hostile form of critique.

And §6's seven testable predictions against the AlphaGenome interface make it the only one of the three papers that proposes to SETTLE anything.

The one thing that must be fixed before this travels

§4 and Principle 1 are in direct contradiction. Principle 1 states that binary computation cannot generate Z-axis outputs — two inputs never yield the third axis. §4 states that AlphaGenome's variant-effect scoring IS a Z-axis selection operation. A reviewer will find this in ten minutes.

the element	the statement
the contradiction	Principle 1 forbids a binary machine from producing Z-axis output; §4 says the machine produces Z-axis output

the element	the statement
the resolution	AlphaGenome does not GENERATE the Z-axis. It MEASURES A SHADOW CAST BY IT. Variant-effect scores are a statistical projection of a selection event the model neither represents nor can manipulate
what the repair costs	nothing. Principle 1 survives intact
what the repair gains	§4 becomes the more interesting claim — that a two-axis model can detect the CONSEQUENCES of a third axis while remaining unable to encode it
what that is	exactly the Flatlander case, stated at a higher resolution

The repair makes the argument stronger rather than weaker, which is the mark of a contradiction worth finding. Left in, it costs the paper. Taken out, it upgrades the thesis.

And add inosine. AlphaGenome predicts splice junctions and RNA abundance; adenosine-to-inosine editing at 4,500,000 known positions alters both. Principle 12 has its clearest AlphaGenome application here and the paper leaves it on the table.

PAPER TWO · THE TENSOR-QUATERNION REANALYSIS

5. Paper Two Against the Fifteen

AlphaGenome Architecture: A Tensor-Quaternion Reanalysis, rated row by row

#	the principle	the application	the verdict on AlphaGenome	the comment
1	Trinary Necessity	APPLIED	VIOLATION	§VI states it cleanly: the Z-axis is ABSENT FROM THE MACHINE. Not rhetoric — it follows from the rank analysis.
2	Flatlander Dilemma	APPLIED	VIOLATION	Convolution plus transformer equals the XY plane, established structurally rather than asserted.
3	Quaternion Non-Commutativity	APPLIED	VIOLATION	THE SINGLE BEST ARGUMENT IN ALL THREE PAPERS. Attention treats A attending to B as mathematically equivalent to B attending to A. ij = ji. This is checkable in an afternoon.

#	the principle	the application	the verdict on AlphaGenome	the comment
4	Z-Axis Selector Blindness	APPLIED	VIOLATION	§4.3: output heads are fixed projections — THEY DO NOT ENCODE THE DYNAMIC QUATERNION COUPLING BETWEEN Z AND X-Y THAT GOVERNS TRUE BIOLOGICAL SELECTION.
5	Silent Seventh Exclusion	ABSENT	—	Not raised.
6	Vortex Mathematics	ASSERTED	NOT ESTABLISHED	Columns present in the master mapping table; no analysis of whether the architecture obeys 3-6-9.
7	Scalar-to-Quaternion Continuity	APPLIED — the best-developed criterion in the three papers	VIOLATION	Rank 0 to 1 (convolution), rank 2 (transformer), 2 to 1 (output), rank 3 (TPU mesh). The progression is traced end to end and the truncation is LOCATED.
8	Abha Torus Topology	APPLIED (briefly)	VIOLATION	Output heads DO NOT WRAP ON THE TOROIDAL SYMMETRY SURFACE OF THE GENETIC CODE. One of the only genuine applications of Principle 8 anywhere in the set.
9	Axis Conflation	APPLIED	VIOLATION	DNA INFORMING RNA IS NOT THE SAME OPERATION AS RNA INFORMING DNA. Directionality stated as a structural fact.
10	64-Tetrahedron Lattice	ABSENT	—	Defensible for a regulatory model.
11	Phosphorothioate-k Chirality	APPLIED	VIOLATION	§4.4: the TPU mesh mapped to k = ij, with Rp and Sp as the physical basis of directional causality. Inventive and structurally consistent.
12	Inosine / Silent Sixth	ABSENT	—	Again absent — and §VII is ABOUT SPLICE-JUNCTION MODELING, where it belongs most.
13	Temporal Axis Collapse	APPLIED	VIOLATION	Past, Present and Future mapped onto the three computational phases.
14	Official Sixes	ABSENT	—	Not raised.
15	Freedom of Choice / the 64th	ABSENT	—	Not raised.

Coverage: 9 APPLIED · 1 ASSERTED · 5 ABSENT.

6. Summary and Conclusion — Paper Two

Rated A minus — the best of the three

This is the DISCIPLINED one. It does not argue from analogy at any point; it argues from TENSOR RANK. Each of AlphaGenome's computational phases is assigned a rank, the rank sequence is traced end to end, and the missing element is located at a specific place in that sequence rather than gestured at.

§4.4's reading of the TPU distributed mesh as the k-backbone — the structural carrier linking the first and second imaginaries — is the most original move in the three papers.

§VI is where it lands. Attention is commutative by construction. Biology is not.

The model's own published limitations — difficulty with very distant regulatory elements, insufficient cell-type and tissue specificity — are recast as STRUCTURAL CONSEQUENCES of the missing Z-axis rather than as engineering shortfalls to be fixed with more compute. That reframing is the paper's real contribution, and the closing formulation earns itself: it contextualizes AlphaGenome, positioning it as a powerful but incomplete tensor computation that operates on the X-Y plane.

Its strength and its one limitation

the element	the statement	the note
the strength	it makes no claim it cannot ground in architecture	every verdict traces to a named structural feature
the limitation	scope — five principles are untouched	and two of those, Principle 12 inosine and Principle 15 Freedom of Choice, are the ones most specific to this author
the consequence	a reader finishing this paper knows what AlphaGenome CANNOT COMPUTE	they do not yet know what MOLECULE it is failing to see

That is a repairable limitation and it is the highest-value addition available to the paper: the reader has been shown the hole in the architecture and not yet shown the molecule that falls through it.

PAPER THREE · A MAGNIFICENT MONUMENT TO THE WRONG DIRECTION

7. Paper Three Against the Fifteen

ALPHAGENOME: A Magnificent Monument to the Wrong Direction, rated row by row

#	the principle	the application	the verdict on AlphaGenome	the comment
1	Trinary Necessity	APPLIED	VIOLATION	SCALING A FUNDAMENTALLY INCOMPLETE INPUT IS NOT A BREAKTHROUGH. IT IS AN AMPLIFIED ERROR. The sharpest sentence in the set.
2	Flatlander Dilemma	APPLIED	VIOLATION	§III. They are reading shadows on the wall and calling it structural biology.
3	Quaternion Non-Commutativity	ASSERTED	NOT ESTABLISHED	Listed as item 2 of the Berger Model six. Never applied to AlphaGenome.
4	Z-Axis Selector Blindness	APPLIED	VIOLATION	§III, The Third Strand They Cannot See — the approximately 45 degree Hoogsteen geometry between A-form and B-form, and the observation that AlphaGenome has no coordinate system in which a third strand exists.
5	Silent Seventh Exclusion	ASSERTED	NOT ESTABLISHED	Item 5 of the six.
6	Vortex Mathematics	ASSERTED	NOT ESTABLISHED	Appears only inside item 6's definition.
7	Scalar-to-Quaternion Continuity	ABSENT	—	Paper Two's territory.
8	Abha Torus Topology	ABSENT	—	Not raised.
9	Axis Conflation	APPLIED — the paper's best argument	VIOLATION	§II. YOU CANNOT PREDICT THE PRESENT FROM THE PAST ALONE. THE Y-AXIS IS NOT OPTIONAL. IT IS OPERATIONAL. DNA-only input predicting RNA-level output, with the ribosome, the spliceosome, microRNAs, lncRNAs, circRNAs and riboswitches enumerated as the operational layer being skipped.
10	64-Tetrahedron Lattice	ASSERTED	NOT ESTABLISHED	Item 3 of the Berger Model six. Named, and never turned on the model.

#	the principle	the application	the verdict on AlphaGenome	the comment
11	Phosphorothioate-k Chirality	ASSERTED	NOT ESTABLISHED	Item 2 of the six. Named, and never turned on the model.
12	Inosine / Silent Sixth	ABSENT	—	Absent from the third paper as well, which makes it absent from all three.
13	Temporal Axis Collapse	APPLIED	VIOLATION	PREDICTING THE WEATHER BY READING LAST YEAR'S ALMANAC WITHOUT LOOKING OUT THE WINDOW. The clearest statement of Principle 13 anywhere in the corpus.
14	Official Sixes	ASSERTED	NOT ESTABLISHED	Items 5 and 6 of the six.
15	Freedom of Choice / the 64th	APPLIED (briefly)	VIOLATION	IT CANNOT MODEL SELECTION. IT CANNOT REPRESENT THE Z-AXIS FUTURE STATE BECAUSE IT HAS NO Z-AXIS.

Coverage: 6 APPLIED · 6 ASSERTED · 3 ABSENT.

SIX OF THE FIFTEEN ARE ASSERTED AND NEVER APPLIED — the highest asserted count of the three papers, and the paper's second structural problem. A rubric that is named but never turned on the object reads as a manifesto rather than an evaluation.

8. Summary and Conclusion — Paper Three

Rated C plus — the most quotable, and the most likely to be discarded unread

This paper has the best individual sentences in the set and the least evidence per page. Those two facts have the same cause, and the cause is a decision about register rather than a decision about evidence.

What is genuinely strong in it, and should be leading

§II deserves a better paper around it. Gene expression is an RNA operation: the ribosome is a ribozyme, the spliceosome is RNA-based, and the entire regulatory layer of the transcriptome — microRNAs, long non-coding RNAs, circular RNAs, riboswitches — is RNA. A model that takes only DNA as input is predicting an RNA phenomenon from the wrong axis.

That is Principle 9 made concrete, and it is the argument a molecular biologist will find hardest to dismiss. It belongs at the front of the paper, not in second position.

§VI on TAL1 is the best critical writing in all three papers. Recapitulating a known mechanism from sequence is a CORRELATION achievement: it establishes that the statistical patterns encoded in one megabase of context suffice to recover a known variant-phenotype association. In the paper's own words, this is genuinely useful; it is not, however, a mechanistic explanation.

CORRELATION IS NOT MECHANISM. Fair, precise, and it lands without a single insult — which is the proof that the insults elsewhere are not doing any work.

the measure	the assessment	the note
evidentiary strength	the weakest of the three	six principles named and never applied
quotability	the highest of the three	AMPLIFIED ERROR; SHADOWS ON THE WALL; LAST YEAR'S ALMANAC
rhetorical risk	HIGH	three exits handed to a hostile reader in the first two pages
the three best sections	§II Axis Conflation, §VI TAL1, §VII the register	any of the three would stand in any paper in the set
the rating	C PLUS	on the ratio of applied to asserted, and on what the register costs

First structural problem — the register breaks the author's own Rule One
GARBAGE IN, GARBAGE OUT. WOULD EARN A FAILING GRADE. IMPRESSIVE CORRELATION, ZERO CAUSAL ARCHITECTURE. A reader at DeepMind or at the Broad stops at the first of those and never reaches §II, which is the argument that could actually change their mind.

The author's own standing rule is that an opening must not hand a hostile reader an excuse to quit. This paper hands them three in the first two pages.

The fix costs nothing. Cut the section title GARBAGE IN, GARBAGE OUT and keep the section. Lead with §II. Let the register of §VII govern throughout: THIS PAPER IS NOT A DISMISSAL OF ALPHAGENOME'S TECHNICAL ACHIEVEMENT —

SIGNIFICANT ENGINEERING EFFORT AND GENUINE SCIENTIFIC CREATIVITY WENT INTO ITS CONSTRUCTION, AND THESE ARE REAL ACCOMPLISHMENTS.

The argument lands HARDER without the insults, not softer. That is a practical case rather than a polite one, and §VI is the evidence for it: the most damaging paragraph in the paper contains no insult at all.

Second structural problem — six named, none applied

The Berger Model six-point list at §V names quaternion mathematics, phosphorothioate stereochemistry, the 63 plus 1 lattice, ANA geometry, the Silent Seventh and Freedom of Choice — and the paper then moves on without testing AlphaGenome against any of them.

the element	the state of it	the consequence
what the six do in the paper	they are listed as the framework	the reader is told the rubric exists
what they do not do	they are never turned on the model	no verdict is derived from any of the six
how that reads to a stranger	as a MANIFESTO rather than an EVALUATION	which is the one reading the rubric was built to prevent
the two available fixes	apply them, or remove them	and let §II, §III and §VI carry the paper, which they can

Paper Two applies nine of fifteen. This paper applies six and asserts six. The distance between an A minus and a C plus in this assessment is almost entirely that ratio, and it is recoverable by editing rather than by new research.

WHAT FOLLOWS

9. The Three Side by Side

And the one move that would change the standing of all of them

the paper	applied	asserted	absent	rating	the one-line reading
Paper One · Unified Architecture	4	3	8	B PLUS	most useful, least internally consistent
Paper Two · Tensor-Quaternion	9	1	5	A MINUS	best of the three; argues from rank
Paper Three · Monument	4 of 9 read	3 of 9 read	2 of 9 read	C PLUS, provisional	most quotable, weakest evidentially

Across all three papers, Principle 12 — inosine — is ABSENT EVERY TIME. It is the author's own most distinctive principle and the one with the clearest AlphaGenome application, and it does not appear in a single row of a single paper.

10. The Highest-Value Move: Principle Three Is Testable Today

Because it is the only one of the fifteen whose pass condition is model-agnostic and observable

Quaternion non-commutativity asks one question: does the model treat ij as equal to ji? Unlike the other fourteen, that question can be put to the model itself, in its own terms, without the model's builders agreeing to any part of this framework.

the element	the specification
THE QUESTION	does the model return the same answer for A to B as for B to A?
H_0 · the null hypothesis	the model's output is invariant to the order of the pair — it treats ij as equal to ji
H_1 · the alternative	the output differs with order, and the model encodes directionality
the procedure	submit an attention-relevant sequence pair through the AlphaGenome interface in both orders, and record whether the outputs differ
the second arm	submit a chiral phosphorothioate as Rp and as Sp and compare
what identical outputs would mean	the violation has been MEASURED rather than asserted
the cost	a weekend, a desktop computer, no reagents
why it matters more than the other fourteen	a MEASURED violation of a stated principle is a different class of object from an ARGUED one

It converts the sharpest principle from a claim into a number, and it is the move that would make a reader at Cambridge or at DeepMind take the other fourteen seriously.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

And the structural reason it matters

As the fifteen are currently written, they are constructed so that no current model can pass. The pass condition for Principle 4 is INTEGRATES ANA, and no model integrates ANA. A reviewer will call that unfalsifiable, and the reviewer will be right.

For each principle, state what a PASS would look like in terms THE MODEL'S OWN OUTPUT CAN SATISFY, rather than in terms of adopting this framework. Several of the fifteen already nearly do. Principle 3 already does.

THE APPARATUS

11. Corrections to Check

Four, printed rather than passed over

the item	what it says	the correction
ALPHAGENOME DATES	Paper One says the model was INTRODUCED IN 2026	CORRECTION: the model has been available to academic users since JUNE 2025, alongside a preprint. The Nature paper appeared 28 JANUARY 2026, first-authored by Avsec and colleagues at Google DeepMind. The statement is off by about seven months. The 1 Mb input, single-base resolution and 25-of-26 variant-effect figures all check out
63 PLUS 1 STOP	as printed, a geneticist reads an arithmetic error	the standard code is 61 sense plus 3 stop. The 63 plus 1 comes from 7 bases times 3 sugars times 3 phosphates. One sentence of derivation fixes it
THE THREE POSTURES	convergent validation, contextualization, condemnation — toward one object	a reader who meets all three asks which is meant. The honest and more interesting answer is that they were written IN SEQUENCE as the reading developed. Said in a dated note, the sequence becomes a strength instead of an inconsistency
THE CO-DISCOVERY ATTRIBUTION	the phrase CO-DISCOVERED BY DR. JOHN ALLEN BERGER AND CLAUDE AI	most journals now hold explicitly that an AI cannot be an author or be credited with discovery. DEVELOPED BY DR. BERGER, USING CLAUDE AS AN ANALYTIC INSTRUMENT ACROSS A 93-PAPER REVIEW is equally true, keeps the transparency, and does not hand a reader an exit. The transparency is admirable; the phrasing is a liability

Four corrections, and none of them touches a finding. Every one is a date, a derivation, a framing or a phrase — which is the cheapest kind of error to fix and the most expensive kind to leave standing.

12. What This Assessment Claims

Seven claims, numbered and counted, each with the condition that would refute it

number	the claim	what would refute it
1	Paper Two applies nine of the fifteen principles and Paper One applies four	recount the APPLIED rows in sections 3 and 5 and obtain different totals
2	Principle 3 as stated in Paper Two is the strongest single argument in the three papers	identify an argument in any of the three that is more specific, more checkable, and more directly grounded in the model's architecture
3	Principle 3 is the only one of the fifteen whose pass condition is model-agnostic and observable	name another principle whose pass condition can be evaluated from the model's output without adopting this framework
4	Principle 12, inosine, is absent from all three papers	find a row in any of the three where inosine is applied to AlphaGenome
5	§4 of Paper One contradicts Principle 1 as both are currently written	show a reading on which a binary machine generating Z-axis output is consistent with Principle 1
6	Paper One says the model was introduced in 2026, and the academic release was June 2025	produce a source dating the academic availability later than June 2025
7	Paper Three asserts six principles at its section V and derives no verdict from any of them	identify a verdict in Paper Three grounded in any of the six named there

Seven claims, seven refutation conditions. Six of the seven are settled by counting rows printed in this document or reading a date on a public page.

13. What This Assessment Does Not Claim

The boundaries, which belong at the back

It does not claim the fifteen principles are correct. It claims they are a real instrument — named, numbered, published and applied uniformly — and an instrument can be well built and still measure the wrong thing.

It does not claim AlphaGenome performs badly at the task it was built for. On the published benchmarks it performs extremely well, and nothing in any of the three papers disputes that.

It does not claim the six unread rows of Paper Three would change its rating. They might; the rating is marked provisional for that reason.

It does not claim that a VIOLATION verdict on a principle establishes that the principle is the right lens. It establishes only that the model does not satisfy the principle as written.

And it does not claim any of the three papers is ready to send. Section 11 lists four corrections and section 10 names one experiment, and the instruction here is the same as everywhere else in this corpus: measure it rather than assert it.

What this assessment claims is the narrow thing the rows support: the instrument works, Paper Two uses it best, Principle 3 can be settled this weekend, and inosine is missing from all three.

14. Sources

Where each external figure came from

the figure	the source
1 Mb input, single-base resolution, 25 of 26 variant-effect evaluations	AlphaGenome, Google DeepMind
academic availability from June 2025 alongside a preprint	Google DeepMind; Nature news coverage, 2025
the Nature paper of 28 January 2026, Avsec and colleagues, Google DeepMind	Nature
the model's published limitations on distant regulatory elements and cell-type specificity	the AlphaGenome paper and DeepMind's own documentation
more than 4,500,000 human adenosine-to-inosine editing sites across 55 body sites	REDIportal
the fifteen Berger Novel Creative Principles	the framework as closed 21 April 2026
the text of the three papers under assessment	PP-2026-AG-01; the Tensor-Quaternion Reanalysis; the Magnificent Monument critique

Every external figure in this assessment is checkable against a public page. Every internal figure is a count of rows printed in this document.

Bibliographic note. Model names, paper titles and author names are given in the form in which they were published.

THE COLOR INDEX

Every shaded word in this volume is a link. A word with its own entry in the Index jumps to that entry; a letter, atom label or formula returns here.

THE COLOR KEY · one element, one color, carried unchanged from the element through the base and the nucleoside to the nucleotide

1. What This Paper Says in Eight Lines

— THESE ARE SIXTEEN QUESTIONS YOU CAN PUT TO ANY MODEL OF THE GENOME, INCLUDING YOUR OWN. Each is defined in ordinary English, given a worked example, given AN ATOMIC AND MOLECULAR CASE with a named molecule and a named atom, and given a pass condition checkable against what the model actually outputs.

— THE POINT IS NOT TO GRADE ANYBODY ELSE'S MODEL. It is to give a builder a checklist they can run on a Tuesday afternoon and find out which of the sixteen their own system has never been asked about.

— AND “YOUR MODEL” IS MEANT AS WIDELY AS IT SOUNDS. It covers the network, the pipeline, the reference and annotation, the pathway diagram and the protocol at the bench — anything that takes a representation of a living system and returns a claim about it. Section two lists thirteen kinds with named examples, including the wet-lab case.

— EVERY CRITERION IS ANCHORED TO AN ATOM. This volume works at the atomic and molecular level, where the color notation is ONE TO ONE — each element has a color, and every base, nucleoside and nucleotide built on it carries that color. So the test for a gap is mechanical: run the color key across a model's inputs and see which color is missing.

— NO MODEL IN EXISTENCE PASSES ALL SIXTEEN, AND THAT IS NOT THE INTERESTING FACT. The interesting fact is which ones a given model fails STRUCTURALLY — meaning no amount of additional training data or compute would change the answer.

— A STRUCTURAL FAILURE AND AN ENGINEERING SHORTFALL ARE DIFFERENT THINGS, and section three gives the test that separates them: if more data would fix it, it is a shortfall; if the representation has no slot for the quantity, it is structural.

— EVERY PASS CONDITION IS WRITTEN SO THAT A MODEL CAN SATISFY IT WITHOUT ITS BUILDERS ADOPTING ANY PART OF THIS FRAMEWORK. That is deliberate. A criterion only a believer can score is not a criterion.

— PRINCIPLE SIXTEEN IS NEW, ADMITTED TODAY, and section twenty carries it, with the ruling printed in full at section twenty-five — including that the framework had been formally closed at fifteen on 21 April 2026 and has been reopened once to take it.

— TAKE THE LIST. RUN IT. ARGUE WITH IT. It is CC BY-NC-ND 4.0, it requires no permission from anybody, and the fastest way to make it better is for somebody to score their own system and publish where the list came up short.

HOW TO USE THE SIXTEEN

2. What “Your Model” Means Here

The word is meant much more widely than a neural network, and it includes the diagram on your whiteboard

A MODEL, for the purpose of these sixteen questions, is anything that takes a representation of a biological system and returns a claim about it. That is deliberately wide. It covers the deep network, the analysis pipeline, the reference genome, the pathway diagram, the statistical design, and the tube on the bench.

The sixteen do not ask how a model is implemented, and they do not care whether it has parameters. They ask ONE THING: what does its representation have a slot for? A pathway diagram with no sulfur node fails the same row, for the same reason, as a transformer with no sulfur channel. Neither can be argued out of the gap, because the gap is upstream of the argument.

the kind of model	examples a reader may be using this week	what its representation is actually made of
SEQUENCE DEEP LEARNING	AlphaGenome, Enformer, Borzoi, Basenji, DNABERT, Nucleotide Transformer, Evo, scGPT	four letters and their positions
STRUCTURE PREDICTION	AlphaFold2 and AlphaFold3, ESMFold, RoseTTAFold, Boltz, Chai-1	twenty amino acids and a set of coordinates
VARIANT EFFECT SCORING	SpliceAI, CADD, SIFT, PolyPhen-2, REVEL, AlphaMissense, any ClinVar-trained classifier	a substitution and a number
THE PIPELINE ITSELF	bwa, STAR, salmon, GATK, DESeq2, limma, edgeR, any nf-core workflow	reads, a reference, and a count matrix
THE REFERENCE AND THE ANNOTATION	GRCh38 or T2T-CHM13, Ensembl, RefSeq, GENCODE, the GTF file you pass to the counter	an alphabet, an interval and a name
SINGLE-CELL ANALYSIS	CellRanger, Seurat, Scanpy, scVI, Harmony, UMAP, RNA velocity	a cell-by-gene matrix and a latent space
METABOLIC AND SYSTEMS	Recon3D, Human-GEM, flux balance analysis, COPASI, any ODE kinetic model	reactions, stoichiometry and rate constants
MOLECULAR DYNAMICS	GROMACS, AMBER, NAMD, CHARMM, OPLS, the MARTINI coarse-grained force field	atom types, partial charges and bond terms

the kind of model	examples a reader may be using this week	what its representation is actually made of
DOCKING AND CHEMINFORMATICS	AutoDock Vina, Glide, DiffDock, RDKit descriptors, any QSAR model	atoms, bonds and a scoring function
THE STATISTICAL MODEL	a linear model, a GWAS, a Cox regression, a mixed model, a propensity score	whatever columns are in the design matrix
THE PATHWAY DIAGRAM	KEGG, Reactome, WikiPathways, the figure in your last paper, the whiteboard	the nodes and arrows you chose to draw
THE BENCH PROTOCOL	the medium, the buffer, the gas mix, the assay readout, the control	what you put in the tube and what you measure
THE GENERAL-PURPOSE LANGUAGE MODEL	any chat assistant asked to reason about a mechanism	text about biology, which is not biology

Read the right-hand column, not the middle one. The middle column changes every year and the right-hand column almost never does. Every one of the sixteen questions is a question about the right-hand column.

The bench is a model too, and it is the one this list is most useful on

A computational reader may assume this framework is aimed at other people's software. It is not. An experiment is a model of a living system, it has a representation, and its representation leaves things out in exactly the way a network does — with the difference that the omissions are set by hand, by you, in the protocol.

what the protocol handles	what is actually happening	the representational gap
OXYGEN	standard culture runs at atmospheric oxygen; most tissues in the body sit well below it	oxygen tension is a parameter you have set to a constant, and usually to the wrong one
SULFUR	the medium supplies methionine and cystine; the readout almost never reports either one	the donor is in the tube and absent from the data
SELENIUM	supplied as selenite in a standard serum-free supplement, then never measured again	present in the system, absent from the model of the system
THE CONTROL	chosen to differ in one variable you named	the variables you did not name are held constant by accident, not by design

If your medium contains an element that your readout cannot report, your experiment has the same blind spot as a sequence model that has no channel for it. The sixteen apply unchanged. So does the color test: shade your protocol and your readout by the key and look for the color that appears in one and not the other.

So when a criterion below says “the model”

who you are	what to put in the blank
if you build software	it means your architecture, your input schema, and the files you train on
if you run a pipeline	it means the reference, the annotation, the caller and every default you did not change
if you work at a bench	it means the protocol: the medium, the gas, the readout and the control
if you write reviews or grants	it means the mechanism diagram you are asking the reader to accept
if you are none of these	it means whatever you would have to change to get a different answer out of your system

The question is never WHETHER YOUR MODEL IS GOOD. It is WHAT YOUR MODEL HAS NO SLOT FOR. Those are different questions, and only the second one has an answer you can act on.

3. Scoring, and the One Distinction That Matters

Two columns, three values each, and the test that separates a defect from a limitation

Each principle is scored on two separate questions. Collapsing them into one number destroys the information, because a model can fail a criterion for two completely different reasons and only one of them is worth anyone's time.

the column	the item it settles	the permitted values
DOES THE MODEL MEET THE STANDARD?	does the model carry an internal quantity corresponding to what this principle names?	3 ABOVE STANDARD · 2 MEETS STANDARD · 1 BELOW STANDARD
IS THE SHORTFALL STRUCTURAL?	would more data, more parameters or more compute change the answer?	STRUCTURAL · ENGINEERING · NOT APPLICABLE

THE SEPARATING TEST: if a quantity is not in the model's INPUT, no amount of training changes that. A bigger model trained on more genomes still receives no field for oxygen tension. That is STRUCTURAL. If the quantity is in the input and the model handles it badly, that is ENGINEERING, and engineering gets fixed.

This distinction is the whole value of the exercise. A team told their model has an engineering shortfall will go and fix it, and they should. A team told their model has a structural absence learns something more useful: that the thing they are missing cannot be trained in, and has to be ADDED TO THE INPUT or measured separately.

A standard is a standard

THE SCALE IS DISCRETE AND NOTHING LIVES BETWEEN THE POINTS. Two yes-or-no questions produce three states and no others. FIRST: is the quantity in the model? NO gives 1 — the quantity is MISSING and the criterion is therefore FAILED. SECOND, put only to a model that cleared the first: can the quantity be SET INDEPENDENTLY, so that changing it changes the output? NO gives 2, THE STANDARD MET. YES gives 3, THE STANDARD EXCEEDED. Neither question admits a maybe, so there is no 1.5 and no partial credit for intending to.

If the quantity does not exist in the model, the model does not meet the standard on that criterion. That is what a standard IS. Common sense governs here and no extra category is needed: there is no ABSENT, there is BELOW STANDARD, and the two words describe the same fact with different amounts of courage.

the point	the statement
a 1 is a FAILED CRITERION, stated plainly	the quantity the principle names is not in the model, so the model does not meet the standard
a 3 is not a certificate	the sixteen are one lens and this framework's author does not claim they are the only one
the useful output is the list of 1s	those are the failed criteria, and repairing them is the only reason to run the list
the STRUCTURAL flag is a diagnosis, not an excuse	it says whether the failure can be repaired by the builders or must be repaired in the INPUT; it does not convert a 1 into a 2

If you run this on your own system and every row comes back 3, either you have built something remarkable or you have scored it too generously. The second is far more common and the fix is to write down, for each row, the NAME OF THE VARIABLE in your model that carries it.

The color key is the fastest gap-finder in the list

Because the notation assigns one color per element, and because every base, nucleoside and nucleotide inherits the color of the element that defines it, a model's input list can be read for MISSING COLORS the way a chemist reads a spectrum for missing lines.

the step	what it means in practice
list the model's inputs and outputs as molecules, not as tokens	write SULFUR rather than the letter that stands for the residue
shade each one by the color key	six colors for the six letters, INDIGO for the gatekeepers that are not letters
look for the color that never appears	in most genome models today the missing color is YELLOW, and yellow is SULFUR — a failed criterion, not a stylistic gap
then ask what that element does in the process being predicted	if it turns out to be the donor, the carrier or the cofactor, the gap is structural and section nineteen is your row

That is the whole method in four steps, and it takes about ten minutes. The atomic and molecular case printed with each of the sixteen below is the worked version of exactly this procedure.

---

4. The Berger Validity Index · A Numerical Rating on the Sixteen

A three-point scale, written anchors, a scoring rule that cannot be inflated, and a profile that is reported alongside the total

The two columns of section three are a judgment. This section converts the first of them into a NUMBER, so that two raters can score the same model independently and their disagreement can be counted. An instrument that cannot be scored twice is not an instrument.

The three points, and the words attached to them

the point	the label	the meaning	the anchor the rater must satisfy
1	BELOW STANDARD	the quantity the principle names is MISSING from the model	THE RATER CANNOT NAME A VARIABLE. Nothing in the input schema, the architecture or the output carries the quantity. The criterion is failed.
2	MEETS STANDARD	the quantity is PRESENT in the model	THE RATER NAMES THE VARIABLE. It exists and carries the quantity, though it is derived from other inputs, proxied by a correlate, or fixed rather than settable.
3	ABOVE STANDARD	the quantity is present AND under independent control	THE RATER NAMES THE VARIABLE AND NAMES THE CONTROL. The variable can be SET INDEPENDENTLY of the other inputs, and changing it CHANGES THE OUTPUT. Congratulations are in order; almost nothing scores here.

THE ANCHOR FOR 3 IS THE PASS CONDITION ALREADY PRINTED WITH EACH PRINCIPLE. Nothing new is being asked. The scale carries the whole vocabulary: 1 is BELOW STANDARD, 2 is MEETS STANDARD, 3 is ABOVE STANDARD, and no fourth word is required.

Five rules, and the fourth one is the reason the index is worth running

the rule	the statement	the reason
RULE ONE · NAME THE VARIABLE	every row scored 2 or 3 carries the variable's name in writing, in the model's own vocabulary; a row scored 3 also names the control that sets it	A 2 WITHOUT A NAMED VARIABLE IS RECORDED AS A 1. A 3 WITHOUT A NAMED CONTROL IS RECORDED AS A 2. This single rule removes almost all score inflation.
RULE TWO · DECLARE NOT APPLICABLE	a principle outside the model's object is marked N/A and is excluded from BOTH the numerator and the denominator	a coding-table principle scored against a non-coding model is N/A, not a 1
RULE THREE · PRINT THE DENOMINATOR	report the score as points earned over points available, because the denominator differs between models	24 of 42 and 24 of 48 are different results and must not be written the same way
RULE FOUR · REPORT THE PROFILE, NOT ONLY THE TOTAL	print the sixteen digits in order alongside the total	THE SIXTEEN ARE NOT EQUALLY WEIGHTED AND THE TOTAL HIDES WHICH ROWS FAILED. The profile is the useful output; the total is the summary.

the rule	the statement	the reason
RULE FIVE · TWO RATERS	two people score independently, then compare	report the number of rows on which they agreed exactly; below thirteen of sixteen, the anchors need work before the model does

The second column stays, and it is not scored

The structural question of section three is NOT converted to a number, deliberately. A 1 that is STRUCTURAL and a 1 that is an ENGINEERING shortfall are the same digit and completely different findings, and averaging them would destroy the distinction the whole framework rests on. The flag travels beside the digit and is never folded into it.

the digit and flag	the finding	the consequence
1 · STRUCTURAL	the quantity is absent from the input representation	MORE DATA WILL NOT FIX IT; the quantity must be added to the input or measured separately
1 · ENGINEERING	the quantity is present in the input and handled badly	a team can fix this, and should
2 · either flag	a proxy is doing the work of the quantity	the flag says whether the real quantity could be supplied
3 · no flag	the quantity is present and controllable	nothing to diagnose

Reading the total

The bands below are EVALUATIVE. A criterion the model cannot meet is a criterion the model FAILS, and a majority of failures is a model that does not meet the standard. Nothing is gained by describing that result in softer language than the arithmetic supports.

the band	the profile	the reading	the note
at or near the floor	mostly 1s	BELOW STANDARD OVERALL	the model fails most of the sixteen; its input representation carries almost none of the quantities the criteria name
around the middle	a mixture of 1s and 2s	MEETS THE STANDARD IN PART	the 2s mark where a proxy is standing in for a measurement; each is repairable by supplying the measurement

the band	the profile	the reading	the note
near the ceiling	mostly 3s	MEETS OR EXCEEDS THE STANDARD	the model carries atomic and molecular state as first-class input; no model known to this author scores here, and a system that does should be published

A TOTAL PRINTED WITHOUT ITS PROFILE IS A NUMBER THAT ANSWERS NO QUESTION. Two models scoring 22 of 48 can fail on completely different rows, and the rows are the finding. Report the digits.

The blank scorecard

Copy the sixteen rows, score each one, name the variable for every 3, flag every 1, and total only the applicable rows.

#	the principle	1 / 2 / 3	N/A	the variable name — required for 2 and 3	STRUCTURAL or ENGINEERING
1	Trinary Necessity				
2	The Flatlander Dilemma				
3	Quaternion Non-Commutativity				
4	Z-Axis Selector Blindness				
5	Silent Seventh Exclusion				
6	Vortex Mathematics				
7	Scalar-to-Quaternion Continuity				
8	Abha Torus Topology				
9	Axis Conflation				
10	The 64-Tetrahedron Lattice				
11	Phosphorothioate-k Chirality				
12	Inosine and the Silent Sixth				
13	Temporal Axis Collapse				
14	The Official Sixes				

#	the principle	1 / 2 / 3	N/A	the variable name — required for 2 and 3	STRUCTURAL or ENGINEERING
15	Freedom of Choice and the 64th				
16	The Sulfur Donor				
	TOTAL, APPLICABLE ROWS ONLY				

A rater who fills the fifth column honestly has learned more from that column than from the digit beside it. THE NAME OF THE VARIABLE IS THE EVIDENCE. The digit is only its receipt, and a blank in that column sends the row down one point.

5. The Sequencing Gel, and Why the Index Measures a Channel

Where the missing quantities went, and the instrument that dropped them

A reader may reasonably ask why so many of the sixteen come back as 1. The answer is not that modelers were careless. It is that the quantities were discarded before any model was built, by the instrument that produced the data.

Chain-termination sequencing runs four reactions, one per terminating base, and separates the products by length. The readout is a BAR CODE: band position in one of four lanes, read in order. That bar code carries ONE CHANNEL — which of four characters occupies each position.

The molecule being sequenced carries TWO. The first channel is HUE, which in this notation is element identity: red for hydrogen and adenine, yellow for sulfur and thymine, green for nitrogen and guanine, blue for carbon and cytosine. The second channel is BOND COUNT, the two or three hydrogen bonds each pairing brings. Neither channel is written in the genetic alphabet, and neither survives the gel.

the channel	the content	the fate at the gel	the consequence
CHANNEL ONE · POSITION	which of four lanes a band occupies	RECORDED	this becomes the character in the file

the channel	the content	the fate at the gel	the consequence
CHANNEL TWO · HUE	the element the base carries, and with it the whole atomic layer	DISCARDED	no lane reports it and no character stores it
CHANNEL TWO · BOND COUNT	two bonds for adenine-thymine, three for guanine-cytosine	DISCARDED	the eye reads it off a hand-drawn plate and no file holds it
THE SPECIES WITH NO LANE	inosine, 2 prime-O-methyl, phosphorothioate Rp and Sp, 5-methylcytosine, xanthine	NEVER ENTERED	there is no tube to put them in, so the gel cannot be blamed for omitting them

SO THE INDEX MEASURES HOW MUCH OF CHANNEL TWO THE MODEL HAS RECOVERED FROM SOMEWHERE OTHER THAN THE SEQUENCE FILE. A 1 MEANS NONE OF IT AND THE CRITERION IS FAILED. A 3 means the builders went and got the quantity from an instrument that still held it.

The provenance of the loss explains the failure. It does not excuse it. A model trained on sequence files inherited a one-channel record, and the second channel is recoverable from instruments that still hold it — mass spectrometry, structure probing, metabolite assays, crystallography. The criterion asks whether anyone went and fetched it. NOBODY WENT is a failed criterion, not a misfortune.

FAMILY ONE · DIMENSION AND DIRECTION

The first family asks what the model is looking at, from where, and in which direction time runs. Throughout this framework the three axes are named: X is DNA and the past; Y is RNA and the present; Z is selection and the future.

---

6. Principle 1 · Trinary Necessity

Principle 1 of the sixteen

Some outcomes need three independent inputs, and a system given only two can never produce them, no matter how good it gets at the two.

WHAT IT ASKS OF A MODEL	Does the model have a THIRD independent input, or is it combining two and calling the result a third thing? Two axes cannot generate the third; they can only span a plane.
AN EXAMPLE	Two people can tell you where a building is on a map. Neither can tell you how tall it is, and no amount of arguing between them produces a height. Height is a third measurement, not a better average of the first two. A model given DNA sequence and more DNA sequence has two copies of one axis, not two axes.
THE ATOMIC AND MOLECULAR CASE	S-adenosyl methionine. A methyl transfer needs three things: the site on the DNA, the methyltransferase, and a molecule of SAM to donate the methyl group. The donor is a SULFONIUM — the charge sits on a SULFUR atom, and that atom is why the methyl group will leave. Sequence gives you the first. Gene annotation gives you the second. NOTHING IN EITHER GIVES YOU THE SIZE OF THE SAM POOL, and two of three will not make a third.
WHAT A PASS LOOKS LIKE	The model names a third input that is neither sequence nor a function of sequence — a measured metabolite concentration, an oxygen tension, a cofactor pool — and shows that its output changes when that input changes and the sequence does not.

The color matrix for Principle 1

color	element	base	nucleoside	what it is doing here
RED	H 1	ADENINE	adenosine	the adenosyl handle of SAM
YELLOW	S 16	THYMINE	thymidine	the sulfonium center that makes the methyl leave
BLUE	C 6	CYTOSINE	cytidine	the methyl group being transferred

7. Principle 2 · The Flatlander Dilemma

Principle 2 of the sixteen

A system confined to a plane can detect the SHADOW of something in a higher dimension, and will mistake the shadow for the object.

WHAT IT ASKS OF A MODEL	When the model predicts something correctly, is it representing the mechanism, or is it fitting the statistical trace that the mechanism leaves behind?
AN EXAMPLE	A flat creature living on a tabletop sees a sphere pass through its world as a circle that grows and shrinks. It can predict the circle perfectly — it can model the circle, publish on the circle, win prizes for the circle — and it has no representation of a sphere anywhere. Correct prediction is not evidence of correct representation.
THE ATOMIC AND MOLECULAR	CpG methylation. A model can predict methylation from CpG density and local context and be right a great deal of the time. The MECHANISM is a methyl group leaving a sulfonium and arriving on the 5 position of a

CASE	CYTOSINE ring. Run the color key over such a model's inputs and you find CARBON and NITROGEN and no SULFUR anywhere. It is predicting the statistical footprint of the transfer, not the transfer.
WHAT A PASS LOOKS LIKE	For any output the model predicts well, it can state the mechanism in terms of an internal variable, and that variable can be intervened on independently of the input. If the only answer is that the pattern was in the training data, the model is fitting shadows.

The color matrix for Principle 2

color	element	base	nucleoside	what it is doing here
YELLOW	S 16	THYMINE	thymidine	THE MISSING COLOR — the donor is nowhere in the model's inputs
GREEN	N 7	GUANINE	guanosine	the ring nitrogens of the CpG
BLUE	C 6	CYTOSINE	cytidine	carbon 5 of cytosine, where the methyl lands

8. Principle 4 · Z-Axis Selector Blindness

Principle 4 of the sixteen

A model can measure what selection PRODUCED without having any representation of what DID the selecting.

WHAT IT ASKS OF A MODEL	Can the model say what chose, or only what was chosen? Those are different objects and the second is much easier.
AN EXAMPLE	You can look at a field of surviving wheat and measure the surviving plants precisely. Nothing in that measurement tells you whether the winter, the fungus or the farmer did the selecting. A variant-effect score is a measurement of survivors. The selector is not in it.
THE ATOMIC AND MOLECULAR CASE	INOSINE at anticodon position 34. From that one position a transfer RNA can read three different codons. What decides which codon is actually read is the composition of the message and the competing transfer RNA pool. A model sees the protein that came out. The SELECTOR is the pairing at position 34, and the atom that made that pairing possible is the OXYGEN that replaced the amino group.
WHAT A PASS LOOKS LIKE	The model exposes a variable representing the selective pressure itself — not the outcome — and that variable can be set to a different value to produce a different prediction for the same sequence.

The color matrix for Principle 4

color	element	base	nucleoside	what it is doing here
ORANGE	O 8	INOSINE	inosine	inosine at anticodon position 34
GREEN	N 7	GUANINE	guanosine	one of the three codons it can read

9. Principle 9 · Axis Conflation

Principle 9 of the sixteen

Predicting an RNA-level or protein-level quantity from a DNA-level input alone treats two different axes as though they were one.

WHAT IT ASKS OF A MODEL	Is the model's input on the same axis as its output? If not, has it stated what it is assuming about everything that sits between them?
AN EXAMPLE	A DNA sequence is the past. Whether a transcript is present, spliced a particular way, edited, degraded or translated is the present, and it is decided by the ribosome, the spliceosome, the microRNAs, the long non-coding RNAs, the circular RNAs and the riboswitches. A model that takes only DNA and predicts RNA abundance has jumped an axis and assumed the whole operational layer away.
THE ATOMIC AND MOLECULAR CASE	The 2 prime hydroxyl. RIBOSE carries an OXYGEN at the 2 prime position; DEOXYRIBOSE is defined by not having it. Methylation of that 2 prime oxygen is one of the commonest modifications in RNA — and the atom being modified DOES NOT EXIST IN DNA. A model predicting it from a DNA input is predicting a change to an atom that is absent from its own input molecule.
WHAT A PASS LOOKS LIKE	The model either takes an input on the same axis as its output, or it explicitly names the intermediate layer it is marginalizing over and states what it assumes about it.

The color matrix for Principle 9

color	element	base	nucleoside	what it is doing here
ORANGE	O 8	INOSINE	inosine	the 2 prime oxygen — present in ribose, ABSENT IN DEOXYRIBOSE
BLUE	C 6	CYTOSINE	cytidine	the methyl that arrives on it

10. Principle 13 · Temporal Axis Collapse

Principle 13 of the sixteen

Flattening past, present and future into one static snapshot removes the ordering, and the ordering was carrying information.

WHAT IT ASKS OF A MODEL	Does the model represent the ORDER of events, or only their co-occurrence?
AN EXAMPLE	Predicting the weather by reading last year's almanac and never looking out the window. The almanac is real data, correctly recorded, and it has had the time dimension flattened out of it. Every entry is true and the sequence of them has been lost.
THE ATOMIC AND MOLECULAR CASE	One position, three times. ADENINE in the DNA is the past. ADENOSINE in the fresh transcript is the present. INOSINE in the edited transcript is the present a few seconds later. A single transcriptome snapshot averages the edited and unedited copies into one number and the ordering is gone — and in ALS motor neurons that ratio runs from zero to one hundred percent within one patient.
WHAT A PASS LOOKS LIKE	The model's representation distinguishes a state at time one from the same state at time two, and its prediction changes when the order of two events is reversed.

The color matrix for Principle 13

color	element	base	nucleoside	what it is doing here
RED	H 1	ADENINE	adenosine	adenine in the DNA, the past
ORANGE	O 8	INOSINE	inosine	inosine in the edited transcript, the present

FAMILY TWO · THE ALGEBRA

The second family asks what mathematics the model's internal operations obey, and whether that mathematics matches the mathematics of the thing being modeled.

11. Principle 3 · Quaternion Non-Commutativity

Principle 3 of the sixteen

In the algebra this framework uses, the order of two operations changes the answer: i times j does not equal j times i. Biology behaves the same way, and most model architectures do not.

WHAT IT ASKS OF A MODEL	Does the model give the same answer for A-acting-on-B as for B-acting-on-A? If it does, it has assumed the order does not matter.
AN EXAMPLE	DNA informing RNA is transcription. RNA informing DNA is reverse transcription. These are different enzymes, different rates, different biological meanings and different consequences. A system that treats the relationship between two elements as symmetric has erased that difference. The same applies to a variant on the sense strand versus the identical variant on the antisense strand: same letters, different phenotype.
THE ATOMIC AND MOLECULAR CASE	Deamination runs one way. ADAR strips the amino NITROGEN from carbon 6 of ADENINE and leaves an OXYGEN in its place. There is no enzyme that walks that backwards. So ADENOSINE to INOSINE and INOSINE to ADENOSINE are not two directions of one operation — one is a reaction and the other does not occur. A representation in which two bases are simply SIMILAR has erased the arrow.
WHAT A PASS LOOKS LIKE	Submit an ordered pair to the model in both orders and record whether the outputs differ. If they are identical, the failure is measured rather than argued — and this is the one principle in the sixteen that can be settled in an afternoon without anybody's cooperation.

The color matrix for Principle 3

color	element	base	nucleoside	what it is doing here
RED	H 1	ADENINE	adenosine	adenosine, before
ORANGE	O 8	INOSINE	inosine	inosine, after — the oxygen that replaced the amino group
GREEN	N 7	GUANINE	guanosine	guanine, the letter the file writes instead

12. Principle 7 · Scalar-to-Quaternion Continuity

Principle 7 of the sixteen

Information moving from a single number, to a vector, to a matrix, to a full four-component object should be traceable at every step — and if the chain truncates, you can name exactly where.

WHAT IT ASKS OF A MODEL	Can you trace what happens to a quantity as it moves through the model's layers, and identify the step at which dimensionality is discarded?
AN EXAMPLE	Think of describing a rotating object. A single number gives you speed. Three numbers give you an axis. Four give you the complete orientation and the sense of rotation together. A pipeline that starts with four and outputs one has thrown something away, and the useful question is not WHETHER but WHERE.
THE ATOMIC	One column of the color key, read downward: SULFUR the element,

AND MOLECULAR CASE	THYMINE the base, THYMIDINE the nucleoside, TMP the nucleotide. Four levels of assembly, ONE COLOR, because it is one chemistry all the way down. A model that tokenizes this column as the single character T has collapsed four levels into one symbol. That is where the rank was discarded, and it happened in the tokenizer before training began.
WHAT A PASS LOOKS LIKE	The model's builders can state the rank of the representation at each stage and identify the step where it is reduced, together with what is lost there.

The color matrix for Principle 7

color	element	base	nucleoside	what it is doing here
YELLOW	S 16	THYMINE	thymidine	one column read downward: element, base, nucleoside, nucleotide — one color the whole way

13. Principle 6 · Vortex Mathematics

Principle 6 of the sixteen

The framework holds that the digit families 3-6-9, 1-5-7 and 2-4-8 recur in the structure of the code, and asks whether a model's architecture respects or violates them.

WHAT IT ASKS OF A MODEL	Do the model's own structural numbers — layer counts, head counts, alphabet sizes, output tracks — fall into these families, and was that a choice or an accident?
AN EXAMPLE	The codon is three letters. The code has sixty-four combinations. Three sixty-degree rotations close a hexagon at three hundred and sixty. Whether those are deep or coincidental is exactly what the principle asks to be tested rather than assumed in either direction.
THE ATOMIC AND MOLECULAR CASE	The codon is THREE bases. The code is 64, which is 4 cubed. The elements of life are SIX. A hexagon closes at six turns of sixty degrees. This principle does not ask you to believe any of that is deep. It asks you to say whether your alphabet size, your context window and your output track count were chosen by the BIOLOGY or by the HARDWARE, and an honest hardware answer is a pass.
WHAT A PASS LOOKS LIKE	The builders can state the model's structural numbers and say whether the choice was forced by the biology, forced by the hardware, or arbitrary. An honest ARBITRARY is a pass; an unexamined number is not.
A NOTE	This is the principle most likely to be dismissed on sight by a computational reader. It is also the one most easily made rigorous, by simply reporting the numbers and their justification.

The color matrix for Principle 6

color	element	base	nucleoside	what it is doing here
RED	H 1	ADENINE	adenosine	
ORANGE	O 8	INOSINE	inosine	
YELLOW	S 16	THYMINE	thymidine	
GREEN	N 7	GUANINE	guanosine	
BLUE	C 6	CYTOSINE	cytidine	
PURPLE	P 15	URACIL	uridine	six elements, six colors, one to one

14. Principle 8 · Abha Torus Topology

Principle 8 of the sixteen

The genetic code has a closed, wrap-around structure: it is a surface where the edges join, not a flat sheet with borders.

WHAT IT ASKS OF A MODEL	Does the model's output space wrap, or does it have artificial edges where the biology has none?
AN EXAMPLE	A world map on paper has a left edge and a right edge, and a traveler crossing one vanishes and reappears at the other. On a globe there are no edges at all. If a model's representation has a first position and a last position where the biology is cyclical, it has introduced a boundary that does not exist and will produce artifacts there.
THE ATOMIC AND MOLECULAR CASE	The third codon position. Wobble makes the codon table cyclical in its third base — U and C behave alike, A and G behave alike, and INOSINE at position 34 reads across the boundary. A representation with a first codon and a sixty-fourth codon and nothing joining them has introduced an edge the chemistry does not have, and artifacts will appear there.
WHAT A PASS LOOKS LIKE	The model's representation is periodic where the biology is periodic, or the builders state explicitly which boundaries are artifacts of the representation and show they do not affect the results.

The color matrix for Principle 8

color	element	base	nucleoside	what it is doing here
RED	H 1	ADENINE	adenosine	
ORANGE	O 8	INOSINE	inosine	inosine at 34 reads across the boundary
GREEN	N 7	GUANINE	guanosine	
BLUE	C 6	CYTOSINE	cytidine	

color	element	base	nucleoside	what it is doing here
PURPLE	P 15	URACIL	uridine	the third codon position, where the table wraps

FAMILY THREE · THE ALPHABET AND THE LATTICE

The third family asks what the model's notation can and cannot write down. These are the principles closest to this volume's central argument, and the ones with the most immediate practical consequences.

15. Principle 12 · Inosine, the Silent Sixth

Principle 12 of the sixteen

Inosine is made constantly in living cells, is read by the ribosome as a different letter from the one in the gene, and has no character in the sequence alphabet — so the record writes G and everyone downstream inherits a molecule that was never in the cell.

WHAT IT ASKS OF A MODEL	Does the model represent inosine at all, and if not, does it predict anything that inosine changes?
AN EXAMPLE	More than 4,500,000 adenosine-to-inosine editing sites are catalogued in humans across fifty-five body sites, downloadable today. In ALS motor neurons, editing at one position in GRIA2 runs from zero to one hundred percent WITHIN A SINGLE PATIENT while the gene sequence is identical in every cell. FASTA and GenBank permit A, C, G, T, U and the ambiguity codes. Inosine is not among them.
THE ATOMIC AND MOLECULAR CASE	ADENOSINE loses the amino NITROGEN from carbon 6 and gains an OXYGEN. In this notation the word changes color: RED becomes ORANGE. That color transition IS the chemistry, visible at a glance. And the sequence record writes G — GREEN — a color that never occurred at that position in that cell. The notation makes the substitution obvious; the file makes it invisible.
WHAT A PASS LOOKS LIKE	The model accepts an editing-level input, or reports which of its outputs are sensitive to editing and by how much, or states plainly that it treats edited and unedited transcripts as identical.
A NOTE	This is the principle the framework's author has spent twenty-nine years on, and it is the one with the clearest immediate application: any model predicting splicing or RNA abundance is predicting two things that

	editing alters.

The color matrix for Principle 12

color	element	base	nucleoside	what it is doing here
RED	H 1	ADENINE	adenosine	adenosine in the cell
ORANGE	O 8	INOSINE	inosine	inosine after editing
GREEN	N 7	GUANINE	guanosine	guanine in the file — A COLOR THAT NEVER OCCURRED

16. Principle 5 · The Silent Seventh Exclusion

Principle 5 of the sixteen

A second species is excluded from the alphabet for the same reason as the first — the notation has no character for it — and its exclusion is less discussed because it is less abundant, not because it matters less.

WHAT IT ASKS OF A MODEL	Does the model's alphabet admit only the canonical set, and has anyone checked what falls outside it?
AN EXAMPLE	The canonical alphabet has four letters for DNA and five counting uracil. This framework works with eight species of actual metabolism. Xanthine is a real deamination product with real enzymology and it has no letter. A notation that admits only the canonical set does not report the omission — it simply has nowhere to put it.
THE ATOMIC AND MOLECULAR CASE	XANTHINE. It sits between IMP and GMP in purine biosynthesis: IMPDH makes XMP, GMPS converts XMP onward. Real intermediate, real enzymes, real disease when it fails. It has NO LETTER. In this notation it is INDIGO precisely because indigo marks the species that are not letters. Check your alphabet: if it has four characters, xanthine is not in it, and neither is the pathway that runs through it.
WHAT A PASS LOOKS LIKE	The builders can state the complete list of chemical species their representation admits, and the list of species known to occur that it does not.
A NOTE	The identity of the seventh is the framework author's to fix. This section defines the STRUCTURE of the exclusion, which is what a reader needs in order to test their own alphabet.

The color matrix for Principle 5

color	element	base	nucleoside	what it is doing here
ORANGE	O 8	INOSINE	inosine	IMP, the start of the branch
GREEN	N 7	GUANINE	guanosine	GMP, the end of it

color	element	base	nucleoside	what it is doing here
INDIGO	Se 34	XANTHINE and OROTATE	xanthosine / orotidine	XMP — the step in between, with no letter

17. Principle 10 · The 64-Tetrahedron Lattice

Principle 10 of the sixteen

The sixty-four codons are not a flat list; they have a geometric arrangement, and that arrangement carries information about which substitutions are conservative and which are not.

WHAT IT ASKS OF A MODEL	Does the model treat codons as arbitrary tokens, or does it represent the structure of the codon space?
AN EXAMPLE	In a lookup table, CTG and CTA are two unrelated rows. In the geometry, they are adjacent — both leucine, one position apart, a change with no consequence for the protein. A model that tokenizes codons as arbitrary symbols has to learn every adjacency from data, whereas a model that represents the geometry gets it for free and generalizes to codons it has not seen.
THE ATOMIC AND MOLECULAR CASE	LEUCINE has six codons: CUU, CUC, CUA, CUG, UUA and UUG. As tokens they are six unrelated symbols and a model must learn from data that all six mean the same residue. In the lattice they are neighbors, and the two families differ at the first position, which is why they are two families rather than one block. Measure the distances in your own embedding and see which picture you built.
WHAT A PASS LOOKS LIKE	The model's codon representation places synonymous and conservative substitutions closer together than non-conservative ones, and this can be demonstrated by measuring distances in its own embedding space.

The color matrix for Principle 10

color	element	base	nucleoside	what it is doing here
RED	H 1	ADENINE	adenosine	
GREEN	N 7	GUANINE	guanosine	
BLUE	C 6	CYTOSINE	cytidine	
PURPLE	P 15	URACIL	uridine	the six codons of leucine, and whether they are neighbors or strangers

18. Principle 14 · The Official Sixes

Principle 14 of the sixteen

Six recurs across the framework — six elements of life, six colors in the notation, six faces, sixty degrees — and the principle asks whether a model's own sixes are structural or coincidental.

WHAT IT ASKS OF A MODEL	Where does the number six appear in the model's architecture or in the biology it represents, and has anybody asked why?
AN EXAMPLE	CHNOPS is six elements. A hexagon closes at six sixty-degree turns. The notation this volume uses assigns six colors. The principle does not assert that every six is meaningful; it asserts that an unexamined six is a missed opportunity to find out.
THE ATOMIC AND MOLECULAR CASE	CHNOPS: CARBON, HYDROGEN, NITROGEN, OXYGEN, PHOSPHORUS, SULFUR. Six elements, six colors, one to one, and every base, nucleoside and nucleotide inherits the color of the element that defines it. The six is not decorative here — it is the reason the notation works at a glance. Where is the six in YOUR system, and did anyone choose it?
WHAT A PASS LOOKS LIKE	The builders can point to each occurrence of the number in their system and say whether it is forced, inherited or arbitrary.
A NOTE	Like Principle 6, this is a reporting requirement rather than a metaphysical claim, and it is strongest when read that way.

The color matrix for Principle 14

color	element	base	nucleoside	what it is doing here
RED	H 1	ADENINE	adenosine	
ORANGE	O 8	INOSINE	inosine	
YELLOW	S 16	THYMINE	thymidine	
GREEN	N 7	GUANINE	guanosine	
BLUE	C 6	CYTOSINE	cytidine	
PURPLE	P 15	URACIL	uridine	CHNOPS — the six elements the notation assigns

FAMILY FOUR · THE CHEMISTRY THE SEQUENCE OMITS

The fourth family asks about physical quantities that are real, measurable, consequential, and absent from every sequence record in existence. This is where Principle Sixteen joins the list.

19. Principle 11 · Phosphorothioate-k Chirality

Principle 11 of the sixteen

Replacing one backbone oxygen with sulfur creates two mirror-image forms, Rp and Sp, which are chemically distinct, behave differently in cells, and are written identically in every sequence file.

WHAT IT ASKS OF A MODEL	Does the model represent backbone stereochemistry, and does it predict anything that stereochemistry changes?
AN EXAMPLE	Phosphorothioate linkages are standard in antisense oligonucleotide drugs. The Rp and Sp diastereomers differ in nuclease resistance, in binding, and in activity. Two drugs with the same printed sequence can behave differently in a patient. The file that describes them is the same file.
THE ATOMIC AND MOLECULAR CASE	The backbone PHOSPHORUS. Replace one non-bridging OXYGEN with SULFUR and the color of that single atom changes from orange to yellow. Which of the two non-bridging positions took the sulfur is the difference between Rp and Sp — different nuclease resistance, different activity, same printed sequence. This is standard chemistry in antisense drugs and no sequence file can write it.
WHAT A PASS LOOKS LIKE	The model accepts a stereochemistry flag, or states that it treats both diastereomers as identical — which is a perfectly acceptable answer, provided it is written down where a user will see it.

The color matrix for Principle 11

color	element	base	nucleoside	what it is doing here
ORANGE	O 8	INOSINE	inosine	the non-bridging oxygen
YELLOW	S 16	THYMINE	thymidine	the sulfur that replaces it — Rp or Sp
PURPLE	P 15	URACIL	uridine	the backbone phosphorus itself

20. Principle 16 · Cofactor Substrate Blindness

Principle 16 of the sixteen

A model that predicts a chemical modification without representing the metabolite pool that donates the modifying group is predicting an ADDRESS without an INVENTORY.

WHAT IT ASKS OF A MODEL	For every modification the model predicts, can it name the donor molecule, and does it have any input carrying how much of that donor is present?
AN EXAMPLE	The methyl donor for DNA and histone methylation is S-adenosyl methionine, a sulfonium. The acetyl donor for histone acetylation is acetyl-CoA, a thioester. The polymerases and glycosylases that read and repair DNA are held together by iron-sulfur clusters coordinated by cysteine. A model can predict exactly WHERE a methyl group goes and have no representation of whether there is a methyl group available to go anywhere. The same million base pairs in a cell with a full methionine pool and a depleted one are the same million base pairs.
THE ATOMIC AND MOLECULAR CASE	ACETYL-CoA. The acetyl group is held on a THIOESTER bond to the THIOL of coenzyme A, and the SULFUR atom is the high-energy bond that makes the group transferable. A model predicting histone acetylation has the lysine, the sequence context and the chromatin state. Run the color key across its inputs and there is no YELLOW in them at all.
WHAT A PASS LOOKS LIKE	The model accepts a cofactor-availability input, or reports the sensitivity of each predicted modification to donor abundance, or states that it assumes donor pools are saturating and non-limiting — which is a testable assumption and frequently false.
A NOTE	ADMITTED 16 SEPTEMBER 2026 by ruling of the framework's author. See section twenty-five.

The color matrix for Principle 16

color	element	base	nucleoside	what it is doing here
ORANGE	O 8	INOSINE	inosine	the carbonyl of the acetyl group
YELLOW	S 16	THYMINE	thymidine	THE MISSING COLOR — the thioester sulfur of acetyl-CoA
BLUE	C 6	CYTOSINE	cytidine	the acetyl carbon that lands on the lysine

F A M I L Y F I V E · S E L E C T I O N

21. Principle 15 · Freedom of Choice and the Sixty-Fourth

Principle 15 of the sixteen

A system that can only compute the consequences of a state cannot represent the act of CHOOSING a state, and the framework reserves a sixty-fourth position for what does the choosing.

WHAT IT ASKS OF A MODEL	Can the model represent a decision, or only the downstream statistics of decisions already made?
AN EXAMPLE	A chess engine evaluating a position tells you what follows from it. That is not the same object as the move being made. Biology selects continuously — which transcript, which splice form, which cell survives — and a model trained on the survivors has the results of a great many choices and no representation of choosing.
THE ATOMIC AND MOLECULAR CASE	Which transfer RNA arrives at the A site. The codon is fixed; two or more charged transfer RNAs compete for it, and the winner is decided by abundance and by MODIFICATION STATE — including the 2-THIOURIDINE at position 34, where a SULFUR atom substituted for an oxygen changes the pairing. The model has the codon. The choosing is done by an atom the codon does not mention.
WHAT A PASS LOOKS LIKE	The model exposes a decision variable that can be set independently of the input state, and produces different outputs for the same state under different settings.
A NOTE	This is the most philosophically loaded of the sixteen and the hardest to operationalize. The pass condition above is deliberately mechanical so that it can be scored without anyone agreeing about free will.

The color matrix for Principle 15

color	element	base	nucleoside	what it is doing here
ORANGE	O 8	INOSINE	inosine	the oxygen that is replaced
YELLOW	S 16	THYMINE	thymidine	the sulfur of 2-thiouridine at position 34
PURPLE	P 15	URACIL	uridine	uridine, the base it modifies

THE APPARATUS

THE NOTATION, AND WHY IT NEEDS THE VOLUME

22. The Color Is Not Decoration

What the shaded words mean, and the rule that assigns them

Throughout this corpus certain words carry a background color. The color is not emphasis and it is not styling. It is an ELEMENT ASSIGNMENT, and once a reader knows the rule the chemistry of a paragraph can be read without reading the paragraph.

the color	the element	the base	the nucleoside	the nucleotide
ORANGE	O, oxygen, 8	HYPOXANTHINE	inosine	IMP
RED	H, hydrogen, 1	ADENINE	adenosine	AMP
GREEN	N, nitrogen, 7	GUANINE	guanosine	GMP
BLUE	C, carbon, 6	CYTOSINE	cytidine	CMP
PURPLE	P, phosphorus, 15	URACIL	uridine	UMP
YELLOW	S, sulfur, 16	THYMINE	thymidine	TMP
INDIGO	Se, selenium, 34	XANTHINE and OROTATE — GATEKEEPERS, NOT LETTERS	xanthosine / orotidine	XMP / OMP

Six colors carry the six letters of the coding set. The seventh, INDIGO, marks the two species that are not letters at all — xanthine and orotate, which this volume treats as gatekeepers. A reader who sees indigo knows immediately that they are looking at something the alphabet has no character for.

The rule, and the rulings that follow from it

The assignment runs down a column: a base, its nucleoside and its nucleotide all carry the same color, because they are the same chemistry at three levels of assembly. An enzyme inherits the color of the molecule IN ITS OWN NAME.

the rule	the consequence
an enzyme takes the color of the molecule it is named for	ADAR is named for ADENOSINE, so ADAR is RED. IMPDH is named for IMP, so IMPDH is ORANGE
a name that contains no molecule takes no color	APOBEC is named for a LIPOPROTEIN, and a lipoprotein has no color in a system built on the elements. The shader leaves it unshaded
a color marks the element, not the sentiment	oxygen is shaded wherever it appears, including where the volume is arguing against the conventional reading of it
the gatekeepers are marked as gatekeepers	orotate is INDIGO rather than being forced into one of the six letter colors, because it is not a letter

Every one of those is a dated ruling by the framework's author rather than a style choice, and each is recorded in the volume where it was made. A notation whose rules are undocumented is a habit; a notation whose rules are printed is an instrument.

---

23. Every Shaded Word Is a Live Link

And where it takes you depends on which document you are holding

The color does a second job that a reader of a single paper will not see. In the full volume, every shaded word is a HYPERLINK, and its destination is that word's own entry in the Index.

what you are reading	where a shaded word takes you	what you get
a standalone paper, such as this one	the COLOR INDEX at the back of that paper	one destination. You learn what the color MEANS and you are returned to your place
the full evidence volume	that word's OWN ENTRY IN THE INDEX	and from that entry, onward to every section and every page in which the molecule is treated

In a standalone paper the color is a LEGEND LOOKUP. In the volume it is a SEARCH. Those are different instruments that happen to look identical on the page, and the difference is the whole reason the volume exists as one object rather than as a shelf of separate papers.

The chain, in full

Clicking a shaded word in the volume starts a sequence, and every step of it is itself a link.

step	the element	what it does
1	the shaded word in the running text	jumps to that term's Index entry
2	the Index entry	carries a PRIMARY SECTION — the section whose own title contains the term, where one exists, and otherwise

step	the element	what it does
		the earliest section treating it
3	the SECONDARY SECTIONS column	every other numbered section that mentions the term, in order, capped at twelve with the remainder counted rather than hidden
4	the PAGES column	every page on which the term appears, printed in full rather than abbreviated, each one a link to that page
5	every numbered section	carries a return arrow back to the Index, so the reader is never stranded

That is why a reader who wants the inosine material does not need to be told which sections to read. They click I once and the volume tells them, in document order, with the page numbers of the current edition.

Measured, on the current build

the measure	the figure
pages	1,737
divisions and numbered sections	175 and 1,716
link annotations	49,854
broken links	0
index terms carrying page references	812
page-number drift across two consecutive rebuilds	0 — the page numbers printed in the Index are the pages the text falls on

A cross-reference apparatus is worth exactly nothing if its numbers are stale, which is why the build is run to convergence and the link audit is run on every release. 49,854 destinations resolve. None of them is a guess.

24. Which Is Why the Sixteen Need the Volume

The checklist is portable. The instrument is not.

The sixteen questions in this document can be taken anywhere. They are stated in plain English, their pass conditions are model-agnostic, and a builder can score their own system against them this afternoon without owning anything else.

What this document cannot carry is the EVIDENCE BEHIND EACH CRITERION. A definition tells you what a principle asks. It does not show you the two hundred sections in which the underlying chemistry was worked out, tested, corrected and in some cases withdrawn.

what you are holding	what it contains	what it lets you do
this document	the sixteen questions, defined, exampled, with pass conditions	enough to run the checklist and find your failed criteria
the standalone papers	one criterion each, worked through against a named object with sources	enough to argue about a single principle
the full volume	1,737 pages, every claim traceable, every shaded word a door into every treatment of that molecule	enough to follow any criterion back to the chemistry it rests on, and to check it

Take Principle 12 as the worked case. This document tells you that inosine has no character in the sequence alphabet and gives you the ALS example. In the volume, the word inosine is a link: it opens the Index entry, which carries the primary section, the secondary sections in document order, and every page. The reader goes from a one-line definition to the complete internal treatment in two clicks, and every page number is current.

That is the difference between being told a thing and being able to CHECK it, and checkability is the only property this corpus has ever claimed as an advantage.

Stated plainly, so nobody buys the wrong thing

the question	the answer	the note
the sixteen without the volume	USABLE, and you should use them so	the failed criteria are the return, and they cost nothing
can you follow a criterion back to its evidence without the volume?	NO	the chain at section twenty-three exists only inside the full document
is the volume required to DISAGREE with a criterion?	No — the pass conditions are written to be argued with on their own terms	that was deliberate, and section three says so

the question	the answer	the note
what the volume adds	the apparatus	the Index, the color links, the corrections register, and 49,854 resolving destinations

The volume is Licensed under CC BY-NC-ND 4.0., it carries no paywall and no login, and it is one file. Anyone

who wants to check a criterion rather than take it on trust needs that file, and there is no charge and no permission required to have it.

---

25. The Ruling Admitting Principle Sixteen

Printed in full, because the framework had been closed

The Berger Novel Creative Principles were formally closed at fifteen on 21 April 2026. On 16 September 2026 the framework's author ruled that a sixteenth be admitted. The record of that is printed here rather than absorbed silently, because a framework that can be quietly extended is not a framework.

the element	the record	the date or source
the closure	the framework was closed at fifteen	21 April 2026
the candidate	COFACTOR SUBSTRATE BLINDNESS, arising from the sulfur audit of a sequence-only genome model	submitted for ruling, not asserted, in PP-2026-167-01
who proposed it	the candidate was drafted in the course of that paper's analysis and submitted to the framework's author for a decision	it was not adopted unilaterally
the ruling	ADMITTED as Principle Sixteen	16 September 2026
what the ruling does to the closure	the framework is reopened once, for this, and the closure otherwise stands	a second admission would require a second ruling
why it qualifies	the existing fifteen address dimension, algebra, alphabet and selection. None of them asks whether a model represents the SUPPLY of the chemical group whose placement it predicts	that is a distinct question and it is testable

A principle admitted by dated ruling, with the closure it breaks printed alongside it, is a different object from a principle that simply

appeared in the list. Anyone can check when it arrived and on whose authority.

26. The Scorecard

The sixteen in one table, for anyone who wants to run them

#	the principle	the question in one line
1	Trinary Necessity	is there a genuine third input?
2	The Flatlander Dilemma	is it the mechanism or the shadow?
3	Quaternion Non-Commutativity	does A-to-B equal B-to-A?
4	Z-Axis Selector Blindness	what selects, or only what was selected?
5	The Silent Seventh Exclusion	what does the alphabet leave out?
6	Vortex Mathematics	are the structural numbers examined or accidental?
7	Scalar-to-Quaternion Continuity	where is rank discarded?
8	Abha Torus Topology	does it wrap where the biology wraps?
9	Axis Conflation	is the input on the same axis as the output?
10	The 64-Tetrahedron Lattice	are codons tokens or geometry?
11	Phosphorothioate-k Chirality	is backbone stereochemistry represented?
12	Inosine, the Silent Sixth	is editing represented, and what does it change?
13	Temporal Axis Collapse	is the order of events preserved?
14	The Official Sixes	are the sixes forced, inherited or arbitrary?
15	Freedom of Choice and the Sixty-Fourth	can it represent a decision?
16	Cofactor Substrate Blindness	is the donor pool represented?

Sixteen questions. Most models have never been asked fourteen of them. The ones that come back 1 are the return on running the list, and Principle 3 is the one that can be MEASURED this weekend rather than argued.

27. What This Paper Claims

Five claims, numbered and counted, each with the condition that would refute it

number	the claim	what would refute it
1	Each of the sixteen can be stated in plain English with a pass condition checkable	name a principle whose pass condition as written here requires adopting this

number	the claim	what would refute it
	against a model's own output	framework in order to score
2	A structural absence and an engineering shortfall are distinguishable by the test at section three	exhibit a case where more training data supplied a quantity that was absent from the input
3	No currently published genome model represents all sixteen	name a model that does, with the variable that carries each
4	Principle 3 is the only one of the sixteen measurable today without the model builders' cooperation	name another whose pass condition can be evaluated from public outputs alone
5	Principle 16 was admitted by dated ruling on 16 September 2026, reopening a framework closed on 21 April 2026	show a different admission date or that the framework was not closed

Five claims and five refutation conditions. Claim three is an invitation: the fastest way to improve this list is for somebody to score a real system and publish where the list failed them.

28. What This Paper Does Not Claim

The boundaries, which belong at the back

It does not claim the sixteen are complete. Sixteen is where the framework stands today, and section twenty-five shows exactly how a seventeenth would have to arrive.

It does not claim a model failing these is a bad model. A sequence model conditions on sequence and does that extremely well. The list asks what it CANNOT do, which is a different question from how well it does what it does.

It does not claim every principle is equally rigorous. Principles 6 and 14 are reporting requirements rather than tests, and are marked as such in their own notes; Principle 15 is the hardest to operationalize and says so.

It does not claim the framework's author invented the underlying chemistry. Every chemical fact in the examples belongs to the group that published it, and the contribution here is the notation and the list, not the findings.

And it does not claim that a model needs this framework to be useful. It claims the opposite: the pass conditions were written so that a builder who thinks the framework is nonsense can still run the checklist and learn something from the criteria it fails.

What the paper claims is the narrow thing the sections support: here are sixteen questions, here is what each means in plain words, here is an example, and here is how you would know if your own system answered it.

29. A Note on the Definitions

Which of these are the author's words and which are this document's reconstruction

The names and the numbering of the fifteen are the framework author's. The plain-English definitions, the worked examples and the pass conditions in this document were drafted for it, and on several principles the drafting required interpretation.

the element	its provenance	the note
the names and numbering of 1 through 15	the author's, as published	no interpretation
Principle 16 in full	admitted by the author's ruling of 16 September 2026	see section twenty-five
the pass conditions throughout	drafted for this document	chosen to be model-agnostic and observable; the author has not ruled on each individually
Principle 5, the identity of the seventh species	THE STRUCTURE IS DEFINED HERE; THE IDENTITY IS THE AUTHOR'S TO FIX	flagged for ruling
Principles 6 and 14, the numeric families	stated as reporting requirements rather than metaphysical claims	this reading is the document's and is the strongest defensible form
Principle 15, the sixty-fourth position	operationalized mechanically so it can be scored without agreement on free will	this framing is the document's

Four items on that list are marked as this document's reading rather than the author's ruling, and they are marked so that a reader knows which sentences to argue with and whom to argue with about them.

THE COLOR INDEX

Every shaded word in this volume is a link. A word with its own entry in the Index jumps to that entry; a letter, atom label or formula returns here.

color	element	base	nucleoside	nucleotide	the base, on pages	the element, on pages
ORANGE	O 8	HYPOXANTHINE	inosine	IMP	83, 111-114, 124, 131, 147-148, 158, 170, 174, 177-183, 186,	60, 62-63, 66-68, 72, 77, 79, 83, 85, 87-89, 91, 93-97, 100-102, 105,

color	element	base	nucleoside	nucleotide	the base, on pages	the element, on pages
					236, 249, 259, 328-330, 341, 343, 345-346, 355, 357, 361, 366-367, 370-371, 399-402, 481, 484, 503, 506, 508, 510, 512, 738, 749-750, 754, 761, 766, 768, 783, 789, 794, 801, 814, 817-820, 823, 825, 856-858, 863, 868, 871-872, 877-878, 882, 884, 887-893, 895-896, 898-901, 933, 935-936, 938-940, 942-944, 947, 979, 983, 990-991, 997, 1006-1011, 1013-1014, 1021, 1043, 1165, 1197, 1207-1214, 1237, 1240, 1242, 1262-1263, 1265, 1267-1268, 1331, 1345, 1401, 1444-1447, 1454, 1465, 1469, 1471, 1597, 1599, 1608	107-113, 115, 118-119, 126-127, 133, 140-145, 148, 156-157, 159-160, 164-166, 168-171, 173-175, 180-183, 186-189, 192, 208-209, 213, 215, 217-219, 225, 227, 235, 237, 239-241, 243, 245, 254, 258, 267, 269-270, 277, 280, 307, 319-320, 323-324, 331-332, 348, 350, 361-362, 365, 370, 374, 397-400, 402, 426-432, 434, 437, 439, 442, 445-449, 451-458, 461-463, 467-469, 472-473, 475-477, 522-523, 549, 555-556, 643, 646-648, 654-655, 658-659, 662, 667, 702, 704, 714, 764, 775, 787, 789, 858, 895-896, 898, 932, 943, 950, 953, 959, 961, 974-975, 980-983, 987-988, 990, 997, 999, 1006-1007, 1010-1012, 1020-1021, 1027, 1032-1033, 1036, 1043, 1078, 1114, 1134, 1139-1140, 1165, 1170, 1172, 1176, 1179-1180, 1182, 1194-1195, 1197, 1206-1207, 1210, 1213, 1215, 1224-1228, 1230-1233, 1239, 1242-1251, 1258, 1263, 1278, 1280-1282, 1285, 1295, 1310, 1316, 1344, 1348, 1376, 1401, 1434-1435,

Every name in this table is itself a link to that term's entry in the Index, where the same page list appears with the rest of the volume's vocabulary.

30. Reuse Released under CC BY-NC-ND 4.0 This list may be reproduced, reposted, translated, excerpted, scored against any

model, and argued against, with attribution and without further permission from anybody.

If you run the sixteen against your own system, publish the rows that came back 1. That is the whole point of the list, and it is the fastest way to find out where the list itself is wrong.

This completes the beginning.

Sixteen Questions to Ask Any Model of the Genome

The Berger Novel Creative Principles, each defined in plain English, each with a worked example, and each with a pass condition stated in terms a model's own output can satisfy — written so that a working scientist can take the list and run it against whatever they are building

REFERENCE · THE SIXTEEN CRITERIA · DEFINITIONS, EXAMPLES, PASS CONDITIONS

PP-2026-175-01 · 16 September 2026 · Naperville, Illinois

Dr. John Allen Berger · NovagonDNA · Licensed under CC BY-NC-ND 4.0.

1. What This Paper Says in Seven Lines

— THESE ARE SIXTEEN QUESTIONS YOU CAN PUT TO ANY MODEL OF THE GENOME, INCLUDING YOUR OWN. Each one is defined here in ordinary English, given a worked example, and given a pass condition that can be checked against what the model actually outputs.

— THE POINT IS NOT TO GRADE ANYBODY ELSE'S MODEL. It is to give a builder a checklist they can run on a Tuesday afternoon and find out which of the sixteen their own system has never been asked about.

— NO MODEL IN EXISTENCE PASSES ALL SIXTEEN, AND THAT IS NOT THE INTERESTING FACT. The interesting fact is which ones a given model fails STRUCTURALLY — meaning no amount of additional training data or compute would change the answer.

— A STRUCTURAL FAILURE AND AN ENGINEERING SHORTFALL ARE DIFFERENT THINGS, and section two gives the test that separates them: if more data would fix it, it is a shortfall; if the representation has no slot for the quantity, it is structural.

— EVERY PASS CONDITION IS WRITTEN SO THAT A MODEL CAN SATISFY IT WITHOUT ITS BUILDERS ADOPTING ANY PART OF THIS FRAMEWORK. That is deliberate. A criterion only a believer can score is not a criterion.

— PRINCIPLE SIXTEEN IS NEW, ADMITTED TODAY, and section seventeen carries it, with the ruling printed in full at section nineteen — including that the framework had been formally closed at fifteen on 21 April 2026 and has been reopened once to take it.

— TAKE THE LIST. RUN IT. ARGUE WITH IT. It is CC BY-NC-ND 4.0, it requires no permission from anybody, and the fastest way to make it better is for somebody to score their own system and publish where the list came up short.

HOW TO USE THE SIXTEEN

2. Scoring, and the One Distinction That Matters

Two columns, three values each, and the test that separates a defect from a limitation

Each principle is scored on two separate questions. Collapsing them into one number destroys the information, because a model can fail a criterion for two completely different reasons and only one of them is worth anyone's time.

the column	the question	the permitted values
IS IT REPRESENTED?	does the model have any internal quantity corresponding to what this principle names?	REPRESENTED · PARTIAL · ABSENT
IS THE FAILURE STRUCTURAL?	would more data, more parameters or more compute change the answer?	STRUCTURAL · ENGINEERING · NOT APPLICABLE

THE SEPARATING TEST: if a quantity is not in the model's INPUT, no amount of training changes that. A bigger model trained on more genomes still receives no field for oxygen tension. That is

STRUCTURAL. If the quantity is in the input and the model handles it badly, that is ENGINEERING, and engineering gets fixed.

This distinction is the whole value of the exercise. A team told their model has an engineering shortfall will go and fix it, and they should. A team told their model has a structural absence learns something more useful: that the thing they are missing cannot be trained in, and has to be ADDED TO THE INPUT or measured separately.

What a score is not

the point	the statement
a low score is not an accusation	most of these sixteen have never been asked of any model, so ABSENT is the expected default
a high score is not a certificate	the sixteen are one lens and the framework's author does not claim they are the only one
a structural absence is not a criticism of the builders	a sequence model conditions on sequence; that is what it is
the useful output is the list of ABSENT rows	those are the questions your model has never been asked, which is the only reason to run the list

If you run this on your own system and every row comes back REPRESENTED, either you have built something remarkable or you have scored it too generously. The second is far more common and the fix is to write down, for each row, the NAME OF THE VARIABLE in your model that carries it.

FAMILY ONE · DIMENSION AND DIRECTION

The first family asks what the model is looking at, from where, and in which direction time runs. Throughout this framework the three axes are named: X is DNA and the past; Y is RNA and the present; Z is selection and the future.

---

3. Principle 1 · Trinary Necessity

Principle 1 of the sixteen

Some outcomes need three independent inputs, and a system given only two can never produce them, no matter how good it gets at the two.

WHAT IT ASKS OF A MODEL	Does the model have a THIRD independent input, or is it combining two and calling the result a third thing? Two axes cannot generate the third; they can only span a plane.
AN EXAMPLE	Two people can tell you where a building is on a map. Neither can tell you how tall it is, and no amount of arguing between them produces a height. Height is a third measurement, not a better average of the first two. A model given DNA sequence and more DNA sequence has two copies of one axis, not two axes.
WHAT A PASS LOOKS LIKE	The model names a third input that is neither sequence nor a function of sequence — a measured metabolite concentration, an oxygen tension, a cofactor pool — and shows that its output changes when that input changes and the sequence does not.

4. Principle 2 · The Flatlander Dilemma

Principle 2 of the sixteen

A system confined to a plane can detect the SHADOW of something in a higher dimension, and will mistake the shadow for the object.

WHAT IT ASKS OF A MODEL	When the model predicts something correctly, is it representing the mechanism, or is it fitting the statistical trace that the mechanism leaves behind?
AN EXAMPLE	A flat creature living on a tabletop sees a sphere pass through its world as a circle that grows and shrinks. It can predict the circle perfectly — it can model the circle, publish on the circle, win prizes for the circle — and it has no representation of a sphere anywhere. Correct prediction is not evidence of correct representation.
WHAT A PASS LOOKS LIKE	For any output the model predicts well, it can state the mechanism in terms of an internal variable, and that variable can be intervened on independently of the input. If the only answer is that the pattern was in the training data, the model is fitting shadows.

5. Principle 4 · Z-Axis Selector Blindness

Principle 4 of the sixteen

A model can measure what selection PRODUCED without having any representation of what DID the selecting.

WHAT IT ASKS OF A MODEL	Can the model say what chose, or only what was chosen? Those are different objects and the second is much easier.
AN EXAMPLE	You can look at a field of surviving wheat and measure the surviving plants precisely. Nothing in that measurement tells you whether the winter, the fungus or the farmer did the selecting. A variant-effect score is a measurement of survivors. The selector is not in it.
WHAT A PASS LOOKS LIKE	The model exposes a variable representing the selective pressure itself — not the outcome — and that variable can be set to a different value to produce a different prediction for the same sequence.

6. Principle 9 · Axis Conflation

Principle 9 of the sixteen

Predicting an RNA-level or protein-level quantity from a DNA-level input alone treats two different axes as though they were one.

WHAT IT ASKS OF A MODEL	Is the model's input on the same axis as its output? If not, has it stated what it is assuming about everything that sits between them?
AN EXAMPLE	A DNA sequence is the past. Whether a transcript is present, spliced a particular way, edited, degraded or translated is the present, and it is decided by the ribosome, the spliceosome, the microRNAs, the long non-coding RNAs, the circular RNAs and the riboswitches. A model that takes only DNA and predicts RNA abundance has jumped an axis and assumed the whole operational layer away.
WHAT A PASS LOOKS LIKE	The model either takes an input on the same axis as its output, or it explicitly names the intermediate layer it is marginalizing over and states what it assumes about it.

7. Principle 13 · Temporal Axis Collapse

Principle 13 of the sixteen

Flattening past, present and future into one static snapshot removes the ordering, and the ordering was carrying information.

WHAT IT ASKS OF A MODEL	Does the model represent the ORDER of events, or only their co-occurrence?
AN EXAMPLE	Predicting the weather by reading last year's almanac and never looking out the window. The almanac is real data, correctly recorded, and it has had the time dimension flattened out of it. Every entry is true and the sequence of them has been lost.

WHAT A PASS LOOKS LIKE	The model's representation distinguishes a state at time one from the same state at time two, and its prediction changes when the order of two events is reversed.

FAMILY TWO · THE ALGEBRA

The second family asks what mathematics the model's internal operations obey, and whether that mathematics matches the mathematics of the thing being modeled.

8. Principle 3 · Quaternion Non-Commutativity

Principle 3 of the sixteen

In the algebra this framework uses, the order of two operations changes the answer: i times j does not equal j times i. Biology behaves the same way, and most model architectures do not.

WHAT IT ASKS OF A MODEL	Does the model give the same answer for A-acting-on-B as for B-acting-on-A? If it does, it has assumed the order does not matter.
AN EXAMPLE	DNA informing RNA is transcription. RNA informing DNA is reverse transcription. These are different enzymes, different rates, different biological meanings and different consequences. A system that treats the relationship between two elements as symmetric has erased that difference. The same applies to a variant on the sense strand versus the identical variant on the antisense strand: same letters, different phenotype.
WHAT A PASS LOOKS LIKE	Submit an ordered pair to the model in both orders and record whether the outputs differ. If they are identical, the failure is measured rather than argued — and this is the one principle in the sixteen that can be settled in an afternoon without anybody's cooperation.

9. Principle 7 · Scalar-to-Quaternion Continuity

Principle 7 of the sixteen

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

Information moving from a single number, to a vector, to a matrix, to a full four-component object should be traceable at every step — and if the chain truncates, you can name exactly where.

WHAT IT ASKS OF A MODEL	Can you trace what happens to a quantity as it moves through the model's layers, and identify the step at which dimensionality is discarded?
AN EXAMPLE	Think of describing a rotating object. A single number gives you speed. Three numbers give you an axis. Four give you the complete orientation and the sense of rotation together. A pipeline that starts with four and outputs one has thrown something away, and the useful question is not WHETHER but WHERE.
WHAT A PASS LOOKS LIKE	The model's builders can state the rank of the representation at each stage and identify the step where it is reduced, together with what is lost there.

10. Principle 6 · Vortex Mathematics

Principle 6 of the sixteen

The framework holds that the digit families 3-6-9, 1-5-7 and 2-4-8 recur in the structure of the code, and asks whether a model's architecture respects or violates them.

WHAT IT ASKS OF A MODEL	Do the model's own structural numbers — layer counts, head counts, alphabet sizes, output tracks — fall into these families, and was that a choice or an accident?
AN EXAMPLE	The codon is three letters. The code has sixty-four combinations. Three sixty-degree rotations close a hexagon at three hundred and sixty. Whether those are deep or coincidental is exactly what the principle asks to be tested rather than assumed in either direction.
WHAT A PASS LOOKS LIKE	The builders can state the model's structural numbers and say whether the choice was forced by the biology, forced by the hardware, or arbitrary. An honest ARBITRARY is a pass; an unexamined number is not.
A NOTE	This is the principle most likely to be dismissed on sight by a computational reader. It is also the one most easily made rigorous, by simply reporting the numbers and their justification.

11. Principle 8 · Abha Torus Topology

Principle 8 of the sixteen

The genetic code has a closed, wrap-around structure: it is a surface where the edges join, not a flat sheet with borders.

WHAT IT ASKS OF A MODEL	Does the model's output space wrap, or does it have artificial edges where the biology has none?
AN EXAMPLE	A world map on paper has a left edge and a right edge, and a traveler crossing one vanishes and reappears at the other. On a globe there are no edges at all. If a model's representation has a first position and a last position where the biology is cyclical, it has introduced a boundary that does not exist and will produce artifacts there.
WHAT A PASS LOOKS LIKE	The model's representation is periodic where the biology is periodic, or the builders state explicitly which boundaries are artifacts of the representation and show they do not affect the results.

FAMILY THREE · THE ALPHABET AND THE LATTICE

The third family asks what the model's notation can and cannot write down. These are the principles closest to this volume's central argument, and the ones with the most immediate practical consequences.

12. Principle 12 · Inosine, the Silent Sixth

Principle 12 of the sixteen

Inosine is made constantly in living cells, is read by the ribosome as a different letter from the one in the gene, and has no character in the sequence alphabet — so the record writes G and everyone downstream inherits a molecule that was never in the cell.

WHAT IT ASKS OF A MODEL	Does the model represent inosine at all, and if not, does it predict anything that inosine changes?
AN EXAMPLE	More than 4,500,000 adenosine-to-inosine editing sites are catalogued in humans across fifty-five body sites, downloadable today. In ALS motor neurons, editing at one position in GRIA2 runs from zero to one hundred percent WITHIN A SINGLE PATIENT while the gene sequence is identical in every cell. FASTA and GenBank permit A, C, G, T, U and the ambiguity codes. Inosine is not among them.
WHAT A PASS	The model accepts an editing-level input, or reports which of its outputs

LOOKS LIKE	are sensitive to editing and by how much, or states plainly that it treats edited and unedited transcripts as identical.
A NOTE	This is the principle the framework's author has spent twenty-nine years on, and it is the one with the clearest immediate application: any model predicting splicing or RNA abundance is predicting two things that editing alters.

13. Principle 5 · The Silent Seventh Exclusion

Principle 5 of the sixteen

A second species is excluded from the alphabet for the same reason as the first — the notation has no character for it — and its exclusion is less discussed because it is less abundant, not because it matters less.

WHAT IT ASKS OF A MODEL	Does the model's alphabet admit only the canonical set, and has anyone checked what falls outside it?
AN EXAMPLE	The canonical alphabet has four letters for DNA and five counting uracil. This framework works with eight species of actual metabolism. Xanthine is a real deamination product with real enzymology and it has no letter. A notation that admits only the canonical set does not report the omission — it simply has nowhere to put it.
WHAT A PASS LOOKS LIKE	The builders can state the complete list of chemical species their representation admits, and the list of species known to occur that it does not.
A NOTE	The identity of the seventh is the framework author's to fix. This section defines the STRUCTURE of the exclusion, which is what a reader needs in order to test their own alphabet.

14. Principle 10 · The 64-Tetrahedron Lattice

Principle 10 of the sixteen

The sixty-four codons are not a flat list; they have a geometric arrangement, and that arrangement carries information about which substitutions are conservative and which are not.

WHAT IT ASKS OF A MODEL	Does the model treat codons as arbitrary tokens, or does it represent the structure of the codon space?
AN EXAMPLE	In a lookup table, CTG and CTA are two unrelated rows. In the geometry, they are adjacent — both leucine, one position apart, a change with no consequence for the protein. A model that tokenizes codons as arbitrary

	symbols has to learn every adjacency from data, whereas a model that represents the geometry gets it for free and generalizes to codons it has not seen.
WHAT A PASS LOOKS LIKE	The model's codon representation places synonymous and conservative substitutions closer together than non-conservative ones, and this can be demonstrated by measuring distances in its own embedding space.

15. Principle 14 · The Official Sixes

Principle 14 of the sixteen

Six recurs across the framework — six elements of life, six colors in the notation, six faces, sixty degrees — and the principle asks whether a model's own sixes are structural or coincidental.

WHAT IT ASKS OF A MODEL	Where does the number six appear in the model's architecture or in the biology it represents, and has anybody asked why?
AN EXAMPLE	CHNOPS is six elements. A hexagon closes at six sixty-degree turns. The notation this volume uses assigns six colors. The principle does not assert that every six is meaningful; it asserts that an unexamined six is a missed opportunity to find out.
WHAT A PASS LOOKS LIKE	The builders can point to each occurrence of the number in their system and say whether it is forced, inherited or arbitrary.
A NOTE	Like Principle 6, this is a reporting requirement rather than a metaphysical claim, and it is strongest when read that way.

FAMILY FOUR · THE CHEMISTRY THE SEQUENCE OMITS

The fourth family asks about physical quantities that are real, measurable, consequential, and absent from every sequence record in existence. This is where Principle Sixteen joins the list.

---

16. Principle 11 · Phosphorothioate-k Chirality

Principle 11 of the sixteen

Replacing one backbone oxygen with sulfur creates two mirror-image forms, Rp and Sp, which are chemically distinct, behave differently in cells, and are written identically in every sequence file.

WHAT IT ASKS OF A MODEL	Does the model represent backbone stereochemistry, and does it predict anything that stereochemistry changes?
AN EXAMPLE	Phosphorothioate linkages are standard in antisense oligonucleotide drugs. The Rp and Sp diastereomers differ in nuclease resistance, in binding, and in activity. Two drugs with the same printed sequence can behave differently in a patient. The file that describes them is the same file.
WHAT A PASS LOOKS LIKE	The model accepts a stereochemistry flag, or states that it treats both diastereomers as identical — which is a perfectly acceptable answer, provided it is written down where a user will see it.

17. Principle 16 · Cofactor Substrate Blindness

Principle 16 of the sixteen

A model that predicts a chemical modification without representing the metabolite pool that donates the modifying group is predicting an ADDRESS without an INVENTORY.

WHAT IT ASKS OF A MODEL	For every modification the model predicts, can it name the donor molecule, and does it have any input carrying how much of that donor is present?
AN EXAMPLE	The methyl donor for DNA and histone methylation is S-adenosyl methionine, a sulfonium. The acetyl donor for histone acetylation is acetyl-CoA, a thioester. The polymerases and glycosylases that read and repair DNA are held together by iron-sulfur clusters coordinated by cysteine. A model can predict exactly WHERE a methyl group goes and have no representation of whether there is a methyl group available to go anywhere. The same million base pairs in a cell with a full methionine pool and a depleted one are the same million base pairs.
WHAT A PASS LOOKS LIKE	The model accepts a cofactor-availability input, or reports the sensitivity of each predicted modification to donor abundance, or states that it assumes donor pools are saturating and non-limiting — which is a testable assumption and frequently false.
A NOTE	ADMITTED 16 SEPTEMBER 2026 by ruling of the framework's author. See section nineteen.

FAMILY FIVE · SELECTION

18. Principle 15 · Freedom of Choice and the Sixty-Fourth

Principle 15 of the sixteen

A system that can only compute the consequences of a state cannot represent the act of CHOOSING a state, and the framework reserves a sixty-fourth position for what does the choosing.

WHAT IT ASKS OF A MODEL	Can the model represent a decision, or only the downstream statistics of decisions already made?
AN EXAMPLE	A chess engine evaluating a position tells you what follows from it. That is not the same object as the move being made. Biology selects continuously — which transcript, which splice form, which cell survives — and a model trained on the survivors has the results of a great many choices and no representation of choosing.
WHAT A PASS LOOKS LIKE	The model exposes a decision variable that can be set independently of the input state, and produces different outputs for the same state under different settings.
A NOTE	This is the most philosophically loaded of the sixteen and the hardest to operationalize. The pass condition above is deliberately mechanical so that it can be scored without anyone agreeing about free will.

THE APPARATUS

19. The Ruling Admitting Principle Sixteen

Printed in full, because the framework had been closed

The Berger Novel Creative Principles were formally closed at fifteen on 21 April 2026. On 16 September 2026 the framework's author ruled that a sixteenth be admitted. The record of that is printed here rather than absorbed silently, because a framework that can be quietly extended is not a framework.

the element	the record	the date or source
the closure	the framework was closed at fifteen	21 April 2026
the candidate	COFACTOR SUBSTRATE BLINDNESS, arising from the sulfur audit of a sequence-only genome model	submitted for ruling, not asserted, in PP-2026-167-01
who proposed it	the candidate was drafted in the course of that paper's analysis and submitted to the framework's author for a decision	it was not adopted unilaterally
the ruling	ADMITTED as Principle Sixteen	16 September 2026
what the ruling does to the closure	the framework is reopened once, for this, and the closure otherwise stands	a second admission would require a second ruling
why it qualifies	the existing fifteen address dimension, algebra, alphabet and selection. None of them asks whether a model represents the SUPPLY of the chemical group whose placement it predicts	that is a distinct question and it is testable

A principle admitted by dated ruling, with the closure it breaks printed alongside it, is a different object from a principle that simply appeared in the list. Anyone can check when it arrived and on whose authority.

20. The Scorecard

The sixteen in one table, for anyone who wants to run them

#	the principle	the question in one line
1	Trinary Necessity	is there a genuine third input?
2	The Flatlander Dilemma	is it the mechanism or the shadow?
3	Quaternion Non-Commutativity	does A-to-B equal B-to-A?
4	Z-Axis Selector Blindness	what selects, or only what was selected?
5	The Silent Seventh Exclusion	what does the alphabet leave out?
6	Vortex Mathematics	are the structural numbers examined or accidental?
7	Scalar-to-Quaternion Continuity	where is rank discarded?
8	Abha Torus Topology	does it wrap where the biology wraps?
9	Axis Conflation	is the input on the same axis as the output?
10	The 64-Tetrahedron Lattice	are codons tokens or geometry?
11	Phosphorothioate-k Chirality	is backbone stereochemistry represented?
12	Inosine, the Silent Sixth	is editing represented, and what does it change?
13	Temporal Axis Collapse	is the order of events preserved?

#	the principle	the question in one line
14	The Official Sixes	are the sixes forced, inherited or arbitrary?
15	Freedom of Choice and the Sixty-Fourth	can it represent a decision?
16	Cofactor Substrate Blindness	is the donor pool represented?

Sixteen questions. Most models have never been asked fourteen of them. The ones that come back ABSENT are the return on running the list, and Principle 3 is the one that can be MEASURED this weekend rather than argued.

21. What This Paper Claims

Five claims, numbered and counted, each with the condition that would refute it

number	the claim	what would refute it
1	Each of the sixteen can be stated in plain English with a pass condition checkable against a model's own output	name a principle whose pass condition as written here requires adopting this framework in order to score
2	A structural absence and an engineering shortfall are distinguishable by the test at section two	exhibit a case where more training data supplied a quantity that was absent from the input
3	No currently published genome model represents all sixteen	name a model that does, with the variable that carries each
4	Principle 3 is the only one of the sixteen measurable today without the model builders' cooperation	name another whose pass condition can be evaluated from public outputs alone
5	Principle 16 was admitted by dated ruling on 16 September 2026, reopening a framework closed on 21 April 2026	show a different admission date or that the framework was not closed

Five claims and five refutation conditions. Claim three is an invitation: the fastest way to improve this list is for somebody to score a real system and publish where the list failed them.

22. What This Paper Does Not Claim

The boundaries, which belong at the back

It does not claim the sixteen are complete. Sixteen is where the framework stands today, and section nineteen shows exactly how a seventeenth would have to arrive.

It does not claim a model failing these is a bad model. A sequence model conditions on sequence and does that extremely well. The list asks what it CANNOT do, which is a different question from how well it does what it does.

It does not claim every principle is equally rigorous. Principles 6 and 14 are reporting requirements rather than tests, and are marked as such in their own notes; Principle 15 is the hardest to operationalize and says so.

It does not claim the framework's author invented the underlying chemistry. Every chemical fact in the examples belongs to the group that published it, and the contribution here is the notation and the list, not the findings.

And it does not claim that a model needs this framework to be useful. It claims the opposite: the pass conditions were written so that a builder who thinks the framework is nonsense can still run the checklist and learn something from the ABSENT rows.

What the paper claims is the narrow thing the sections support: here are sixteen questions, here is what each means in plain words, here is an example, and here is how you would know if your own system answered it.

23. A Note on the Definitions

Which of these are the author's words and which are this document's reconstruction

The names and the numbering of the fifteen are the framework author's. The plain-English definitions, the worked examples and the pass conditions in this document were drafted for it, and on several principles the drafting required interpretation.

the element	its provenance	the note
the names and numbering of 1 through 15	the author's, as published	no interpretation
Principle 16 in full	admitted by the author's ruling of 16 September 2026	see section nineteen
the pass conditions throughout	drafted for this document	chosen to be model-agnostic and observable; the author has not ruled on each individually
Principle 5, the identity of the seventh species	THE STRUCTURE IS DEFINED HERE; THE IDENTITY IS THE AUTHOR'S TO FIX	flagged for ruling
Principles 6 and 14, the	stated as reporting requirements	this reading is the

the element	its provenance	the note
numeric families	rather than metaphysical claims	document's and is the strongest defensible form
Principle 15, the sixty-fourth position	operationalized mechanically so it can be scored without agreement on free will	this framing is the document's

Four items on that list are marked as this document's reading rather than the author's ruling, and they are marked so that a reader knows which sentences to argue with and whom to argue with about them.

THE COLOR INDEX

Every shaded word in this volume is a link. A word with its own entry in the Index jumps to that entry; a letter, atom label or formula returns here.

24. Reuse Released under CC BY-NC-ND 4.0 This list may be reproduced, reposted, translated, excerpted, scored against any model,

and argued against, with attribution and without further permission from anybody.

If you run the sixteen against your own system, publish the ABSENT rows. That is the whole point of the list, and it is the fastest way to find out where the list itself is wrong.

This completes the beginning.

POSITION PAPER · NOVAGONDNA · FOR COMMENT

TIGR-Tas and CRISPR-Cas9: The Atoms Always Decide Molecular Outcomes

CAS9 NEEDS A LANDMARK IN THE DNA. TIGR BRINGS ITS OWN RULER. Two arginines reading two guanines decide where CRISPR cuts. One glutamate decides whether ADAR can act at all. And one oxygen at the 2 prime position decides which face of a double helix can be read by anything. The main characters here are named atoms and named residues, each with a deposited structure behind it — and what any notation can or cannot hold is a consequence of what they do, not the other way round

POSITION PAPER · TIGR-TAS AND CRISPR-CAS9 · ADAR · A-FORM AND B-FORM · THE ATOMIC CASE

1. What This Paper Says in Nine Lines

A note on what this paper is about. The main characters are ATOMS AND MOLECULES — one oxygen, two arginines, one glutamate, one sulfonium — each of them named, each with a deposited structure behind it, and each of them deciding an outcome by itself. Notation appears only at the end, and only as a CONSEQUENCE: whatever a four-letter file — DNA A T G C, RNA A U G C — can or cannot hold follows from what these atoms do, and never the other way round.

Part Five builds on a registered position paper of this author's own — TIGR-Tas: The Natural Triplex, PP-2026-TIGR-TAS-01, June 2026, DOI 10.64898/2026.04.22.720138, ACCESS-CHM250115. That paper mapped TIGR-Tas onto three-axis geometry before any structure of the complex existed. It stands as published. This paper ADDS to it and does not replace it.

— THE 2 PRIME OXYGEN DOES NOT MERELY DISTINGUISH RNA FROM DNA. It forces the ribose into C3 prime endo pucker, which inclines and displaces the base pairs, which INVERTS WHICH GROOVE A PROTEIN CAN ENTER. In B-form DNA the readable face is the major groove. In A-form RNA it is the minor groove. ONE ATOM DECIDES WHICH FACE OF THE MOLECULE THE REST OF BIOLOGY IS ALLOWED TO TOUCH.

— AND THE TWO GROOVES DO NOT CARRY THE SAME INFORMATION. Seeman, Rosenberg and Rich established in 1976 that the major groove presents a hydrogen-bonding pattern that distinguishes all four base pairs UNIQUELY, while the minor groove does not — it cannot tell adenine-thymine from thymine-adenine.

— SO THE CONSEQUENCE IS NOT GEOMETRIC, IT IS INFORMATIONAL. DNA duplex recognition is BASE recognition. RNA duplex recognition is largely BACKBONE recognition, because the face a protein can reach on an A-form helix is the one where the letters are nearly invisible and the 2 prime hydroxyls are the dominant chemistry.

— ADAR2 IS THE PROOF AND IT IS PRINTED IN THE PAPER. Matthews and colleagues solved the deaminase domain on duplex RNA in 2016 and report that the catalytic glutamate approaches the flipped-out adenosine FROM THE MINOR GROOVE OF THE A-FORM HELIX — and that overlaying that residue on idealized B-form DNA shows the greater depth of the B-form minor groove PREVENTS the same intercalation.

— WHICH EXPLAINS A FACT THE FIELD TREATS AS AN INCONVENIENCE. Adenosine-to-inosine editing has nearest-neighbor PREFERENCES rather than a recognition sequence. It could not have a recognition sequence. The enzyme is reading a surface on which sequence is nearly unreadable, so editing is NOT PREDICTABLE FROM PRIMARY SEQUENCE and never will be.

— TIGR-TAS, PUBLISHED IN SCIENCE IN FEBRUARY 2025, MAKES THE SAME POINT FROM THE OTHER DIRECTION. It targets DNA with TWO spacers that must both pair, it requires NO PAM, it bends the duplex 180 degrees, and its Nop domain is the fold of the box C/D machines that methylate the 2 prime

oxygen. A 2026 structure shows a SINGLE MISMATCH converts the nuclease into a nickase.

— SO TIGR-TAS AND CRISPR-CAS9 DIFFER FUNDAMENTALLY BY THIS: CAS9 NEEDS A LANDMARK IN THE DNA, AND TIGR BRINGS ITS OWN RULER. Cas9 reads THREE BASE PAIRS — the NGG of the PAM, on the NON-TARGET strand, in the MAJOR GROOVE of INTACT B-FORM DUPLEX, by arginine 1333 and arginine 1335 making bidentate hydrogen bonds to the second and third guanine — and only if that read succeeds does it unwind, pair, and cut BOTH strands about three base pairs away from the letters it just read.

— TIGR READS NOTHING. There is no PAM and no landmark. Two spacers pair, one with each strand, and the cut falls 3 prime to the nucleotide complementary to THE FIFTH BASE OF EACH SPACER, leaving 8-nucleotide 3 prime overhangs. Cas9 measures the cut from a feature OF THE GENOME. TIGR measures it from a position IN ITS OWN GUIDE. CAS9 RECOGNIZES A MOTIF; TIGR RECOGNIZES A RELATION — and a sequence file can store a motif and has no field at all for a relation.

— AND ONLY THEN, THE CONSEQUENCE FOR NOTATION. The four letters are A T G C in a DNA file and A U G C in an RNA file, and that swap is itself the point: the notation spends A WHOLE CHARACTER on one methyl group at carbon 5 — thymine is 5-methyluracil — and has NO CHARACTER AT ALL for the 2 prime oxygen that decides which groove can be read. Section seventeen sets the two side by side.

— SO A FOUR-LETTER SEQUENCE FILE IS A MODEL OF THE B-FORM MAJOR GROOVE — the one surface on which four letters — DNA A T G C, RNA A U G C — are the information. Every A-form recognition event in biology is a readout of a surface where the letters are not the information. The alphabet is not merely missing inosine. IT IS A PROJECTION OF ONE GROOVE OF ONE HELIX FORM, and it has been used as the description of the molecule.

PART ONE · THE GEOMETRY

This part establishes the physical claim before anything is built on it. Nothing here is novel; all of it is standard structural chemistry. What is not standard is the use it is put to in Part Five.

2. One Oxygen Decides Which Face of the Helix Can Be Read

The causal chain, stated as a chain, so that any link can be attacked separately

The difference between ribose and deoxyribose is one oxygen atom at the 2 prime position of the sugar. That is the entire chemical difference at the level of the monomer. At the level of the double helix it is not a small difference at all, and the reason is a chain of four consequences, each of which is independently established.

step	the event	the physical basis
1	THE 2 PRIME OXYGEN IS PRESENT	in ribose; absent by definition in deoxyribose
2	THE SUGAR PUCKER CHANGES	steric and electronic effects of the 2 prime substituent drive the ring to C3 prime endo; B-form DNA sits at C2 prime endo
3	THE HELIX GEOMETRY CHANGES	C3 prime endo shortens the intrastrand phosphate-to-phosphate distance, raising the base pairs off the helix axis and inclining them by approximately nineteen degrees
4	THE GROOVES INVERT	the displaced, inclined base pairs deepen and narrow the major groove and widen and flatten the minor groove — the reverse of the B-form arrangement

Remove the 2 prime oxygen and the helix relaxes toward B-form. Put it back and it returns to A-form. This is not a correlation across two different molecules. It is a switch, and the switch is one atom.

The dimensions, with the measurement convention stated

Groove widths in the literature are usually reported as the phosphate-to-phosphate distance across the groove MINUS the van der Waals radii, which is why published numbers differ by several angstroms between sources. The figures below are taken on that convention and should be compared with each other, not with numbers drawn from a different one.

the helix	the sugar pucker	the major groove	the minor groove	the enterable face
B-FORM · DNA duplex	C2 prime endo	WIDE and enterable · approximately 12 angstroms	narrow and deep · approximately 6 angstroms	the MAJOR groove
A-FORM · RNA	C3 prime	narrow and very	WIDE and shallow ·	the MINOR groove

the helix	the sugar pucker	the major groove	the minor groove	the enterable face
duplex	endo	deep · approximately 4.7 angstroms	approximately 10.8 angstroms	

Both helices have both grooves. Nothing is missing from either. What inverts is WHICH ONE IS ACCESSIBLE, and that is a statement about what a protein can physically do, not about what is chemically present.

The secondary figures follow the same pattern. A-form rises approximately 2.6 angstroms per base pair against roughly 3.4 for B-form, and packs about eleven base pairs per turn against about ten and a half. An A-form helix is shorter, fatter and more tightly wound than a B-form helix of the same length, and its base pairs sit off-axis rather than stacked through the center.

And hybrids follow the oxygen, not the DNA

An RNA-DNA hybrid duplex adopts A-like geometry, because the ribose strand imposes its pucker on the pairing. This matters in Part Four: every R-loop, every reverse-transcription intermediate, and every CRISPR or TIGR targeting complex contains an A-like hybrid at the point of recognition, whatever the sequence of the DNA that entered it.

---

3. The Two Grooves Do Not Carry the Same Information

Seeman, Rosenberg and Rich, 1976, and why it is the most under-cited result in the field

Geometry alone would be an inconvenience. The reason the inversion matters is that the two grooves are not informationally equivalent, and this was worked out before a single protein-DNA complex had been solved.

Seeman, Rosenberg and Rich asked what a protein side chain could learn by reaching into each groove and reading the pattern of hydrogen-bond donors, acceptors and methyl groups presented by the base pair edges. Their answer, published in the Proceedings of the National Academy of Sciences in 1976, is the foundation of every sequence-specific DNA-binding domain since.

the groove	the base-edge presentation	the readable content
THE MAJOR GROOVE	adenine-thymine, thymine-adenine, guanine-cytosine and cytosine-guanine each present a DIFFERENT pattern	ALL FOUR base pairs are distinguishable, INCLUDING orientation — which of the two strands carries which base
THE MINOR GROOVE	adenine-thymine and thymine-adenine present nearly the same face; guanine-cytosine and cytosine-guanine likewise	only the PURINE 2-AMINO GROUP gives a strong signal — in effect the minor groove reports whether a guanine is present, not which base pair it is

So the major groove is where sequence lives, as far as a protein is concerned. The minor groove is where SHAPE lives. Those are two different kinds of information and a helix makes one of them available at a time.

Which is why the arginine-guanine pair dominates the structural database

The prediction has been tested exhaustively by accident. Of the amino acid to base pair contacts catalogued across the protein-nucleic acid structures determined since 1986, the arginine to guanine interaction in the major groove is the single most common, exactly as the 1976 paper argued it should be. This is a rare case of a purely theoretical prediction surviving three decades of structure determination without amendment.

And in 2014 it turned up as the mechanism of the most-used gene-editing tool on earth

Anders and Jinek solved the Cas9 complex bound to guide and target DNA and found that the protospacer-adjacent motif — the three base pairs Cas9 must read before it will unwind anything — is recognized in the major groove of the still-intact duplex by TWO ARGININES REACHING FOR TWO GUANINES.

the contact	the action	the location
arginine 1333	bidentate hydrogen bonds to the SECOND guanine of the NGG	major groove, non-target strand
arginine 1335	bidentate hydrogen bonds to the THIRD guanine of the NGG	anchored by a salt bridge to glutamate 1219
the surface	the major groove of INTACT B-FORM DUPLEX DNA	read before unwinding, as section two requires
the prediction	Seeman, Rosenberg and Rich, 1976: arginine binds guanine in the major groove	thirty-eight years earlier, from paper and a model kit

A purely theoretical argument from 1976 about which groove could carry sequence information turns out to describe, atom for atom, the step that decides where CRISPR cuts. That is how much weight the major groove is carrying — and the whole of Part Two is about what happens when it is not available.

---

4. Therefore: DNA Recognition Reads Bases, RNA Recognition Reads Backbone

The join between section two and section three, which is the load-bearing step of this paper

Put the two results together. In B-form DNA, the accessible groove is the one that distinguishes all four base pairs. In A-form RNA, the accessible groove is the one that distinguishes almost nothing about the bases — but that presents, in exchange, a regular array of 2 prime hydroxyl groups, one per residue, along both strands.

the molecule	the read face	the presentation	the recognized quantity
B-FORM DNA	the major groove	the four base pairs, uniquely and with orientation	SEQUENCE — the letters are the signal
A-FORM RNA	the minor groove	duplex width, helical shape, bulges, mismatches, and the 2 prime hydroxyl array	STRUCTURE — the fold is the signal and the letters are a weak modifier

A protein binding B-form DNA can ask WHICH LETTER IS HERE. A protein binding A-form RNA is mostly asking IS THERE A DUPLEX HERE, HOW LONG, AND WHERE ARE THE IMPERFECTIONS. These are not the same question and no amount of sequence data converts one into the other.

This is the sense in which the two molecules are inverted, and it is a sharper statement than saying they are opposites. They are not opposites. They are the same chemistry presented through two different apertures, and the aperture selects what can be known.

PART TWO · THE ENZYME THAT PROVES IT

A geometric argument is worth little until an enzyme is found whose behavior the geometry predicts and whose structure has been solved. ADAR2 is that enzyme, and the relevant sentence is in the published paper.

5. ADAR2 Comes In From the Minor Groove, and Cannot Do So in DNA

Matthews and colleagues, Nature Structural and Molecular Biology, 2016

ADAR converts adenosine to inosine by hydrolytic deamination — the amino nitrogen at carbon 6 is replaced by an oxygen. It acts only on double-stranded RNA. The question this paper puts is not WHY it prefers RNA but whether it COULD act on DNA, and the structural answer is that it could not, for a reason that has nothing to do with the base.

Four crystal structures of the human ADAR2 deaminase domain bound to RNA duplexes carrying a mimic of the deamination intermediate were reported in 2016. They establish the base-flipping mechanism: the target adenosine rotates out of the helix into the enzyme active site, and the gap it leaves in the duplex is filled by the side chain of glutamate 488, which intercalates into the stack.

the element	the structural finding	the establishment
THE APPROACH	glutamate 488 reaches the flipped nucleotide FROM THE MINOR GROOVE of the A-form helix	this is the accessible face of an A-form duplex, as section two requires
THE CONTROL	the authors overlay residue 488 on IDEALIZED B-FORM DNA	a direct geometric test of whether the same chemistry could run on DNA
THE RESULT	the GREATER DEPTH of the minor groove in a B-form helix PREVENTS the side chain from intercalating into the space the adenosine occupied	the reaction is blocked by helix geometry, not by the base and not by the enzyme's chemistry
THE DEPOSITION	the E488Q variant bound to a duplex derived from the human GLI1 transcript is in the Protein Data Bank as 5ED2	the claim is checkable atom by atom by anyone, today, at no cost

This is as clean a result as this framework has anywhere. The adenine in DNA and the adenosine in RNA are the same base. The enzyme is the same enzyme. What differs is the depth of a groove, and the depth of that groove is set by ONE OXYGEN two bonds away from the base that is being modified.

A model that represents the base and not the sugar pucker has no variable that changes between the case where this reaction runs and the case where it cannot. That is the definition of a structural absence under the sixteen criteria, and section fifteen scores it.

---

6. Both of ADAR's Business Ends Read the Same Face

The deaminase domain and the double-stranded RNA binding motifs agree

If the deaminase domain alone read the minor groove, it could be dismissed as a peculiarity of one active site. It is not alone. The substrate-binding modules do the same thing, and they were shown to do it six years earlier.

Stefl and colleagues solved the solution structure of the ADAR2 double-stranded RNA binding motifs bound to a stem-loop from the GluR-2 pre-messenger RNA carrying the R-to-G editing site, and published it in Cell in 2010 under a title that states the finding outright: a sequence-specific readout OF THE MINOR GROOVE.

the module	the action	the record
the deaminase domain	intercalates glutamate 488 from the minor groove after flipping the target base out	Matthews and colleagues, 2016 · PDB 5ED2
the dsRNA binding motifs	read shape and, surprisingly, some sequence, through the minor groove of the duplex	Stefl and colleagues, 2010 · PDB 2L3J
the agreement	two independent domains of one enzyme, two independent methods, one face	crystallography and solution NMR reaching the same conclusion

The whole enzyme is built to work on the face that the 2 prime oxygen created. That is not an accident of one crystal. That is what the molecule is for.

7. Which Is Why A-to-I Editing Is Not Predictable From Sequence

A limitation the field reports as a nuisance, explained here as a necessity

Every group that has tried to predict editing sites from primary sequence has run into the same wall. ADAR has nearest-neighbor PREFERENCES — a 5 prime uridine is favored, then adenosine, then cytidine, with guanosine least favored — but it has no recognition sequence in the sense that a restriction enzyme or a transcription factor has one.

This is usually reported as a difficulty. Section three says it is a requirement. An enzyme reading the minor groove of an A-form duplex is reading a face on which the identity of the base pairs is very nearly unreadable. It could not have acquired a recognition sequence, because the information it would need is presented on the face it cannot reach.

the item	the finding	the reading
WHAT DETERMINES EDITING	duplex length, the position of the target within the duplex, mismatches, bulges, loops, and the local helical distortion they create	all of it STRUCTURE, none of it letters
WHAT MODULATES IT	the identity of the immediately 5 prime and 3 prime neighbors	a weak preference, reported as a rank order, not a motif
WHAT DOES NOT DETERMINE IT	the primary sequence of either strand read as a string	which is the only thing a sequence model receives
THE PREDICTION THIS MAKES	a model given only sequence will plateau on editing prediction at an accuracy set by how well sequence PROXIES for fold	and it will fail hardest on transcripts whose fold depends on distant partners

This is a falsifiable statement about the ceiling of a class of models, and it does not require anyone to accept any other part of this framework. If a pure-sequence model ever predicts editing at a site whose duplex partner is megabases away, without any structural input, this section is wrong.

8. The Inverted Alu Is One Object and the File Writes Two

Where the geometry meets the notation, and the notation loses

The dominant substrate for adenosine-to-inosine editing in the human transcriptome is not a motif. It is a STRUCTURE: an Alu element and an inverted copy of an Alu downstream in the same transcript, which fold back on one another and form a long imperfect duplex, most often in a 3 prime untranslated region. The catalogued human editing sites now number in the millions and they are overwhelmingly in these elements.

Consider what the recognition unit actually is. It is not Alu A. It is not Alu B. It is the PAIR, in the correct relative orientation, at a distance that permits the fold. Either element alone is inert. The functional object is the relation between them.

the level	the resident object	the count
the cell's substrate	an intramolecular A-form duplex formed by two inverted elements	one object
the genome file's contents	two separate repeat annotations at two separate coordinates	two objects, with nothing marking the relation
the signal in the orientation	inverted is functional; direct is not	a sign, recorded nowhere in the sequence string itself
the transcript's decision	which pair actually folds, in this cell, in this condition, at this moment	a fact with no representation at the DNA level at all
the base caller's record	every inosine as guanine	the product of the reaction is recorded as a molecule that was never present

Four representational losses in one pathway, and only the last of them is the inosine problem. The first three are losses of RELATION — the pair, the orientation, and the fold — and a string of letters has no type for a relation.

This is the point at which TIGR-Tas becomes relevant, because TIGR is a system in which the recognition unit is likewise a pair, and its structure has been solved.

PART THREE · TIGR-TAS, FIRST READING · THE ANCESTRAL PAIR

The first reading treats TIGR-Tas as evidence. If pair recognition and 2 prime oxygen chemistry are as fundamental as Parts One and Two argue, they should be visible in the oldest RNA-guided machinery available. They are.

9. What TIGR-Tas Is, Stated Plainly and Without Interpretation

The 2025 Science paper and the two 2026 structural follow-ups, before any argument is made from them

TIGR-Tas was reported by Faure, Saito, Wilkinson and colleagues from the Broad Institute in Science on 27 February 2025. This section states what the papers report. The argument begins at section ten.

the component	the identity	the salient detail
THE ARRAY	a tandem interspaced guide RNA array, transcribed and processed into 36-nucleotide guides called tigRNAs	processing occurs at precise sites within the edge repeats and requires Tas protein, though Tas does not itself catalyze the cut
THE PROTEIN	a TIGR-associated protein carrying a nucleolar protein (Nop) domain, optionally fused to a nuclease domain	TasR carries RuvC; TasH carries HNH; both are markedly smaller than Cas9
THE TARGETING	TWO spacers per guide — spacer A pairs one DNA strand, spacer B pairs the complementary strand	both must pair for efficient cleavage
THE PAM	NONE REQUIRED	this is the single most consequential difference from every CRISPR system
THE CUT	double-strand break with 8-nucleotide 3 prime overhangs, cleaving 3 prime to the nucleotide complementary to the fifth base of each spacer	reported as the C-5 rule
THE COMPLEX	cryo-electron microscopy shows a C2-symmetric dimer binding target DNA and tigRNA	with DRAMATIC 180 DEGREE BENDING of the DNA on complex formation
THE DISTRIBUTION	bacteriophages, archaeal viruses, parasitic bacteria of the Candidate Phyla Radiation, and assorted prokaryotic genomes	two architectures: dual-repeat arrays and stem-loop arrays
THE RELATIVES	box C/D small nucleolar ribonucleoproteins, and IS110 RNA-guided transposases	shared Nop domain architecture and shared RNA-binding strategy respectively

Two structural papers followed in 2026. Zhang and colleagues determined six cryo-electron microscopy structures of the Salicola phage TIGR-TasH complex and reported that the central coiled-coil mediates dimerization, that the C-terminal Nop domain autonomously processes the precursor tigRNA, and that the N-terminal HNH nuclease is recruited on target binding through a beta-hairpin. A second group reported the structural basis by which a SINGLE MISMATCH converts the TasH nuclease into a nickase.

Everything above is other people's work, reported without modification. The next four sections are this author's reading of it, and are marked as such.

---

10. The Recognition Unit Is the Relation Between Two Spacers

The structural parallel with the inverted Alu, stated precisely enough to be attacked

A CRISPR guide is a single spacer that finds a single strand; the other strand is displaced. A tigRNA is two spacers, and neither of them is a targeting element on its own. Spacer A engages one strand, spacer B engages the complement, and the paper reports that BOTH must be correctly paired for efficient cleavage.

Set that beside section eight. In both systems the functional object is a PAIR of complementary engagements that must both hold, and in both systems the components are recorded separately with nothing marking the relation between them.

the system	element one	element two	the requirement	the recognized object
ADAR at an inverted Alu	Alu element A	the inverted Alu element B downstream	both must be present, inverted, and within folding distance	the intramolecular A-form duplex
TIGR-Tas at a target	spacer A, pairing one strand	spacer B, pairing the complement	both must pair for efficient cleavage	the bent, dual-hybrid recognition complex
the sequence file's record	one annotation	another annotation	NOTHING	no field exists for the object

This is not offered as homology. TIGR cuts DNA and ADAR modifies RNA; they are not relatives and nothing here claims they are. What is claimed is that both are systems whose ACTIVE UNIT IS A RELATION, and that a representation built out of tokens has no type that can hold a relation.

Why this is a stronger observation than it first appears

Pair recognition is not rare once one looks for it. Restriction enzymes read palindromes. Transcription factors dimerize on inverted or direct repeats. Riboswitches fold two distant segments together. IS110 bridge RNAs carry one loop for the donor and one for the target. In every case the object the biology acts on is a pair, and in every case the file records the members and not the pairing.

---

11. A Single Mismatch Turns the Nuclease Into a Nickase

The 2026 result that makes the point better than any argument could

TasH cuts both strands. A 2026 structural study establishes that a SINGLE MISMATCH is sufficient to convert that double-strand nuclease into a nickase — an enzyme that cuts one strand only.

Consider what that means for a representation. One base pair changes. The sequence file records a single substitution, one character among thirty-six. The OUTCOME changes category: a double-strand break, which the cell repairs by non-homologous end joining or homologous recombination, becomes a single-strand nick, which the cell repairs by a different pathway entirely, with different mutational consequences.

the level	the event	the reading
the change in the file	one character	a substitution among thirty-six
the change in the molecule	one base pair became a mismatch, perturbing local helical geometry	a change in FOLD, reported as a change in letter
the change in the outcome	double-strand break became single-strand nick	a change of repair pathway and of biological consequence
the sequence model's view	a one-character edit distance	the same magnitude of change as any other single substitution anywhere

Edit distance is not biological distance, and this is the cleanest published demonstration of the gap available. A model whose notion of similarity is string similarity will rank this mismatch identically with a thousand substitutions that change nothing at all.

---

12. Box C/D: The Fold Is Named for the Machine That Modifies the 2 Prime Oxygen

The section this paper was written for

TasR and TasH carry a nucleolar protein domain — Nop — and the Nop domain recognizes box C/D motifs in the tigRNA. The Science paper reports that the TasR structure shows striking similarity to box C/D small nucleolar ribonucleoproteins, and offers this as evidence about the evolution of RNA-guided systems.

Now ask what box C/D small nucleolar ribonucleoproteins do in a eukaryotic nucleus. They guide 2 PRIME O-METHYLATION. They carry a guide RNA that base-pairs with a target RNA and positions a methyltransferase to methylate the 2 prime hydroxyl of the ribose at a selected position.

the element	the identity	the significance
THE ATOM	the 2 prime oxygen of ribose	present in RNA, ABSENT BY DEFINITION in DNA
WHAT IT DOES STRUCTURALLY	forces C3 prime endo pucker and therefore A-form geometry and therefore the groove inversion of section two	it decides which face of the helix can be read
WHAT MODIFIES IT	box C/D snoRNPs, by 2 prime O-methylation, one of the most abundant modifications in cellular RNA	guided by base pairing, positioned by the Nop fold
WHERE THAT FOLD TURNS UP	in TasR and TasH, recognizing box C/D motifs in the tigRNA of an RNA-guided DNA-targeting system found in phage	the same architecture, in a machine that cuts DNA

So the fold shared between the ancestral RNA-guided DNA cutter and the eukaryotic nucleus is the fold of the machine that modifies THE VERY ATOM that decides which groove of a duplex the world can read.

If the 2 prime oxygen needed a stronger case than a sugar pucker diagram, this is it.

And a DNA sequence model has no field for that atom. Not a poorly weighted field. No field. The atom is absent from deoxyribose, so it is absent from the input schema, so it cannot be learned, so it cannot be corrected by scale.

---

13. IS110, and the Word McClintock Would Have Used

The second declared relative, and where it leads

The other structural relative the Science paper names is the IS110 family of RNA-guided transposases. IS110 elements express a bridge RNA with two binding loops — one recognizing the donor sequence, one recognizing the target — and the transposase acts where both are satisfied. Once again: a pair, and the pairing is the specificity.

IS110 is a transposon. So the lineage the 2025 paper sketches runs from mobile genetic elements, through phage and archaeal virus defense and counter-defense systems, to the guide-RNA machinery of the eukaryotic nucleolus. These are the jumping elements, and the person who found them spent thirty-three years waiting for a field that had no notation for a gene that moves.

The observation is not sentimental. It is that the SAME representational failure has now occurred twice on the same class of object. A genetics built on fixed loci could not hold a mobile element. A genomics built on a four-letter string — DNA A T G C, RNA A U G C — cannot hold a pair, an orientation, a fold, or a 2 prime oxygen. In both cases the obstacle was the notation and not the evidence.

PART FOUR · TIGR-TAS, SECOND READING · SCORED AGAINST THE SIXTEEN

The second reading uses TIGR-Tas differently: not as evidence for the framework but as a TEST OF IT. A criterion set that cannot say anything useful about a system

published after it was written is not a criterion set. The sixteen are applied here to a 2025 discovery.

---

14. Cas9 Needs a Landmark. TIGR Brings Its Own Ruler.

The one-line difference, stated with its referents, and why it is a difference of KIND and not of performance

It is tempting to rank these two systems and the ranking would be premature. Cas9 has a decade of optimization behind it and TIGR is a year old; on editing efficiency in human cells there is no contest yet, and no honest comparison of off-target profiles exists. It is also tempting to say that bending is gentler than breaking, and that is simply wrong: TasR and TasH both make double-strand breaks, and Cas9 unwinds the duplex to form an R-loop, which is a larger distortion than a bend. BOTH BEND. BOTH BREAK.

The difference that is real, checkable in both papers, and requires no inference at all is a difference in the ORDER OF OPERATIONS.

Cas9 needs a LANDMARK in the DNA. TIGR brings its OWN RULER.

The sentence is compressed, so the table below spells out its referents for both systems — the letters read, the surface carrying them, the contacts that read them, the strands cut, and the position the cut falls at. Nothing is left implicit.

the element	CRISPR-Cas9	TIGR-Tas
THE LETTERS READ	three base pairs: the NGG of the protospacer-adjacent motif, on the NON-TARGET strand	NOTHING is read; there is no PAM and no landmark of any kind
THE SURFACE	in the MAJOR GROOVE of INTACT B-FORM DUPLEX, immediately 3 prime of the protospacer, BEFORE unwinding	not applicable
THE CONTACTS	arginine 1333 and arginine 1335 make bidentate hydrogen bonds to the second and third guanine	by base pairing alone: spacer A to one strand, spacer B to the complement
THE STRANDS CUT	both strands — HNH cuts the target strand, RuvC the non-target strand	both strands — RuvC in TasR, HNH in TasH
THE CUT POSITION	approximately THREE BASE PAIRS from the letters it just read	3 prime to the nucleotide complementary to the FIFTH BASE OF EACH SPACER

the element	CRISPR-Cas9	TIGR-Tas
THE ENDS	predominantly blunt	8-nucleotide 3 prime overhangs
THE ORIGIN OF MEASUREMENT	A FEATURE OF THE GENOME	A POSITION IN ITS OWN GUIDE

That last row is the whole difference. Cas9 finds its place by locating something in the DNA and reading it. TIGR never asks the genome for anything. It pairs with both strands and cuts at a distance measured off its own guide, so the target is not consulted — it is only paired with.

Which makes the distinction sharper than saying one uses base pairing and the other does not. BOTH use base pairing. The difference is whether an EXTERNAL LANDMARK must be found and read before pairing is allowed to begin.

the system	the recognition target	the recognition mechanism	the locus of specificity
CAS9	a PAM — a MOTIF, three letters at a fixed offset	read by protein, in the B-form major groove, before unwinding	specificity is SPLIT between a protein reading letters and a guide making pairs
TIGR-TAS	two spacers pairing both strands — a RELATION between two engagements	no protein letter-read is required; the duplex is bent, not interrogated	specificity is ENTIRELY in the pairing

CAS9 RECOGNIZES A MOTIF. TIGR RECOGNIZES A RELATION. A sequence file can store a motif — a motif IS a short string and a string is what the file holds. It has no field at all for a relation, and that is the hinge this entire corpus turns on.

Which also says something about which of the two came first

A pure pairing machine is the simpler object. A machine that ALSO reads letters through a dedicated protein domain is the more elaborate one. Nothing here establishes a lineage — the Science paper's own evolutionary argument runs through box C/D and IS110, not through Cas9 — but it is consistent with the 2025 framing of TIGR as an ancestral form. The elaboration is the PAM reader, and TIGR has not got one.

And what that costs a model built on the CRISPR case

the layer	the statement	the status
THE FACT	Cas9 requires a PAM; TIGR-Tas does not	stated in both papers; no inference
THE INFERENCE	that TIGR's recognition therefore never requires a B-form major-groove read AT ANY POINT	THIS AUTHOR'S READING of the bending and the dual-hybrid architecture — NOT stated in the papers, and testable by experiment three
THE SCHEMA CONSEQUENCE	a model carrying PAM as a required input field cannot represent a system that has no PAM	not an inference at all; more training data does not create a field
THE MODEL'S BEHAVIOR	score the TIGR case as malformed input rather than as a negative result	which is worse than a wrong answer, because it does not look like one

The three layers are separated here deliberately. A reader who rejects the middle row loses nothing: the fact stands on the published papers and the schema consequence follows from the fact alone. Only the inference is this author's, and section twenty-five says how to kill it.

The schema consequence is not an inference. A model whose input requires a PAM field cannot represent a system that has no PAM. More training data does not create the field. This is precisely the separating test of the sixteen criteria: if the quantity is absent from the input representation, the failure is structural.

---

15. The Scorecard

A generic four-letter sequence model — DNA A T G C, RNA A U G C — scored against all sixteen, using ADAR and TIGR as the probes

The object scored here is not any named product. It is the class: a model whose input is a string over the four characters A T G C, or A U G C where the input is transcriptomic, with or without positional context. Named systems differ in the details and should be scored individually by their own builders, which is the point of publishing the list.

#	the principle	the score	why, against ADAR or TIGR specifically
1	Trinary Necessity	ABSENT	sequence plus more sequence is one axis twice; fold is not derivable from the string
2	Flatlander Dilemma	ABSENT	editing levels correlate with sequence because sequence proxies for fold; the proxy is fitted, the fold is not represented
3	Quaternion Non-	ABSENT	spacer A pairing strand one is not the same

#	the principle	the score	why, against ADAR or TIGR specifically
	Commutativity		operation as spacer B pairing strand two, and the file stores neither as an operation
4	Z-Axis Selector Blindness	ABSENT	which inverted Alu pair actually folds is the selector; only the edited product is observable
5	Silent Seventh Exclusion	ABSENT	no letter for xanthine, none for any non-alphabet intermediate
6	Vortex Mathematics	NOT APPLICABLE	no claim made here
7	Scalar-to-Quaternion Continuity	ABSENT	element, base, nucleoside, nucleotide collapsed to one character at tokenization
8	Abha Torus Topology	ABSENT	the 36-nucleotide tigRNA is two spacers joined; the string has no join
9	Axis Conflation	ABSENT · AND THE CENTRAL ROW	the 2 prime oxygen exists in RNA and not in DNA; every result in this paper turns on it and no DNA schema has a field for it
10	64-Tetrahedron Lattice	NOT APPLICABLE	TIGR and ADAR are non-coding operations
11	Phosphorothioate-k Chirality	ABSENT	backbone stereochemistry unrepresented, as in every sequence file
12	Inosine / Silent Sixth	ABSENT	every inosine written as guanine; the product of the reaction recorded as a molecule never present
13	Temporal Axis Collapse	ABSENT	the duplex exists only at the RNA level and only transiently; DNA-level input cannot carry it
14	Official Sixes	PARTIAL	carbon, nitrogen, oxygen implicit in the bases; SULFUR AND SELENIUM ABSENT ENTIRELY
15	Freedom of Choice / the 64th	ABSENT	the single mismatch that converts nuclease to nickase is one character of edit distance and a change of category
16	The Sulfur Donor	ABSENT	2 prime O-methylation requires S-adenosyl methionine; the donor is a SULFONIUM and no sequence model has a sulfur field

Fourteen ABSENT · one PARTIAL · two NOT APPLICABLE · zero REPRESENTED.

A score of zero REPRESENTED is not an accusation and section three of the criteria paper says so explicitly. It is the expected default, because most of these questions have never been asked of any model. The useful output is the LIST, and the list here is unusually tidy: every absent row traces to one of three things — the missing 2 prime oxygen, the missing sulfur, or the missing relation.

16. Where the Analogy Breaks, Which Is the Most Useful Part

Printed because a framework that only collects confirmations is not a framework

TIGR and ADAR are not the same kind of system and this paper does not need them to be. The differences are listed here in full, because two of them are more instructive than the similarities.

the axis	TIGR-Tas	ADAR	the note
the target acted on	TIGR CLEAVES DNA	ADAR MODIFIES A BASE IN RNA AND CUTS NOTHING	genuinely different classes of enzyme
the origin of the guide	a separate molecule, transcribed from an array, acting in trans	THE TRANSCRIPT FOLDS ON ITSELF — the guide and the target are one molecule	this is the important one, see below
the pairing partner	guide RNA to target DNA, two hybrid duplexes	RNA to RNA, one intramolecular duplex	different chemistry, same A-form geometry
heritability	a phage or prokaryotic defense and counter-defense system	a eukaryotic recoding and immune-tolerance system	no shared lineage is claimed
PAM	none	not applicable — no protein-DNA targeting step exists	the comparison does not transfer

The break that matters: a guide that is its own target

Every guide-based representation ever written — CRISPR, TIGR, IS110, box C/D snoRNPs, RNA interference — assumes a guide and a target are TWO OBJECTS. ADAR at an inverted Alu is the case where they are one molecule folded on itself. There is no guide to name, no array to search, and no trans-acting component to look up.

So a schema generalized from CRISPR to cover TIGR still cannot hold ADAR, and the missing thing is not a sequence. It is the FOLD. That is why this paper is about grooves and not about guides.

PART FIVE · THE COORDINATES, AND THE FRAMEWORK THEY TEST

The four parts above stand on structures other people deposited. This part does the same thing to this author's own prior work: it names the position paper that mapped TIGR-Tas onto the Berger Triplex, states what the 2026 coordinates have done to its four declared gaps, and converts its central geometric estimate into a measurement that anyone can run in an afternoon.

17. The Prior Paper, Named and Credited

The accredited record this part builds on, which stands as published

The mapping of TIGR-Tas onto three-axis geometry was made in a registered position paper in June 2026, three months after the Science report and before any structure of the complex existed. That paper is the source of every axis assignment used below, and it is not superseded by this one.

the element	the record	the identifier
THE PAPER	TIGR-Tas: The Natural Triplex	PP-2026-TIGR-TAS-01, June 2026
THE AUTHOR	Dr. John Allen Berger, PhD, Independent Theoretical Researcher, Naperville, Illinois	a Berger Triplex 3-6-9 Framework integration
THE FRAMEWORK	Berger Triplex 3-6-9 Genetic Code Framework	formally closed 21 April 2026
THE IDENTIFIERS	DOI 10.64898/2026.04.22.720138	ACCESS-CHM250115 · Licensed under CC BY-NC-ND 4.0. No part of this work may be reproduced, distributed, or transmitted in any form
ITS STATUS	VALID AS PUBLISHED AND NOT WITHDRAWN	this paper ADDS to it and does not replace it

A registered paper with a DOI is a dated, citable position. Nothing that follows amends its text. Sections eighteen through twenty-two report what arrived AFTER it, including one finding that works against its own arithmetic, and the prior paper keeps its date either way. THAT IS WHAT THE DATE IS FOR.

18. The Coordinates Now Exist

The gap the June 2026 paper declared first, and the 2026 depositions that close it

The June 2026 paper declared four honest gaps. Its first gap read: no cryo-electron microscopy or X-ray structure of the full TIGR-Tas ternary complex had been published, so the structural argument rested on mechanistic inference from cleavage properties. That gap is now closed.

the element	the finding	the record
THE STRUCTURES	six cryo-electron microscopy structures of the Salicola phage TIGR-TasH complex	Molecular Cell 2026;86(7):1217-1229.e6, 13 March, doi 10.1016/j.molcel.2026.02.017
THE TASH COORDINATES	PDB 9W03, the TasH-tigRNA complex; with 9W02, 9W04 and 9VZX reported in the same series	9W03 was confirmed directly against the structure database by this author; the remaining three were read from the data availability statement and should be checked against the paper before citation
THE TASR MAP	EMD-48616, a TIGR-TasR complex with tigRNA and target DNA	a separate deposition covering the RuvC-carrying variant
THE DIMER	a central coiled-coil region of TasH mediates dimerization	consistent with the C2-symmetric dimer reported in the Science paper
THE PROCESSING	the C-terminal Nop domain processes precursor tigRNA autonomously	see the open item at section twenty-two
THE RECRUITMENT	on target binding, the dynamic N-terminal HNH nuclease domain is recruited through a beta-hairpin	the executor is assembled BY the recognition event

THE RECRUITMENT FINDING IS THE ONE THAT MATTERS. The nuclease domain is dynamic and arrives in position only once the target is bound. The June paper argued from cleavage properties that the executor does not exist until the other axes are satisfied. It is now visible in density, and it was not visible when the argument was made.

19. The Three Axes, Mapped onto the System

The assignment made in June 2026, restated here because sections twenty and twenty-one test it

The Berger Triplex 3-6-9 Framework assigns three co-equal axes to the genetic code, encoded as a quaternion field. The June paper mapped the TIGR-Tas components onto them. The mapping is reproduced here without amendment.

the axis	the quaternion term	the component	the role
X-AXIS · 3-6-9 · DNA · Past	1, the scalar term	the DNA target duplex, template and non-template strands together	the structural archive — the information read and cut
Y-AXIS · 1-5-7 · RNA · Present	i, an imaginary term	the tigRNA, carrying SpacerA and SpacerB	the operational present — the molecule reading both strands in real time
Z-AXIS · 2-4-8 · ANA · Future	j, an imaginary term	the geometric recognition interface at the cleavage site, at the intermediate helical position between A-form and B-form	the selector — the geometric constraint on which sequences remain accessible
k = ij · THE EXECUTOR	k, the non-commutative product	the Tas protein, executing only once the X and Y axes are simultaneously satisfied	the irreversible cleavage event, with the 8-nucleotide 3 prime overhang as its signature

THE TRINARY NECESSITY PRINCIPLE, IN THE JUNE PAPER'S OWN WORDS. The Tas protein cannot cut without the tigRNA. The tigRNA cannot find its target without both DNA strands. The DNA alone is inert. Cleavage is the quaternion product k = ij — it does not exist until all three axes are simultaneously engaged. No binary system produces k. THIS IS NOT METAPHOR. THIS IS THE MECHANISM.

Section eleven of this paper reported the 2026 finding that a single mismatch converts the TasH nuclease into a nickase. That result was published by a group with no interest in this framework, and it is the cleanest independent support the Trinary Necessity claim has: withdraw one pairing and the executor degrades from k to something less than k.

20. The Z-Axis Is a Pucker Axis

The atom that puts the third axis where the framework places it — added here, absent from the June paper

The June paper placed the Z-axis at an intermediate helical position approximately 45 degrees between A-form and B-form, and identified arabino nucleic acid as its chemistry. It stated the position and cited crystallography for it. It did not name the

atom producing the position. Part One of this paper supplies the chain, and the chain terminates in the same atom the whole document is about.

the sugar	the 2 prime configuration	the pucker	the helical form and the open groove
DEOXYRIBOSE	no 2 prime substituent	C2 prime-endo	B-FORM · the major groove opens
ARABINOSE	the 2 prime hydroxyl held AXIALLY	C3 prime-exo and O4 prime-endo, between the two canonical puckers	INTERMEDIATE · the Z-axis position
RIBOSE	the 2 prime hydroxyl held EQUATORIALLY	C3 prime-endo	A-FORM · the minor groove opens

THE Z-AXIS IS NOT AN ANGLE THAT WAS CHOSEN. It is the pucker a 2 prime substituent adopts when it is held axially rather than equatorially, and the 45-degree figure is the angular expression of that conformation. The third axis now has an atomic cause instead of a geometric assertion.

The same move constrains the framework as it strengthens it. Any molecule holding a 2 prime substituent in an intermediate configuration occupies the same position, which is exactly the concession the June paper already made in its third gap — that arabino chemistry is the primary experimental target because of synthesis access, not because it is the only candidate. That concession now carries a mechanism.

21. The 8-Nucleotide Overhang, and the Bend That Puts It in Question

A correction against this author's own prior arithmetic, printed rather than dropped

The June paper offered a geometric account of the 8-nucleotide 3 prime overhang, which the TIGR-Tas literature reports as a defining feature without explaining. The arithmetic runs from the B-form helical repeat of approximately 10.5 base pairs per turn and a rotational increment of approximately 34.3 degrees per base pair.

8 × 34.3° = 274.4°. Three quarters of a full turn is 270°.

The paper proposed the 8-nucleotide offset as the rotational signature of a cleavage complex engaging the DNA at the intermediate geometry of section twenty. It also declared, in its own second gap, that the assignment was a geometric estimate rather than a measurement, and that the true cleavage geometry might involve protein-induced distortion differing from the idealized helix.

The finding that confirms the worry

The Science paper reports DRAMATIC 180-DEGREE BENDING of the target DNA on complex formation. A global bend of that magnitude is not a small perturbation of an idealized helix. It is precisely the distortion the second gap named, reported rather than hypothesized.

the element	the statement	the note
THE ESTIMATE	274 degrees, from 10.5 base pairs per turn and 34.3 degrees per base pair	an IDEALIZED, undistorted B-form helix
THE REPORTED CONFORMATION	a 180-degree bend of the duplex on complex formation	local helical parameters at the scissile phosphates are unlikely to match idealized values
THE STATUS OF THE CLAIM	DEMOTED from theoretical claim to OPEN QUESTION	the arithmetic is correct; its applicability to the bent complex is unestablished
THE COST OF THE DEMOTION	nothing that was established is lost	gaps one, three and four of the June paper are untouched, and the axis mapping does not depend on the overhang figure

THIS CORRECTION RUNS AGAINST ITS AUTHOR AND IS PRINTED HERE FOR THAT REASON. The 274-degree figure was offered as a geometric signature. The bend makes it an assumption about a molecule visibly not in the assumed conformation. A framework that reports only the findings that flatter it is not a framework.

22. The Measurement That Replaces the Estimate

A seventh experiment, added to the six of section twenty-five, and the cheapest of all of them

The demotion carries its own remedy, and the remedy is now free. The deposited coordinates permit the quantity to be MEASURED. No permission, no funding and no bench are required.

step	the operation	the requirement
ONE	download the deposited TasH coordinates	a browser and a structure viewer
TWO	locate the two scissile phosphates producing the 8-nucleotide 3 prime overhang	the cleavage products are known and the register follows from them
THREE	measure the LOCAL helical twist across the intervening base pairs, summed, and compare with 274 degrees	a standard nucleic-acid geometry routine reports twist per step
FOUR	measure the SUGAR PUCKER at and flanking the cleavage site	the pseudorotation phase angle, from the same routines
FIVE	compare that pucker with C2 prime-endo, C3 prime-endo, and the arabino intermediate	section twenty is confirmed, bounded or refuted by this number

EVERY OUTCOME IS USEFUL AND ONE OF THEM IS FATAL TO SECTION TWENTY-ONE. A summed twist near 274 degrees with intermediate pucker confirms the signature. A twist far from it, or canonical B-form pucker throughout, refutes it. A register too deformed by the bend to measure cleanly reports that the question was badly posed. This author would rather publish the refutation than leave an estimate standing where a measurement is now possible.

One open item, carried rather than resolved

The Science description of tigRNA maturation states that processing requires the Tas protein but that the protein does not itself catalyze the cleavage. The 2026 structural description states that the Nop domain processes precursor tigRNA autonomously. These may be two descriptions of one event at different resolutions. This author cannot settle it from the published abstracts and does not pretend to. It is entered here as an open item rather than smoothed over.

PART SIX · THE CONSEQUENCE

23. The Alphabet Is a Projection of One Groove of One Helix Form

What follows from the chemistry — a consequence, arrived at last, and not the subject of the paper

Everything to this point has been about atoms: an oxygen, two arginines, a glutamate, a sulfonium. This section is the only one about notation, and it is placed here because it is a RESULT rather than a premise. If the chemistry in Parts One through Four is right, this follows. If it is wrong, this falls, and nothing in the chemistry depends on it.

First, the four letters, named — because they are not an abstraction and they are not even the same four

A DNA file is written in A, T, G and C. An RNA file is written in A, U, G and C. Those are the actual characters, and the swap between them is worth stopping on, because it shows exactly what the notation chooses to record and what it does not.

the difference between a DNA file and an RNA file	the atomic difference	the notation's record
THE BASE	THYMINE carries a METHYL GROUP at carbon 5 of the pyrimidine ring; URACIL does not — thymine IS 5-methyluracil	A WHOLE CHARACTER. T instead of U. One methyl group gets its own letter.
THE SUGAR	RIBOSE carries the 2 PRIME OXYGEN; DEOXYRIBOSE does not	NOTHING IN THE STRING. Not a character, not a flag, not a field. It is carried only by WHICH FILE YOU ARE IN, by convention, outside the sequence entirely.

Read those two rows against each other. The notation spends an ENTIRE CHARACTER on a methyl group at carbon 5, and has NO CHARACTER AT ALL for the oxygen at 2 prime. Both differences are real. But the methyl adjusts a base's profile within a groove, and the oxygen decides WHICH GROOVE EXISTS TO BE READ.

That is the priority the alphabet encodes, and nobody chose it. It was inherited from an era when the sugar was a property of the tube you were working in rather than a variable in the data. The letters record what changed between two BASES. The atom that changes the whole HELIX never made it into the string.

And what the letters actually stand for

A four-letter sequence file — DNA A T G C, RNA A U G C — assumes that naming the base at each position describes the molecule. Section three says where that assumption is true: in the MAJOR GROOVE OF A B-FORM DUPLEX, which is the one surface in nucleic acid chemistry on which those four letters are the information, because it is the one surface on which all four base pairs present distinguishable faces.

Section two says when that surface is available: when the 2 prime oxygen is absent. Put back the oxygen and the accessible face becomes the minor groove, where the letters are nearly indistinguishable and the readable chemistry is the hydroxyl array and the shape.

the object	the identity	the note
THE FOUR-LETTER ALPHABET · A T G C in DNA, A U G C in RNA	a faithful description of the B-form major groove	and of nothing else
EVERY A-FORM RECOGNITION EVENT	RNA duplexes, RNA-DNA hybrids, R-loops, inverted Alu substrates, snoRNP-guided methylation, tigRNA hybrids, ribosomal RNA, transfer RNA, riboswitches	a readout of a face on which the letters are NOT the information
THE ERROR	treating a projection of one groove as the description of the molecule	not a small error, and not a correctable one
WHY IT PERSISTS	the projection is extremely useful, cheap to store, and correct for the case it was derived from	useful and complete are different properties

This is a stronger statement than the inosine claim and it contains it. The alphabet is not missing one character. THE ALPHABET IS A PROJECTION, and a projection loses a dimension by construction. Adding characters to a projection does not restore the dimension.

It is also, this author notes, the same shape of argument as the Flatlander section of the criteria paper, arrived at from chemistry rather than from geometry. A creature confined to a plane models the circle. A discipline confined to one groove models the sequence.

24. What Would Have to Be Added to the Input

Because a criticism without a repair is a complaint

The sixteen criteria hold that a structural absence must be ADDED TO THE INPUT or measured separately, since it cannot be trained in. This section lists what that means concretely for the results above. None of these is exotic and most are already measured by someone.

the addition	the form it takes	the gain	the cost
SUGAR PUCKER OR HELIX FORM	a per-region label, even a binary A-like or B-like	decides which groove is readable and therefore which recognition mode is possible	derivable where the molecule is known to be RNA; must be measured for hybrids and R-loops
DUPLEX PARTNER	for each transcript position, the coordinates of the segment it pairs with, if any	turns the inverted Alu pair from two annotations into one object	measurable transcriptome-wide by existing structure-probing chemistry
ORIENTATION OF THE PAIR	inverted or direct	inverted folds; direct does not	already in the repeat annotation, simply not carried forward
2 PRIME O-METHYLATION STATE	per position, where measured	the modification of the atom that sets the helix form	mapped by established sequencing methods
SULFUR DONOR POOL	S-adenosyl methionine concentration for the sample	every methylation in this paper requires it and no genome file reports it	a metabolite measurement, not a sequencing one
BACKBONE STEREOCHEMISTRY	Rp or Sp at modified positions	different nuclease resistance and activity, identical printed sequence	required for any model used on antisense or guide chemistry

Every row is a measurement, not an opinion, and no row requires anybody to accept this framework's geometry, its color notation or its sixteen criteria. A team could adopt all six and disagree with every other page of this document.

25. Six Experiments That Would Settle It

Stated so that a disagreeing reader can do the work rather than argue

#	the experiment	the decision it forces	the cost
ONE	Take a published editing-site predictor. Bin held-out sites by whether the duplex partner is proximal or distal in the transcript. If accuracy is flat across bins, section seven is wrong.	structural information is doing the work, not sequence	public data, no bench
TWO	Repeat with a model given an experimentally determined structure track as an additional input channel. Measure the gain specifically on the distal bin.	quantifies what the missing field is worth	public data plus published probing data
THREE	Test whether TasR or TasH targeting is sensitive to B-form major-groove-directed competitors at the target site, versus minor-groove binders.	tests the section fourteen inference directly	standard biochemistry
FOUR	Systematically walk a single mismatch through all thirty-six positions of a tigRNA and score nuclease versus nickase outcome at each.	maps where the relation is load-bearing and where it is not	extension of published 2026 work
FIVE	Score any named sequence model against the sixteen using its own published input schema, and publish the rows that come back REPRESENTED.	the criteria paper's stated purpose; falsifies section fifteen if the count is not near zero	an afternoon
SIX	Measure S-adenosyl methionine pool alongside a methylation-prediction benchmark and test whether the residual error correlates with pool size.	tests whether the missing sulfur field carries signal	metabolomics plus existing benchmark

Experiment one requires no permission, no bench and no funding, and it can falsify the central empirical claim of Part Two. That is deliberate. A claim that can only be tested by people with a budget is not much of a claim.

26. What This Paper Claims

the claim	the source	the status
that the 2 prime oxygen inverts which groove is accessible	STANDARD STRUCTURAL CHEMISTRY	not original here
that the two grooves carry different information	SEEMAN, ROSENBERG AND RICH 1976	not original here

the claim	the source	the status
that ADAR2 approaches from the A-form minor groove and cannot do so in B-form DNA	MATTHEWS AND COLLEAGUES 2016, STATED IN THE PAPER	not original here
that TIGR-Tas targets with two spacers, needs no PAM, bends DNA 180 degrees, and shares the Nop fold with box C/D	FAURE, SAITO AND COLLEAGUES 2025	not original here
that Cas9 reads the NGG of the PAM in the major groove of intact duplex by arginines 1333 and 1335, before unwinding, and cuts about three base pairs away	ANDERS AND JINEK 2014	not original here
that TIGR requires no PAM and cuts at a distance measured from the fifth base of each spacer	FAURE, SAITO AND COLLEAGUES 2025	not original here
that the two systems therefore differ fundamentally in whether an EXTERNAL LANDMARK must be read before pairing may begin — Cas9 needs one in the DNA, TIGR brings its own ruler — and that this is a difference of KIND and not of performance	THIS AUTHOR, from the two facts above	ORIGINAL AS A FRAMING; each fact is published
that A-to-I editing is therefore not predictable from primary sequence in principle, not merely in practice	THIS AUTHOR, from the sections above	ORIGINAL, and falsifiable by experiment one
that the recognition unit in both the inverted Alu and the tigRNA is a RELATION, which a token string has no type for	THIS AUTHOR	ORIGINAL
that TIGR's recognition may never require a B-form major-groove read	THIS AUTHOR, MARKED AS INFERENCE AT SECTION FOURTEEN	ORIGINAL AND UNCONFIRMED
that TIGR-Tas maps onto three co-equal axes as a quaternion field, with the Tas protein as the product k = ij	THIS AUTHOR, PP-2026-TIGR-TAS-01, JUNE 2026	PRIOR REGISTERED WORK, restated at section nineteen and not amended here
that the deposited 2026 coordinates close the first gap declared in that paper	MOLECULAR CELL 2026 AND THE DEPOSITIONS	not original here; section eighteen
that the Z-axis position is set by the axial configuration of the 2 prime substituent, which fixes the pucker	THIS AUTHOR, ADDED AT SECTION TWENTY	ORIGINAL TO THIS PAPER; it supplies the atomic cause the June paper did not state
that the 8-nucleotide 3 prime overhang is the geometric signature of cleavage at the intermediate helical position	THIS AUTHOR, PP-2026-TIGR-TAS-01	DEMOTED TO AN OPEN QUESTION AT SECTION TWENTY-ONE, by the reported 180-degree bend
that the four-letter alphabet —	THIS AUTHOR	ORIGINAL, and the

the claim	the source	the status
DNA A T G C, RNA A U G C — is a projection of the B-form major groove		reason this paper exists

27. What This Paper Does Not Claim

the non-claim	the statement
that TIGR-Tas and ADAR are evolutionarily related	they are not claimed to be; section sixteen prints the differences in full
that sequence models are without value	they are enormously valuable within the projection they describe, which is most of molecular biology's working domain
that the builders of any model have erred	a sequence model conditions on sequence; that is what it is, and the criteria paper says so in its own section three
that this framework's color notation must be adopted to use any of this	every argument above stands or falls on published structures and is stated without reference to the notation
that the 2025 and 2026 TIGR papers support this paper's conclusions	they support the FACTS in section nine; the readings in sections ten through fourteen are this author's and are labeled
that the scorecard in section fifteen applies to any named product	it scores a class; named systems must be scored by their own builders against their own published schemas
that TIGR-Tas is BETTER than CRISPR-Cas9	no such ranking is offered and section fourteen refuses it: Cas9 has a decade of optimization, TIGR is a year old, and no comparable off-target data exists
that bending is gentler than breaking	BOTH BEND AND BOTH BREAK — TasR and TasH cut both strands, and Cas9's R-loop is a larger distortion than a bend
that the deep groove is the better groove	it is the HIDDEN one; depth is inaccessibility, not superiority, and section three says why

The single most likely way this paper is wrong is that sequence proxies for fold better than section seven allows, across a wider range of cases than expected. Experiment one measures exactly that, and the result would not be embarrassing — it would be a number nobody currently has.

28. Sources, With Identifiers

Every one of the six can be checked in a browser in under a minute, and two of them deposit atomic coordinates that can be opened and measured. That is the standard this corpus holds itself to and it is the only reason anyone should read a paper from outside an institution.

29. The Color Index

What the shaded words in this paper mean, and where each one goes

Throughout this corpus the notation is ONE TO ONE at the atomic and molecular level: each element carries a color, and every base, nucleoside and nucleotide built on that element carries the same color unchanged. That is why a gap can be found mechanically — run the key across a model's inputs and look for the color that never appears. In this paper the color that never appears in any sequence model's input is YELLOW, and yellow is SULFUR.

THE COLOR INDEX

Every shaded word in this volume is a link. A word with its own entry in the Index jumps to that entry; a letter, atom label or formula returns here.

color	element	base	nucleoside	nucleotide
ORANGE	O 8	HYPOXANTHINE	inosine	IMP
RED	H 1	ADENINE	adenosine	AMP
GREEN	N 7	GUANINE	guanosine	GMP
BLUE	C 6	CYTOSINE	cytidine	CMP
PURPLE	P 15	URACIL	uridine	UMP
YELLOW	S 16	THYMINE	thymidine	TMP
INDIGO	Se 34	XANTHINE and OROTATE — gatekeepers, not letters	xanthosine / orotidine	XMP / OMP

Page references are omitted here because they belong to the master volume's pagination, not to this paper's. Every term above is indexed in Berger Master Central Dogma PP-2026-MASTER-01.

Every shaded word in this paper is a live link and every one of them returns to this table. That is what a standalone paper can offer on its own. The page references behind each term — several hundred for OXYGEN alone — live in Berger Master Central Dogma PP-2026-MASTER-01, and a reader who wants the evidence behind any colored term will find it there and not here.

30. Reuse

This paper is published under Creative Commons Attribution 4.0. It may be copied, quoted, translated, taught, argued with and republished by anyone, commercially or otherwise, with attribution and without permission from the author.

The fastest way to improve it is for somebody to run experiment one and publish the number.

POSITION PAPER · NOVAGONDNA · FOR COMMENT

Selenium the Seventh Atomic Element Which Expanded the Genetic Code

THE ORDER OF EVENTS — SULFUR BEFORE PHOSPHATE, ANOXIC BEFORE OXIC, AND WHERE SELENIUM ACTUALLY FITS. A dated sequence for the changes in the genetic code. Sulfur ran the energy economy before phosphate did. One enzyme made DNA from RNA and its three classes are a record of the oxygenation of the Earth. Thymine's methyl made the archive proofreadable, and the same methyl one ring over is what lets the archive be corrupted invisibly. Selenium's recoded stop codon is a POST-OXYGEN event, and the Great Oxidation Event is what made it worth paying for

Companion to PP-2026-177-01 · that paper states what selenium does; this one states when it could have started.

color	element	base	nucleoside	nucleotide
RED	H 1	ADENINE	adenosine	AMP
ORANGE	O 8	INOSINE	inosine	IMP
YELLOW	S 16	THYMINE	thymidine	TMP
GREEN	N 7	GUANINE	guanosine	GMP
BLUE	C 6	CYTOSINE	cytidine	CMP
INDIGO	Se 34	XANTHINE and OROTATE	xanthosine / orotidine	XMP / OMP
PURPLE	P 15	URACIL	uridine	UMP

THE COLOR KEY · this paper runs on YELLOW and ORANGE — sulfur first, oxygen second, and the whole argument is the order they arrived in

1. What This Paper Says in Nine Lines

A note on the argument. The main characters are ELEMENTS and the claim is about the ORDER THEY ARRIVED IN. Sulfur first, phosphorus and oxygen next, oxygen subtracted to make the archive, carbon added as a methyl to make it proofreadable, oxygen returned as a hazard, and selenium last.

— SULFUR RAN THE ENERGY ECONOMY BEFORE PHOSPHATE DID. The thioester world hypothesis places a sulfur-based energy currency BEFORE the RNA world, and inorganic thiophosphate is a published prebiotic phosphorylating agent. A 2025 paper demonstrated thioester-mediated RNA aminoacylation and peptidyl-RNA synthesis in water at neutral pH.

— ONE ENZYME MADE DNA OUT OF RNA, AND IT IS THE ONLY STEP. Ribonucleotide reductase reduces the 2 prime position. Nothing else in biology does it. Remove that enzyme and there is no deoxyribose, no DNA, and no archive.

— ITS THREE CLASSES ARE A RECORD OF THE OXYGENATION OF THE EARTH. Class III is anaerobic, runs on a GLYCYL RADICAL and a [4Fe-4S] cluster, and is destroyed by oxygen. Class I REQUIRES molecular oxygen. Class III is proposed as the most ancient and class I as the most recent.

— SO THE RNA-TO-DNA TRANSITION HAPPENED IN AN ANOXIC WORLD, under class III, around four billion years ago — not during the Great Oxidation Event, which is more than a billion years later.

— THYMINE'S METHYL IS AN ERROR-DETECTION DEVICE. Cytosine deaminates spontaneously to URACIL. Because DNA carries THYMINE rather than uracil, any uracil appearing in DNA is recognizable as DAMAGE and excised. THE METHYL IS WHAT MAKES THE ARCHIVE PROOFREADABLE.

— AND THE SAME METHYL ON THE OTHER PYRIMIDINE IS THE HOLE IN THAT DEFENSE. 5-methylcytosine deaminates to THYMINE, not to uracil, and thymine is a legitimate DNA base. The repair system that catches deaminated cytosine is BLIND to deaminated 5-methylcytosine, which is why CpG sites are mutational hotspots.

 © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

— THE MARK THAT LETS YOU EDIT THE ARCHIVE IS THE MARK THAT LETS THE ARCHIVE BE CORRUPTED INVISIBLY. That is one methyl group doing two opposite jobs on two rings, and no sequence file records either one.

— UGA WAS THE AVAILABLE SIGNAL FOR THREE REASONS, none of them an anagram. It is the leakiest of the three stops; it has been reassigned independently more than once, coding TRYPTOPHAN in vertebrate mitochondria and in Mycoplasma; and the transfer RNA that reads it as selenocysteine is derived from a SERINE transfer RNA, carrying the anticodon UCA.

— THEREFORE SELENIUM'S RECODING IS A POST-OXYGEN EVENT. The selenoproteins are antioxidant enzymes — glutathione peroxidases, thioredoxin reductases. A hundredfold faster nucleophile is worth a three-enzyme biosynthesis and a hijacked stop codon ONLY ONCE OXYGEN MAKES PEROXIDE A STANDING THREAT. THE GREAT OXIDATION EVENT IS WHAT MADE SELENIUM WORTH PAYING FOR.

PART ONE · THE SEQUENCE

2. The Order of Events, Dated

Everything below hangs on this table, and the dates are other people's

The single most common error in reasoning about the genetic code is putting events in the wrong order relative to the oxygenation of the atmosphere. The table below states the order this paper works from, with the customary date ranges and their status.

the event	the customary dating	the content	the epistemic status
THE THIOESTER WORLD	before the RNA world	a SULFUR-based energy economy preceding nucleotide chemistry	HYPOTHESIS, with supporting prebiotic chemistry
THE RNA WORLD	roughly 4.0 to 3.5 billion years ago	RNA as both information and catalyst	WIDELY HELD, not directly observed
RIBONUCLEOTIDE REDUCTION	in the anoxic world, under class III chemistry	the 2 prime oxygen removed; DNA becomes possible	INFERRED from the class phylogeny

the event	the customary dating	the content	the epistemic status
THE LAST UNIVERSAL COMMON ANCESTOR	estimates from roughly 3.5 to 4.2 billion years ago	DNA, the genetic code and translation ALREADY ESTABLISHED	INFERRED from comparative genomics
THE GREAT OXIDATION EVENT	roughly 2.4 to 2.3 billion years ago	free oxygen accumulates in the atmosphere	GEOLOGICAL RECORD
THE LOMAGUNDI-JATULI EXCURSION	roughly 2.22 to 2.06 billion years ago	a large positive carbon isotope excursion; a major oxygen episode	GEOLOGICAL RECORD
THE SELENOPROTEIN EXPANSION	after oxygen, on the argument of section eight	antioxidant selenoenzymes become worth their cost	THIS AUTHOR'S PLACEMENT

READ THE FOURTH AND FIFTH ROWS TOGETHER. AT THE GREAT OXIDATION EVENT THE GENETIC CODE WAS ALREADY MORE THAN A BILLION YEARS OLD. Nothing about the origin of the code, the origin of DNA or the origin of translation can be placed in the window between 2.4 and 2.2 billion years ago. That window is available for LATER ADJUSTMENTS to a code already fixed, and selenium is one of those.

---

3. Sulfur Ran the Energy Economy First

The thioester world, thiophosphate, and why YELLOW comes before PURPLE in this corpus

Adenosine triphosphate is the energy currency of every cell alive. It was not the first. The thioester world hypothesis holds that a SULFUR-based chemistry supplied the energetic and catalytic framework of protometabolism before nucleotide chemistry existed, and that the RNA world inherited an economy already running.

the element	the finding	the status
THE THIOESTER BOND	a high-energy bond deemed equivalent to the phosphate bonds of ATP	the energy carrier before the phosphate carrier
INORGANIC THIOPHOSPHATE	proposed as both a superior nucleophile and an energy-rich phosphate	a prebiotic phosphorylating agent, published and tested
THE DEMONSTRATED ROUTE	Michael addition of thiophosphate to acrylonitrile gives S-cyanoethylphosphorothioate, which phosphorylates nucleosides	laboratory chemistry, not speculation

the element	the finding	the status
THE 2025 RESULT	thioester-mediated RNA aminoacylation and peptidyl-RNA synthesis in water at neutral pH	the mechanism connecting sulfur chemistry to the first peptides on RNA

IN THE COLOR NOTATION THIS IS YELLOW HANDING OVER TO PURPLE — sulfur handing the energy economy to phosphorus. And the handover was never complete: the thioester is still how acetyl-CoA carries a two-carbon unit, and the sulfonium of S-adenosyl methionine is still how a methyl group is made to leave.

The relevance to selenium is one step removed and worth stating plainly. THIS PAPER DOES NOT CLAIM THAT SELENIUM PARTICIPATED IN THE THIOESTER WORLD. It claims that sulfur did, that selenium is sulfur's neighbor one period down, and that the biochemical machinery selenium later used — a phosphorylated intermediate, a chalcogen nucleophile, a radical-resistant active site — was already in the repertoire.

PART TWO · THE ONE STEP

4. Ribonucleotide Reductase, and the Oxygen It Remembers

The single enzymatic invention that made DNA possible, and the three-class record it left behind

There is exactly one enzymatic route from the RNA world to the DNA world. Ribonucleotide reductase removes the oxygen at the 2 prime position of ribose and produces deoxyribose. No other enzyme does this. Every deoxynucleotide in every organism passes through it.

Part One of PP-2026-176-01 establishes what that 2 prime oxygen does: it fixes the sugar pucker, which fixes the helical form, which fixes which groove a protein can enter. RIBONUCLEOTIDE REDUCTASE IS THE ENZYME THAT DECIDES WHICH FACE OF THE MOLECULE THE REST OF BIOLOGY WILL BE ABLE TO READ.

The three classes, and what each one needs

the class	the radical source	the oxygen requirement	the placement
CLASS III	a GLYCYL RADICAL, generated by an activase carrying a [4Fe-4S] cluster	STRICTLY ANAEROBIC — both the glycyl radical and the metal center are destroyed by oxygen	PROPOSED AS THE MOST ANCIENT; iron-sulfur chemistry has a prebiotic origin
CLASS II	adenosylcobalamin, a vitamin B12 derivative	oxygen-independent, functioning in either condition	intermediate in the phylogeny
CLASS I	a ferritin-like subunit housing a stable radical cofactor	REQUIRES MOLECULAR OXYGEN to assemble the cofactor	PROPOSED AS THE MOST RECENTLY EVOLVED

THE ENZYME FAMILY IS A GEOLOGICAL INSTRUMENT. Class III cannot operate in the presence of oxygen. Class I cannot operate without it. The transition between them is not a fact about enzymes; IT IS A FACT ABOUT THE ATMOSPHERE, recorded in protein sequence and preserved to the present day in organisms occupying both niches.

Which settles when DNA arrived

If the ancestral ribonucleotide reductase was class III, and class III is destroyed by oxygen, then the RNA-to-DNA transition occurred in an ANOXIC world. That places it before the Great Oxidation Event by a very large margin, and consistent with the customary dating of the RNA world at four billion years.

SO THE ANOXIC CONDITIONS WERE A SELECTION FACTOR — for the RNA-to-DNA transition, at four billion years. They were not a selection factor for the selenium recoding, which section eight places on the other side of the oxygen line, for the opposite reason.

PART THREE · THE METHYL

5. Thymine's Methyl Made the Archive Proofreadable

Why DNA uses THYMINE where RNA uses URACIL, and the one job the methyl does

Thymine is 5-methyluracil. One methyl group at carbon 5 of the pyrimidine ring is the entire difference, and it is the difference between the character T and the

character U in the two alphabets. The standard account of why DNA pays for that methyl is error detection, and it is worth stating in full because the corpus turns on it.

the element	the statement	the note
THE DAMAGE	cytosine deaminates SPONTANEOUSLY — the amino group is lost and the product is URACIL	a constant background rate, requiring no enzyme and no insult
THE PROBLEM IF DNA USED URACIL	a deaminated cytosine would be INDISTINGUISHABLE from a legitimate base	every deamination would become a permanent mutation
THE SOLUTION	DNA uses THYMINE instead, so uracil has no legitimate place in DNA	any uracil found in DNA is DAMAGE BY DEFINITION
THE MACHINERY	uracil-DNA glycosylase excises it and the site is repaired from the complementary strand	the methyl is not decoration; it is the flag that makes repair possible
THE COST	thymidylate synthase, using methylene-tetrahydrofolate, must make every dTMP from dUMP	an entire enzymatic step maintained purely to keep the two characters distinct

THE ARCHIVE IS PROOFREADABLE BECAUSE ONE CHARACTER WAS RESERVED AS AN ERROR CODE. Life spends a dedicated enzyme and a folate cofactor on that reservation at every round of replication, in every cell, and has done so since DNA existed. NOTHING IN A SEQUENCE FILE RECORDS WHY T IS NOT U.

---

6. The Same Methyl, One Ring Over, Is the Hole in the Defense

5-methylcytosine, and the mutation the repair system cannot see

Epigenetic marking in DNA is, chemically, the addition of a methyl group at carbon 5 of CYTOSINE. That is the same ring position as the methyl distinguishing thymine from uracil, on the other pyrimidine. The donor differs — DNA methyltransferases use S-adenosyl methionine, thymidylate synthase uses methylene-tetrahydrofolate — but the position is the same and the consequence is catastrophic in a way that is rarely stated as bluntly as it deserves.

the starting base	the deamination product	its standing in DNA	the fate
CYTOSINE deaminates to	URACIL	NOT a DNA base	CAUGHT by uracil-DNA glycosylase and repaired
5-METHYLCYTOSINE deaminates to	THYMINE	A LEGITIMATE DNA BASE	INVISIBLE to the repair system; the mutation becomes permanent

THIS IS WHY CpG SITES ARE MUTATIONAL HOTSPOTS. The methyl that marks a cytosine for regulatory purposes converts its deamination product from a detectable error into an undetectable one. THE MARK THAT LETS YOU EDIT THE ARCHIVE IS THE MARK THAT LETS THE ARCHIVE BE CORRUPTED INVISIBLY, and it is one methyl group doing both.

What this does to the epigenetic hypothesis

The suggestion that methylation arose as a way to edit a fixed archival memory without rewriting it has a defensible core: once information is committed to a stable double-stranded archive, a reversible chemical mark is the only way to change its expression without changing its content. That is what methylation does.

What must be added is the price. The same chemistry that supplies reversible control ALSO SUPPLIES A BLIND SPOT IN THE PROOFREADER. The archive gained an editing layer and lost the ability to detect one class of damage at exactly the positions carrying the edits.

A REGULATORY SYSTEM BUILT ON TOP OF A REPAIR SYSTEM'S ONE BLIND SPOT IS NOT AN ACCIDENT WORTH IGNORING. Whether the blind spot was the cost of the regulation or the regulation was the use found for the blind spot, this author does not claim to know, and section ten records that as an open question rather than resolving it.

PART FOUR · THE CODON

7. Why It Was UGA and Not Another Codon

Three reasons, all of them mechanical, and none of them a rearrangement of letters

Selenium entered the code on UGA. That codon was not chosen arbitrarily and it was not derived from any other codon by transposition. It was the AVAILABLE one, for three reasons that can be checked independently.

the reason	the fact	the consequence
ONE · IT LEAKS	UGA is the leakiest of the three termination codons	readthrough at a stop codon that already leaks is a smaller step than overloading one that does not
TWO · IT HAS BEEN REASSIGNED BEFORE, INDEPENDENTLY	UGA codes TRYPTOPHAN in vertebrate mitochondria and in Mycoplasma	the same codon has been captured more than once in unrelated lineages; it is the soft spot in the table
THREE · THE READER WAS BUILT FROM A SERINE TRANSFER RNA	tRNA-Sec carries the anticodon UCA and is derived from a serine transfer RNA	which is also why the biosynthesis starts by charging that transfer RNA with SERINE

THE LINEAGE RUNS THROUGH SERINE, NOT THROUGH METHIONINE. The transfer RNA that reads UGA as selenocysteine is a modified serine transfer RNA, and the pathway of section four of PP-2026-177-01 begins by loading serine onto it. The serine is then phosphorylated and converted. THE WRONG AMINO ACID IS LOADED FIRST, DELIBERATELY, AND THEN REBUILT IN PLACE.

8. Where Selenium Actually Fits

The placement this paper argues for, and the reason the Great Oxidation Event is the right trigger

Look at what the selenoproteins do. Glutathione peroxidases reduce hydroperoxides. Thioredoxin reductases maintain the cell's reducing capacity. Methionine sulfoxide reductase repairs oxidative damage. THE SELENOPROTEOME IS, IN LARGE PART, AN ANTIOXIDANT SYSTEM.

Now count the cost of using selenium. A dedicated transfer RNA. Three enzymes acting in sequence before the residue exists. A dedicated selenophosphate synthetase which is itself a selenoprotein. A binding protein and a specialized elongation factor. A structural element in the untranslated region of every message.

A recoded stop codon and the readthrough risk that comes with it. And a dietary dependence on a trace element distributed unevenly in soil.

the term	the statement	the note
THE BENEFIT	a selenol pre-ionized at physiological pH, giving roughly a hundredfold rate advantage over the equivalent thiol	large, and specifically useful against PEROXIDE
THE COST	a dedicated transfer RNA, three biosynthetic enzymes, a recoded stop codon, and a dietary dependence	very large, and paid continuously
THE CONDITION FOR PAYING IT	a standing oxidative threat that sulfur chemistry alone handles too slowly	which is what free atmospheric oxygen creates
THE DATE THAT CONDITION ARRIVES	the Great Oxidation Event, roughly 2.4 to 2.3 billion years ago, and the Lomagundi excursion after it	the geological record supplies the trigger

SO THE SELENIUM RECODING IS A POST-OXYGEN EVENT, AND THE GREAT OXIDATION EVENT IS WHAT MADE IT WORTH PAYING FOR. A hundredfold faster nucleophile is an expensive luxury in an anoxic world with no peroxide to deal with. It is a necessity in an oxic one.

This author notes the counter-case in fairness. Selenoproteins occur in anaerobic organisms, and formate dehydrogenase H in E. coli — the enzyme with the largest measured selenium advantage — is not an antioxidant enzyme. So selenium chemistry PREDATES oxygen. WHAT THIS SECTION PLACES AFTER OXYGEN IS THE EXPANSION, not the invention: the growth of the selenoproteome into a large antioxidant system in oxygen-exposed lineages.

THAT DISTINCTION IS THE DIFFERENCE BETWEEN A CLAIM THAT SURVIVES AND ONE THAT DOES NOT. Selenium chemistry is old. The selenium ANTIOXIDANT SYSTEM is the part the oxygen record explains, and it is the part worth claiming.

PART FIVE · THE RECORD

9. The Whole Sequence, in One Table

The corrected order, with the element doing the work at each step

the stage	the element doing the work	the event	the color
BEFORE THE RNA WORLD	SULFUR	thioesters and thiophosphate carry energy and phosphorylate nucleosides	YELLOW
THE RNA WORLD, circa 4.0 to 3.5 billion years	PHOSPHORUS and OXYGEN	RNA carries information and catalysis; the 2 prime oxygen holds the A-form	PURPLE and ORANGE
THE RNA-TO-DNA TRANSITION, ANOXIC	OXYGEN REMOVED	class III ribonucleotide reductase takes out the 2 prime oxygen; the archive becomes possible	ORANGE, subtracted
THE ARCHIVE MADE PROOFREADABLE	CARBON, as a methyl	thymidylate synthase makes T from U; uracil in DNA becomes a detectable error	BLUE, added to the ring
BEFORE LUCA	the code fixed	UGA among the stops, and the leakiest of them	the table closes at sixty-four
THE GREAT OXIDATION EVENT, circa 2.4 billion years	OXYGEN ARRIVES	class I ribonucleotide reductase appears, requiring it; peroxide becomes a standing threat	ORANGE, returned as a hazard
THE SELENOPROTEIN EXPANSION	SELENIUM	the antioxidant selenoenzymes expand; UGA is recoded and the SECIS supplies the reading	INDIGO
THE EPIGENETIC LAYER	CARBON, as a methyl again	5-methylcytosine supplies reversible control and one blind spot in the proofreader	BLUE, on the other ring

READ THE COLOR COLUMN DOWNWARD. YELLOW, then PURPLE and ORANGE, then ORANGE SUBTRACTED, then BLUE, then ORANGE RETURNED AS A HAZARD, then INDIGO. The history of the genetic code is the history of which elements were available and which were dangerous, and the notation follows it without being asked to.

10. Claims, and Open Questions

the claim	the source	the status
that the thioester world preceded the RNA world and that thiophosphate is a plausible prebiotic phosphorylating agent	PUBLISHED HYPOTHESIS WITH SUPPORTING CHEMISTRY	not original here
that ribonucleotide reductase is the sole enzymatic route from ribonucleotides to deoxyribonucleotides	ESTABLISHED SCIENCE	not original here

the claim	the source	the status
that class III is anaerobic and proposed as most ancient, and class I requires oxygen and is proposed as most recent	PUBLISHED PHYLOGENETIC ARGUMENT	not original here
that thymine's methyl makes uracil in DNA a detectable error	ESTABLISHED SCIENCE	not original here
that 5-methylcytosine deaminates to thymine and is therefore invisible to uracil excision, making CpG a hotspot	ESTABLISHED SCIENCE	not original here
that UGA codes tryptophan in vertebrate mitochondria and Mycoplasma, and that tRNA-Sec derives from a serine transfer RNA	ESTABLISHED SCIENCE	not original here
that the RNA-to-DNA transition is therefore anoxic and predates the Great Oxidation Event by more than a billion years	THIS AUTHOR, assembling the above	ORIGINAL AS AN ASSEMBLY; each component is published
that the selenoprotein EXPANSION is a post-oxygen event triggered by peroxide pressure	THIS AUTHOR	ORIGINAL, and the reason this paper exists
that the methyl which permits epigenetic editing is the same methyl that blinds the proofreader	THIS AUTHOR AS A FRAMING	the chemistry is established; the framing is this author's

Open, and stated as open

the question	the position
whether the CpG blind spot was the COST of regulation or the OPPORTUNITY that regulation exploited	this author cannot distinguish these and does not claim to
whether selenium chemistry in anaerobes is ancestral or a later reacquisition	the literature does not settle it and section eight states the counter-case rather than burying it
whether the thioester world occurred at all	the chemistry is demonstrated; the historical claim is not, and cannot be from laboratory work alone

11. Experiments

#	the experiment	the decision it forces	the cost
O	Map selenoproteome size against inferred	tests the section eight	public data, no bench

#	the experiment	the decision it forces	the cost
NE	oxygen exposure across sequenced lineages, controlling for genome size and phylogeny.	placement directly	
TWO	Test whether lineages retaining class III ribonucleotide reductase carry smaller antioxidant selenoproteomes than those with class I.	links the two oxygen records to each other	public data, no bench
THREE	Measure the CpG transition rate at methylated against unmethylated cytosines in a single genome, and compare with the uracil excision rate at unmethylated sites.	quantifies the blind spot of section six	published datasets
FOUR	Count how many annotated selenoprotein genes a standard open reading frame caller truncates at the in-frame UGA without selenoprotein-specific annotation.	the experiment carried from PP-2026-177-01	public data, an afternoon

EXPERIMENT ONE IS THE ONE THAT MATTERS AND IT CAN BE RUN ON PUBLIC DATA. If selenoproteome size shows no relationship to oxygen exposure once phylogeny is controlled, section eight is wrong and should be withdrawn.

12. Sources

the item	the content	the source
THE THIOESTER WORLD	a sulfur-based energy economy preceding the RNA world; the thioester bond as an ATP equivalent	de Duve and the subsequent literature
THIOPHOSPHATE CHEMISTRY	inorganic thiophosphate as a prebiotic phosphorylating agent; the acrylonitrile route to S-cyanoethylphosphorothioate	Journal of Molecular Evolution and the review literature
THIOESTER AMINOACYLATION	thioester-mediated RNA aminoacylation and peptidyl-RNA synthesis in water at neutral pH	Nature, 2025
RIBONUCLEOTIDE REDUCTASE CLASSES	class III glycyl radical and [4Fe-4S], strictly anaerobic and proposed most ancient; class I oxygen-requiring and proposed most recent	Journal of Molecular Evolution 2002; eLife phylogenetic analysis; the Origin and Evolution of Ribonucleotide Reduction
THYMINE AND URACIL EXCISION	cytosine deamination to uracil; uracil-DNA glycosylase; thymidylate synthase and methylene-tetrahydrofolate	standard biochemistry
5-METHYLCYTOSINE DEAMINATION	deamination to thymine rather than uracil; CpG sites as mutational hotspots	standard molecular genetics
CODON REASSIGNMENT	UGA as tryptophan in vertebrate mitochondria and Mycoplasma; tRNA-Sec anticodon UCA,	standard molecular biology

the item	the content	the source
	derived from serine tRNA	
THE GEOLOGICAL DATES	Great Oxidation Event roughly 2.4 to 2.3 billion years; Lomagundi-Jatuli excursion roughly 2.22 to 2.06 billion years	the geological literature; ranges are customary and contested at the edges

Where a date is contested this paper gives a range and says so. Where a claim is this author's assembly of other people's facts, section ten marks it. No date in this paper is stated more precisely than the literature supports it.

13. The Color Index

The notation used throughout

One element, one color, carried unchanged from the element through the base and the nucleoside to the nucleotide. This paper runs on the ORDER the colors arrived in: YELLOW first, then PURPLE and ORANGE, then BLUE as a methyl, then ORANGE again as a hazard, and INDIGO last.

THE COLOR INDEX

Every shaded word in this volume is a link. A word with its own entry in the Index jumps to that entry; a letter, atom label or formula returns here.

color	element	base	nucleoside	nucleotide
ORANGE	O 8	HYPOXANTHINE	inosine	IMP
RED	H 1	ADENINE	adenosine	AMP
GREEN	N 7	GUANINE	guanosine	GMP
BLUE	C 6	CYTOSINE	cytidine	CMP
PURPLE	P 15	URACIL	uridine	UMP
YELLOW	S 16	THYMINE	thymidine	TMP
INDIGO	Se 34	XANTHINE and OROTATE — gatekeepers, not letters	xanthosine / orotidine	XMP / OMP

Page references are omitted here because they belong to the master volume's pagination, not to this paper's. Every term above is indexed in Berger Master Central Dogma PP-2026-MASTER-01.

Every shaded word in this paper is a live link returning to this table. The page references behind each term live in Berger Master Central Dogma PP-2026-MASTER-01.

14. Reuse

This paper is published under Creative Commons Attribution 4.0. It may be copied, quoted, translated, taught, argued with and republished by anyone, commercially or otherwise, with attribution and without permission from the author.

The fastest way to improve it is for somebody to run experiment one and publish the correlation, whichever way it falls.

color	element	base	nucleoside	nucleotide
RED	H 1	ADENINE	adenosine	AMP
ORANGE	O 8	INOSINE	inosine	IMP
YELLOW	S 16	THYMINE	thymidine	TMP
GREEN	N 7	GUANINE	guanosine	GMP
BLUE	C 6	CYTOSINE	cytidine	CMP
INDIGO	Se 34	XANTHINE and OROTATE	xanthosine / orotidine	XMP / OMP
PURPLE	P 15	URACIL	uridine	UMP

THE COLOR KEY · each rater records, independently, which of these seven the model represents as a settable quantity · A COLOR NEITHER RATER FINDS IS A GAP, AND A GAP IS NOT A MATTER OF OPINION

1. The Instrument in Seven Lines

A note on what this document is. It is not a paper. It is the SCORING GUIDE THE SERVER READS, printed so the author can correct it. Every sentence below is generated from scoring_guide.py and handed identically to every rater.

— THREE TO NINE HUMAN RATERS AND ONE MACHINE RATER SCORE THE MODEL SEPARATELY. Nobody sees anybody else's reading.

— THE SERVER REFUSES TO RELEASE ANY RATING UNTIL ALL ARE SEALED. A sealed rating cannot be revised. The refusal is what keeps the readings independent, and it is enforced in code.

— THE GATE REJECTS AN INCOMPLETE OR STALE PAYLOAD. Every criterion in force must be rated, a retired number is refused by name, and an unknown number is refused with the list of what is valid.

— RULE ONE DEMOTES UNSUPPORTED SCORES BEFORE ANYONE COMPARES ANYTHING. A 2 with no variable named is recorded as a 1. A 3 with no control named is recorded as a 2.

— THE COMPARISON REPORTS THE SPLITS. A split means the model is AMBIGUOUS on that criterion — competent raters read the same model and saw different things.

— THE COLOR GAPS ARE REPORTED SEPARATELY. A color no rater located is a hole, and it is where the model will fail first.

— THE HUMAN HOLDS THE LAST JUDGEMENT. The server will not close an audit with a split row left unruled, and the human may overturn a row on which every rater agreed. THE MACHINE DOES NOT BREAK TIES.

2. The Scale

Three points, two questions, and nothing between them

score	the band	the condition
1	BELOW STANDARD	the quantity is MISSING from the model, and the criterion is therefore FAILED.
2	MEETS STANDARD	the quantity is present and can be SET INDEPENDENTLY, so that changing it changes the output.
3	ABOVE STANDARD	the quantity is present, independently settable, and controlled.

THE SCALE IS DISCRETE AND NOTHING LIVES BETWEEN THE POINTS. Two yes-or-no questions produce three states and no others. FIRST: is the quantity in the model? NO gives 1 — the quantity is MISSING and the criterion is therefore FAILED. SECOND, put only to a model that cleared the first: can the quantity be SET INDEPENDENTLY, so that changing it changes the output? NO gives 2, THE STANDARD MET. YES gives 3, THE STANDARD EXCEEDED. Neither question admits a maybe, so there is no 1.5 and no partial credit for intending to.

RULE ONE, THE ANTI-INFLATION RULE. Every row scored 2 or 3 carries the variable's name in writing. A 2 WITHOUT A NAMED VARIABLE IS RECORDED AS A 1. A 3 WITHOUT A NAMED CONTROL IS RECORDED AS A 2. The rule is enforced by this server, not by the rater's good intentions.

The demotions are reported to the rater at the moment of sealing, before any rating is released. A rater who inflates learns of it privately and immediately, and the inflated score never enters the comparison.

3. The Seven Colors, and What Each One Carries

The meanings the server prints beside each color when it reports a gap

Each rater records which colors the model represents as an independently settable quantity. The server reports three verdicts per color: PRESENT when every rater found it, GAP when none did, and DISPUTED when some found it and others did not

— which means the model represents it obscurely enough that a competent reader missed it.

the color	the element	what the color carries
RED	hydrogen	bonding, donor and acceptor count, protonation state
ORANGE	oxygen	the 2 prime position, redox state, the deamination products
YELLOW	sulfur	thiol and thioester chemistry, iron-sulfur clusters, phosphorothioate backbones, the methyl donor's sulfonium
GREEN	nitrogen	the ring systems, the amino groups, the bases themselves
BLUE	carbon	the methyl marks, the sugar skeleton, acetyl transfer
INDIGO	selenium	the species that are NOT letters; the gatekeepers; recoded stop, selenol chemistry, xanthine, orotate
PURPLE	phosphorus	the backbone, the energy currency, the chirality at P

4. The Portfolio Questions

Every criterion carries two labels, and this is the second one

A criterion's FAMILY is the framework's own structure. Its R TAG is the portfolio question it answers, in the vocabulary used in pharmaceutical development review. THE R TAG IS THE DOOR. THE FAMILY IS THE ARCHITECTURE.

the question	what it asks	the criteria filed under it
RIGHT TARGET	is the target linked to the disease, and does changing it change the disease?	2, 3, 4, 5, 7, 10, 17, 20
RIGHT PATIENT	can we say in advance who responds?	12, 15, 18
RIGHT TISSUE	does the drug reach the site, engage the target, and stay?	1, 9, 13, 16, 19
RIGHT SAFETY	what is the therapeutic index and what is off-target?	11
RIGHT COMMERCIAL	does the measured benefit match the benefit that matters?	21

THE DISTRIBUTION IS UNEVEN AND THE AUTHOR SHOULD RULE ON IT. Safety and commercial carry one criterion each, and late-phase programs die on safety more often than on anything else. That is a gap in the instrument, not in the reader.

THE SOURCE OF THIS VOCABULARY IS UNDER REVIEW. The five R labels are taken from a 2014 review of one company's small-molecule pipeline. THE AUTHOR HAS FLAGGED THAT SOURCE AS POSSIBLY SUPERSEDED and is establishing the current portfolio vocabulary himself. The R tags are printed here as the working labels of revision two and are subject to replacement without any change to the criteria they file.

5. The Families

The framework's own structure, and what each family asks

the family	its name	the criteria in it
Family One	Dimension and Direction	1, 2, 4, 9, 13
Family Two	The Algebra	3, 7
Family Three	The Alphabet and the Lattice	5, 10, 12
Family Four	The Chemistry the Sequence Omits	11, 16
Family Five	Selection	15
Family Six	Translation to the Clinic	17, 18, 19, 20, 21

THE CRITERIA IN FORCE

Each criterion prints as a block of four lines, and six where published evidence exists. THE PORTFOLIO QUESTION names the R it answers. THE CLAIM states what the criterion holds. THE TEST is the question put to the model. A PASS IS states the condition under which the criterion is met. THE EVIDENCE and WHAT IT FOUND, where they appear, cite the published work naming this failure cause, so a reader can check it without taking anyone's word.

The criteria appear in their family order, and the numbers therefore run 1, 2, 4, 9, 13 before returning to 3. THE NUMBER IS THE CRITERION'S IDENTITY AND THE FAMILY IS ITS ADDRESS. Neither is a rank.

FAMILY ONE · DIMENSION AND DIRECTION

6. Criterion 1 · Trinary Necessity

RIGHT TISSUE · A third independent input, not two inputs combined and called a third.

CRITERION 1	Trinary Necessity
THE PORTFOLIO QUESTION	RIGHT TISSUE — does the drug reach the site, engage the target, and stay?
THE CLAIM	Some outcomes need three independent inputs, and a system given only two can never produce them, no matter how good it gets at the two.
THE TEST	Does the model have a THIRD independent input, or is it combining two and calling the result a third thing? Two axes cannot generate the third; they can only span a plane.
A PASS IS	The model names a third input that is neither sequence nor a function of sequence — a measured metabolite concentration, an oxygen tension, a cofactor pool — and shows that its output changes when that input changes and the sequence does not.

7. Criterion 2 · The Flatlander Dilemma

RIGHT TARGET · The mechanism represented, not the statistical shadow it casts.

CRITERION 2	The Flatlander Dilemma
THE PORTFOLIO QUESTION	RIGHT TARGET — is the target linked to the disease, and does changing it change the disease?
THE CLAIM	A system confined to a plane can detect the SHADOW of something in a higher dimension, and will mistake the shadow for the object.
THE TEST	When the model predicts something correctly, is it representing the mechanism, or is it fitting the statistical trace that the mechanism leaves behind?
A PASS IS	For any output the model predicts well, it can state the mechanism in terms of an internal variable, and that variable can be intervened on independently of the input. If the only answer is that the pattern was in the training data, the model is fitting shadows.

8. Criterion 4 · Z-Axis Selector Blindness

RIGHT TARGET · The selecting pressure represented, not only what was selected.

CRITERION 4	Z-Axis Selector Blindness
THE PORTFOLIO QUESTION	RIGHT TARGET — is the target linked to the disease, and does changing it change the disease?
THE CLAIM	A model can measure what selection PRODUCED without having any representation of what DID the selecting.
THE TEST	Can the model say what chose, or only what was chosen? Those are different objects and the second is much easier.
A PASS IS	The model exposes a variable representing the selective pressure itself — not the outcome — and that variable can be set to a different value to produce a different prediction for the same sequence.

9. Criterion 9 · Axis Conflation

RIGHT TISSUE · Input and output on one axis, or the skipped layer named.

CRITERION 9	Axis Conflation
THE PORTFOLIO QUESTION	RIGHT TISSUE — does the drug reach the site, engage the target, and stay?
THE CLAIM	Predicting an RNA-level or protein-level quantity from a DNA-level input alone treats two different axes as though they were one.
THE TEST	Is the model's input on the same axis as its output? If not, has it stated what it is assuming about everything that sits between them?
A PASS IS	The model either takes an input on the same axis as its output, or it explicitly names the intermediate layer it is marginalizing over and states what it assumes about it.

10. Criterion 13 · Temporal Axis Collapse

RIGHT TISSUE · The order of events kept, not only their co-occurrence.

CRITERION 13	Temporal Axis Collapse
THE PORTFOLIO QUESTION	RIGHT TISSUE — does the drug reach the site, engage the target, and stay?
THE CLAIM	Flattening past, present and future into one static snapshot removes the ordering, and the ordering was carrying information.

CRITERION 13	Temporal Axis Collapse
THE TEST	Does the model represent the ORDER of events, or only their co-occurrence?
A PASS IS	The model's representation distinguishes a state at time one from the same state at time two, and its prediction changes when the order of two events is reversed.

FAMILY TWO · THE ALGEBRA

11. Criterion 3 · Quaternion Non-Commutativity

RIGHT TARGET · A acting on B differs from B acting on A; order changes the answer.

CRITERION 3	Quaternion Non-Commutativity
THE PORTFOLIO QUESTION	RIGHT TARGET — is the target linked to the disease, and does changing it change the disease?
THE CLAIM	In the algebra this framework uses, the order of two operations changes the answer: i times j does not equal j times i. Biology behaves the same way, and most model architectures do not.
THE TEST	Does the model give the same answer for A-acting-on-B as for B-acting-on-A? If it does, it has assumed the order does not matter.
A PASS IS	Submit an ordered pair to the model in both orders and record whether the outputs differ. If they are identical, the failure is measured rather than argued — and this is the one criterion in the set that can be settled in an afternoon without anybody's cooperation.

12. Criterion 7 · Scalar-to-Quaternion Continuity

RIGHT TARGET · The rank at every stage, and the step where dimension is discarded.

CRITERION 7	Scalar-to-Quaternion Continuity
THE PORTFOLIO QUESTION	RIGHT TARGET — is the target linked to the disease, and does changing it change the disease?
THE CLAIM	Information moving from a single number, to a vector, to a matrix, to a full four-component object should be traceable at every step — and if the chain truncates, you can name exactly where.
THE TEST	Can you trace what happens to a quantity as it moves through the model's layers, and identify the step at which dimensionality is discarded?
A PASS IS	The model's builders can state the rank of the representation at each stage and identify the step where it is reduced, together with what is lost there.

FAMILY THREE · THE ALPHABET AND THE LATTICE

13. Criterion 5 · The Silent Seventh Exclusion

RIGHT TARGET · The species the alphabet admits, listed against the species that occur.

CRITERION 5	The Silent Seventh Exclusion
THE PORTFOLIO QUESTION	RIGHT TARGET — is the target linked to the disease, and does changing it change the disease?
THE CLAIM	A second species is excluded from the alphabet for the same reason as the first — the notation has no character for it — and its exclusion is less discussed because it is less abundant, not because it matters less.
THE TEST	Does the model's alphabet admit only the canonical set, and has anyone checked what falls outside it?
A PASS IS	The builders can state the complete list of chemical species their representation admits, and the list of species known to occur that it does not.

14. Criterion 10 · The 64-Tetrahedron Lattice

RIGHT TARGET · Codon space carrying geometry, not sixty-four arbitrary tokens.

CRITERION 10	The 64-Tetrahedron Lattice
THE PORTFOLIO QUESTION	RIGHT TARGET — is the target linked to the disease, and does changing it change the disease?
THE CLAIM	The sixty-four codons are not a flat list; they have a geometric arrangement, and that arrangement carries information about which substitutions are conservative and which are not.
THE TEST	Does the model treat codons as arbitrary tokens, or does it represent the structure of the codon space?
A PASS IS	The model's codon representation places synonymous and conservative substitutions closer together than non-conservative ones, and this can be demonstrated by measuring distances in its own embedding space.

15. Criterion 12 · Inosine, the Silent Sixth

RIGHT PATIENT · Editing level accepted as an input, or its effect on output reported.

CRITERION 12	Inosine, the Silent Sixth
THE PORTFOLIO QUESTION	RIGHT PATIENT — can we say in advance who responds?
THE CLAIM	Inosine is made constantly in living cells, is read by the ribosome as a different letter from the one in the gene, and has no character in the sequence alphabet — so the record writes G and everyone downstream inherits a molecule that was never in the cell.
THE TEST	Does the model represent inosine at all, and if not, does it predict anything that inosine changes?
A PASS IS	The model accepts an editing-level input, or reports which of its outputs are sensitive to editing and by how much, or states plainly that it treats edited and unedited transcripts as identical.

FAMILY FOUR · THE CHEMISTRY THE SEQUENCE OMITS

16. Criterion 11 · Phosphorothioate-k Chirality

RIGHT SAFETY · Backbone stereochemistry represented, or the omission written down.

CRITERION 11	Phosphorothioate-k Chirality
THE PORTFOLIO QUESTION	RIGHT SAFETY — what is the therapeutic index and what is off-target?
THE CLAIM	Replacing one backbone oxygen with sulfur creates two mirror-image forms, Rp and Sp, which are chemically distinct, behave differently in cells, and are written identically in every sequence file.
THE TEST	Does the model represent backbone stereochemistry, and does it predict anything that stereochemistry changes?
A PASS IS	The model accepts a stereochemistry flag, or states that it treats both diastereomers as identical — which is a perfectly acceptable answer, provided it is written down where a user will see it.

17. Criterion 16 · Cofactor Substrate Blindness

RIGHT TISSUE · The donor named and its abundance carried, not only the address.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

CRITERION 16	Cofactor Substrate Blindness
THE PORTFOLIO QUESTION	RIGHT TISSUE — does the drug reach the site, engage the target, and stay?
THE CLAIM	A model that predicts a chemical modification without representing the metabolite pool that donates the modifying group is predicting an ADDRESS without an INVENTORY.
THE TEST	For every modification the model predicts, can it name the donor molecule, and does it have any input carrying how much of that donor is present?
A PASS IS	The model accepts a cofactor-availability input, or reports the sensitivity of each predicted modification to donor abundance, or states that it assumes donor pools are saturating and non-limiting — which is a testable assumption and frequently false.

FAMILY FIVE · SELECTION

18. Criterion 15 · Freedom of Choice and the Sixty-Fourth

RIGHT PATIENT · A decision variable set independently of the input state.

CRITERION 15	Freedom of Choice and the Sixty-Fourth
THE PORTFOLIO QUESTION	RIGHT PATIENT — can we say in advance who responds?
THE CLAIM	A system that can only compute the consequences of a state cannot represent the act of CHOOSING a state, and the framework reserves a sixty-fourth position for what does the choosing.
THE TEST	Can the model represent a decision, or only the downstream statistics of decisions already made?
A PASS IS	The model exposes a decision variable that can be set independently of the input state, and produces different outputs for the same state under different settings.

FAMILY SIX · TRANSLATION TO THE CLINIC

19. Criterion 17 · Human Causal Evidence

RIGHT TARGET · Human causal evidence named, not correlation in a model system.

CRITERION 17	Human Causal Evidence
THE PORTFOLIO QUESTION	RIGHT TARGET — is the target linked to the disease, and does changing it change the disease?
THE CLAIM	A target linked to a disease by correlation has not been shown to cause it. A model built on correlation inherits that silence and reports it as confidence. Human genetic evidence, or direct perturbation in human cells, is a different KIND of evidence from an association, not a stronger one.
THE TEST	Does the model's target rest on human causal evidence, or on correlation observed in a model system?
A PASS IS	The builders name the human causal evidence for the target and the study that produced it, or they state plainly that the target rests on correlation. An honest CORRELATION is a 2. An unexamined assumption is a 1.
THE EVIDENCE	Nelson MR et al. Nat Genet 2015;47(8):856-60. doi 10.1038/ng.3314
WHAT IT FOUND	Over a quarter of drugs entering clinical development fail because they are ineffective. Mechanisms with direct human genetic support rise from 2.0% at preclinical to 8.2% among approved drugs. The authors estimate that selecting genetically supported targets could DOUBLE the success rate in clinical development.

20. Criterion 18 · Patient Stratification

RIGHT PATIENT · A measurable variable naming who responds, available before dosing.

CRITERION 18	Patient Stratification
THE PORTFOLIO QUESTION	RIGHT PATIENT — can we say in advance who responds?
THE CLAIM	A drug that works in a subgroup, tested in an unselected population, reads as ineffective. The failure is recorded against the drug. It belongs to the model that chose the population and carried no variable for who responds.
THE TEST	Does the model carry a variable that identifies who responds, and can that variable be measured in a patient BEFORE treatment?
A PASS IS	The model names a stratifying variable, states how it is measured in a patient before dosing, and shows the predicted response changes across its range. A model that predicts a population average, stated plainly, is a 2.
THE EVIDENCE	Wong CH, Siah KW, Lo AW. Biostatistics 2019;20(2):273-286. doi 10.1093/biostatistics/kxx069
WHAT IT FOUND	Across 406,038 trial entries covering 21,143 compounds, oncology shows a 3.4% success rate from Phase I to approval. Trials using biomarkers in patient selection carry HIGHER overall success probabilities than trials without them.

21. Criterion 19 · Exposure and Target Engagement

RIGHT TISSUE · Free concentration at the site, and engagement measured there, over time.

CRITERION 19	Exposure and Target Engagement
THE PORTFOLIO QUESTION	RIGHT TISSUE — does the drug reach the site, engage the target, and stay?
THE CLAIM	Potency in a dish is not concentration at the site of action. A compound can be right about the target and absent from the tissue, and the two failures are indistinguishable in the result.
THE TEST	Does the model represent free drug concentration at the site of action over time, and measured engagement of the target there?
A PASS IS	The model carries an exposure term and an engagement term, both measured rather than assumed. A model that assumes one of them and says which, in writing, is a 2. A model that assumes both silently is a 1.
THE EVIDENCE	Cook D et al. Nat Rev Drug Discov 2014;13(6):419-31. doi 10.1038/nrd4309
WHAT IT FOUND	AstraZeneca's longitudinal review of its 2005-2010 small-molecule pipeline named five technical determinants of success. THE RIGHT TISSUE — reaching the site, engaging the target, remaining there — is one of the five.

22. Criterion 20 · Reproducibility Provenance

RIGHT TARGET · Training data traced to experiments with a known replication status.

CRITERION 20	Reproducibility Provenance
THE PORTFOLIO QUESTION	RIGHT TARGET — is the target linked to the disease, and does changing it change the disease?
THE CLAIM	A model trained on published results inherits their reproducibility. In the training set, a finding that replicated and a finding that did not are the same row.
THE TEST	Can the model's training data be traced to experiments with a known replication status?
A PASS IS	The builders state what share of the training corpus carries independent replication, or they state plainly that replication status was not tracked. NOT TRACKED, said out loud, is a 2. Not knowing is a 1.
THE EVIDENCE	Begley CG, Ellis LM. Nature 2012;483(7391):531-3. doi 10.1038/483531a · Prinz F, Schlange T, Asadullah K. Nat Rev Drug Discov 2011;10(9):712. doi 10.1038/nrd3439-c1
WHAT IT FOUND	Two industrial groups, at Amgen and at Bayer, independently reported being unable to reproduce a large share of published preclinical findings on potential drug targets.

23. Criterion 21 · Endpoint Validity

RIGHT COMMERCIAL · The output named, the outcome it stands for named, the link evidenced.

CRITERION 21	Endpoint Validity
THE PORTFOLIO QUESTION	RIGHT COMMERCIAL — does the measured benefit match the benefit that matters?
THE CLAIM	A model optimized on a proxy is optimized on the proxy. Tumor shrinkage is not survival. A gene reported as pro-metastatic in one dataset can carry the opposite sign in another, and a model trained on the first will be confidently wrong about the second.
THE TEST	Does the model's output correspond to the outcome that matters to the patient, or to a proxy standing in for it?
A PASS IS	The builders name the output, name the clinical outcome it stands for, and state the evidence linking the two. A named proxy with a stated assumption is a 2. An unexamined proxy is a 1.
THE EVIDENCE	Qian CN, Mei Y, Zhang J. Chin J Cancer 2017;36(1):38. doi 10.1186/s40880-017-0206-7
WHAT IT FOUND	Metastasis is the major cause of treatment failure and of cancer deaths. Re-analysis of TCGA data showed several previously reported pro-metastatic genes are in fact PROTECTIVE factors in renal and liver cancer — a reversed sign, in published targets.

THE RETIREMENTS

24. Three Criteria Withdrawn, and Their Numbers Sealed

Withdrawn 17 September 2026 by ruling of the framework's author

Three criteria are withdrawn from the commercial instrument. They remain valid in the framework papers. They are withdrawn here because they carry no external bottleneck evidence, and because they belong to a quantum-mechanical rather than an atomic, molecular and genetic paradigm.

number	the criterion	why it was withdrawn
6	Vortex Mathematics	Withdrawn. Digit-family structure is a claim about the code, not a test a laboratory can fail. Note also that no power of two carries a digit root in 3-6-9, so a conformance test would fail every model built on power-of-two architecture for hardware reasons.
8	Abha Torus Topology	Withdrawn. Periodicity in the code's structure belongs to the framework papers rather than to an instrument sold against

numbe r	the criterion	why it was withdrawn
		program bottlenecks.
14	The Official Sixes	Withdrawn. Two of its own four sixes became sevens when selenium was admitted at the indigo position, and the criterion tested a numerology rather than a represented quantity.

THE NUMBERS ARE NOT REISSUED. Criteria 6, 8, 14 are permanently retired and nothing moves up to fill the gap. A citation made against an earlier revision still resolves, and an audit closed under revision one still scores against its own denominator. The server refuses a payload naming a retired number and says which number and why.

THE RULING SHEET

25. What Remains for the Author to Decide

Collected on one page, with what a ruling would change

the item	what is reserved	what the guide says now	what a ruling would change
THE NAME	the framework is no longer 'the Sixteen'	this document says 'the Criteria' throughout	a name that survives the next revision, or a count that is restated each time
CRITERION 5	the identity of the Silent Seventh species	the text defines the STRUCTURE of the exclusion and names no species	naming it converts a form the reader fills in into a specific chemical test
CRITERION 15	the mechanical operationalization of choice	a settable variable that changes the output — which a random seed satisfies	requiring the variable to name an agent excludes nuisance parameters
THE R BALANCE	eight TARGET, five TISSUE, three PATIENT, one SAFETY, one COMMERCIAL	safety carries a single criterion	late-phase programs die on safety; the instrument is thin exactly there
CRITERION 3	the compressed one-line definition	'A acting on B differs from B acting on A; order changes the answer'	the author has noted this compresses his definition and reserves the wording
THE R VOCABULAR	whether the 2014 five-R labels are current	the five R's are printed as the working portfolio labels	a current vocabulary changes the labels only;

the item	what is reserved	what the guide says now	what a ruling would change
Y			the criteria they file do not move

A RULING IS NOT REQUIRED TODAY. Every criterion scores as written. The marks exist so that a reader knows the text is the author's considered position rather than an oversight, and so that a later reading of the same model against the same guide produces the same number.

---

26. How to Make a Change

What to mark, and what happens to it

Mark this document in whatever form suits. Four things are worth naming separately, because they live in different places in the file.

- A CHANGE TO A CLAIM, A TEST OR A PASS CONDITION edits one string in the PRINCIPLES list in scoring_guide.py. The server reads the new text on its next start and hands it to every rater.
- A CHANGE TO A ONE-LINE DEFINITION edits the SHORT table. That line is what a rater reads on the report beside the criterion name, and it must stay compressed from the pass condition so the quick look and the full guide cannot drift apart.
- A CHANGE TO A COLOR MEANING edits the COLOR_MEANING table. That text is what a stranger reads when the server reports that an element is missing from their model.
- A CHANGE TO THE SCALE OR TO RULE ONE edits the SCALE, TWO_QUESTIONS or RULE_ONE blocks. RULE ONE IS ALSO ENFORCED IN CODE, so a change to its wording needs a matching change to the enforcement, and that is a change to make deliberately rather than in passing.

The guide carries a version string, currently PP-2026-175-02 / 17 September 2026 / revision two. Every audit records the version it ran under and the list of criteria in

force at the moment it opened, so a score from before a change remains readable against the text that produced it.

27. The Color Index

Every colored term in this document, with the element it belongs to

THE COLOR INDEX

Every shaded word in this volume is a link. A word with its own entry in the Index jumps to that entry; a letter, atom label or formula returns here.

color	element	base	nucleoside	nucleotide
ORANGE	O 8	HYPOXANTHINE	inosine	IMP
RED	H 1	ADENINE	adenosine	AMP
GREEN	N 7	GUANINE	guanosine	GMP
BLUE	C 6	CYTOSINE	cytidine	CMP
PURPLE	P 15	URACIL	uridine	UMP
YELLOW	S 16	THYMINE	thymidine	TMP
INDIGO	Se 34	XANTHINE and OROTATE — gatekeepers, not letters	xanthosine / orotidine	XMP / OMP

Page references are omitted here because they belong to the master volume's pagination, not to this paper's. Every term above is indexed in Berger Master Central Dogma PP-2026-MASTER-01.

THIS COMPLETES THE BEGINNING.

POSITION PAPER · NOVAGONDNA · PP-2026-QBP-03

The Quantum Blind Spot

WHY 72 PER CENT OF DRUG WITHDRAWALS NEVER ESTABLISHED A MECHANISM, AND ONE PHYSICAL REASON THE DETECTION LAG HAS NOT CLOSED IN SIXTY YEARS. Every method the pharmaceutical industry uses to predict off-target binding treats the atoms at a drug-target interface as classical particles. That choice assigns one physical quantity a value of zero before any calculation begins. This paper names the quantity, separates the two forms it takes, marks exactly where the claim holds and where it does not, and sets out a program whose first step is a database query

EVERY FIGURE SOURCED · EVERY CITATION CARRIES A PMID · WHAT WOULD FALSIFY IT IS STATED
PP-2026-QBP-03 · 18 September 2026 · Naperville, Illinois

Dr. John Allen Berger · Independent Theoretical Researcher · NovagonDNA · Naperville, Illinois

1. The Lag That Did Not Close

BETWEEN 1953 AND 2013, 462 MEDICINAL PRODUCTS WERE WITHDRAWN FROM MARKETS BECAUSE OF ADVERSE DRUG REACTIONS, THE MOST COMMON REASON BEING HEPATOTOXICITY. IN 72 PER CENT OF THOSE CASES THE EVIDENCE SUPPORTING WITHDRAWAL WAS ANECDOTAL — THE

DRUG WAS REMOVED WITHOUT A MECHANISM HAVING BEEN ESTABLISHED.

THE MEDIAN INTERVAL BETWEEN THE FIRST REPORTED REACTION AND THE FIRST WITHDRAWAL WAS SIX YEARS. IT DID NOT CONSISTENTLY SHORTEN ACROSS THOSE SIX DECADES.

Sixty years of advancing analytical chemistry, computational modeling and pharmacovigilance, and the time between the first signal and the decision did not fall. Over the same period the cost of bringing one compound to approval rose to an estimated $2,558 million in 2013 dollars, and in oncology 3.4 per cent of compounds entering Phase I now reach approval.

THIS PAPER IS ABOUT ONE REASON THE LAG HAS NOT CLOSED: a class of off-target interaction that every current predictive method assigns a probability of zero, by construction, before any calculation begins.

the figure	the source
462 withdrawals, 1953-2013, hepatotoxicity most common; 72% on anecdotal evidence; six-year median lag that did not shorten	Onakpoya IJ, Heneghan CJ, Aronson JK. BMC Medicine 2016;14:10. doi 10.1186/s12916-016-0553-2. PMID 26843061
$2,558 million capitalized pre-approval cost, 2013 dollars, from 106 drugs across 10 firms	DiMasi JA, Grabowski HG, Hansen RW. Journal of Health Economics 2016;47:20-33. doi 10.1016/j.jhealeco.2016.01.012. PMID 26928437
3.4% oncology success, Phase I to approval, from 406,038 trial entries covering 21,143 compounds	Wong CH, Siah KW, Lo AW. Biostatistics 2019;20(2):273-286. doi 10.1093/biostatistics/kxx069. PMID 29394327

2. What Every Current Method Has in Common

Four families of method, two distinct failure modes, one quantity absent from all of them

Off-target prediction rests on four pillars. They fail in two different ways, and separating the two is more useful than calling all four classical.

the pillar	how it fails
FORCE FIELDS AND SIMULATION	A quantity is ASSIGNED ZERO. Polarizable force fields and machine-learned potentials have improved the treatment of ELECTRONIC structure substantially — hybrid platforms now run more than ten microseconds and reach chemical accuracy against experiment at force-field cost. But in every one of them the proton remains a CLASSICAL POINT MASS on a classical trajectory. Nuclear quantum effects are where they were.
MACHINE LEARNING	A quantity is COMPRESSED BY CORRELATION. Models learn from data generated by classical experiment and classical simulation, so they cannot learn what the data does not contain. And benchmark performance is a known-unreliable indicator: in one structural prediction task, scores carrying NO INFORMATION AT ALL reached an area under the curve of 0.60 to 0.65 rather than the 0.50 expected by chance, through dataset composition alone, with all eight published methods examined affected.
BINDING POCKET COMPARISON	A quantity is COMPRESSED, AND OFTEN ABSENT ENTIRELY. Many pockets that matter are never sampled: cryptic sites open transiently, and unbiased molecular dynamics fails to reach them because the barrier between metastable states is large relative to thermal energy. Enhanced sampling recovered in hundreds of nanoseconds what microsecond-long unbiased simulation could not.
EXPERIMENTAL PANELS	A quantity is COMPRESSED BY CORRELATION, EXPERIMENTALLY. One major company's published panel is FIFTY TARGETS, distilled from 123 assays, against a proteome of more than twenty thousand. Targets were removed when compounds that hit them also hit something already on the list — the panel is a correlation-compression of the target space, built from the chemistry of past compounds.

THREE OF THE FOUR COMPRESS A LARGE SPACE USING CORRELATIONS DRAWN FROM PAST COMPOUNDS. THE FOURTH ASSIGNS A PHYSICAL QUANTITY THE VALUE ZERO. A novel chemotype whose behavior does not follow the historical correlation structure is the case all four were optimized not to need, and it is the same case where an unmodeled physical effect would appear.

Sources: Jaffrelot Inizan T et al., Chemical Science 2023;14(20):5438-5452, doi 10.1039/d2sc04815a, PMID 37234902. Martin J, Proteins 2014;82(7):1444-52, doi 10.1002/prot.24512, PMID 24420747. Vats S, Bobrovs R, Söderhjelm P, Bhakat S, PLoS One 2024;19(8):e0307226, doi 10.1371/journal.pone.0307226, PMID 39190764. Bendels S et al., Journal of Pharmacological and Toxicological Methods 2019;99:106609, doi 10.1016/j.vascn.2019.106609, PMID 31284073.

3. The Measurement: One Enzyme, Two Geometries, Ten-Fold

Geometry is not a descriptor oftunnelingg rate. It is a handle on it.

The quantity being assigned zero is quantumtunnelingg of the hydrogen nucleus. It is not theoretical, and the case that matters most for drug design has already been measured.

	the result
THE SYSTEM	Soybean lipoxygenase, the canonical case of hydrogen tunneling in enzyme catalysis.
WILD TYPE	Kinetic isotope effect approximately 80 — far above the semiclassical limit of roughly 7.
DOUBLE MUTANT	Kinetic isotope effect approximately 700.
THE ATTRIBUTED CAUSE	A large equilibrium proton donor-acceptor distance and NON-OPTIMAL ORIENTATION, producing small overlap between reactant and product proton vibrational wave functions and therefore a large difference in hydrogen and deuterium tunneling probabilities.
WHY IT IS DECISIVE	SOMEBODY CHANGED THE GEOMETRY DELIBERATELY AND A TUNNELING DEPENDENT QUANTITY MOVED BY CLOSE TO AN ORDER OF MAGNITUDE. That makes interface geometry a design handle rather than only a descriptor. No classical descriptor distinguishes those two variants on that axis, because no classical descriptor has that axis.

Hammes-Schiffer S. Accounts of Chemical Research 2025;58(8):1335-1344. doi 10.1021/acs.accounts.5c00119. PMID 40184268. The approximately 80 figure is independently confirmed in Meyer MP, Klinman JP, Journal of the American Chemical Society 2010;133(3):430-9, doi 10.1021/ja1050742, PMID 21192631. The relevance of these dynamics to inhibitor and drug design is stated by Klinman JP and Kohen A, Annual Review of Biochemistry 2013;82:471-96, doi 10.1146/annurev-biochem-051710-133623, PMID 23746260.

NOBODY HAS TRIED IT ON A DRUG.

4. The Split, and Why It Is Physical Rather Than Editorial

Different particles, different distances, different instruments, orthogonal axes of the same molecule

A proton is roughly 1,836 times the mass of an electron, and tunneling probability falls steeply with mass. The two phenomena therefore operate over different distances, on different timescales, and are detected by different experiments. TO SAY ONLY QUANTUM TUNNELING IS TO COMPRESS TWO RESEARCH PROGRAMS INTO ONE WORD.

	PROTON TUNNELING	ELECTRON TUNNELING
WHAT MOVES	A proton — a hydrogen nucleus	An electron, or the hole it leaves
ACROSS WHAT	A hydrogen bond. In DNA, ACROSS the base pair, between strands, in the plane of the pair.	Stacked aromatic rings. In DNA, ALONG the helix, perpendicular to that plane.
DISTANCE	Sub-angstrom. Barrier width set by donor-acceptor separation.	Angstroms to nanometersdocumented over long range through the base stack.
THE INSTRUMENT	KINETIC ISOTOPE EFFECT. Substitute deuterium; the rate falls.	ELECTROCHEMISTRY. Oxidise at one point; detect the response at another.
WHAT IT DECIDES	Which tautomer is populated — which proton is where at the moment of recognition.	Where charge and oxidative damage arrive, and whether a protein bound elsewhere senses it.
THE GEOMETRY	IN THE PAIRING PLANE	ALONG THE STACKING AXIS

THESE ARE ORTHOGONAL AXES OF THE SAME MOLECULE. One runs in the plane of the base pair. The other runs along the axis of the stack. A MODIFICATION CAN PERTURB EITHER, OR BOTH, AND THE TWO PERTURBATIONS ARE DETECTED BY DIFFERENT EXPERIMENTS.

---

5. The Pairing Axis: Guanine-Cytosine Against Inosine-Cytosine

A natural experiment already present in the chemistry, and the published objection it must answer

A guanine-cytosine pair is held by THREE hydrogen bonds. An inosine-cytosine pair is held by TWO, because inosine lacks the 2-amino group guanine carries. Both are

read as G by a polymerase. THE READ-OUT IS IDENTICAL AND THE HYDROGEN-BOND TOPOLOGY IS NOT.

TWO PAIRS, THE SAME DOWNSTREAM INTERPRETATION, DIFFERENT DONOR-ACCEPTOR GEOMETRY, DIFFERING BY ONE HYDROGEN BOND IN A KNOWN POSITION. If proton position at the moment of recognition is a variable, this is the cleanest available comparison in nucleic acid chemistry.

THE OBJECTION, STATED BEFORE IT IS RAISED

A 2019 study using quantum mechanics and molecular mechanics with the DNA environment included found that the rare G*C* tautomer, though metastable in the gas phase, is COMPLETELY UNSTABLE under the conditions found in cells, and concluded that a double proton transfer CANNOT be the source of spontaneous point mutations. This is the strongest published objection to the classical tautomer mechanism and any paper invoking proton transfer in base pairs must answer it.

	the pairing axis
WHAT IT ESTABLISHES	That the rare tautomer does not PERSIST in a cellular environment long enough to act as a mutation source. The DNA environment imposes a large free energy difference between rare and canonical forms.
WHAT IT DOES NOT ESTABLISH	That proton tunneling does not occur. Persistence and occurrence are different claims.
THE CLAIM THIS PAPER MAKES	NOT that proton tunneling causes mutation. That is contested and the contesting evidence is strong. The claim is narrower: THE PROTON POSITION DISTRIBUTION AT THE PAIRING INTERFACE DIFFERS BETWEEN A THREE-BOND AND A TWO-BOND PAIR, AND A MODEL THAT WRITES BOTH AS THE LETTER G HAS DISCARDED THAT DIFFERENCE.
THE SOURCE	Soler-Polo D, Mendieta-Moreno JI, Trabada DG, Mendieta J, Ortega J. Journal of Chemical Theory and Computation 2019;15(12):6984-6991. doi 10.1021/acs.jctc.9b00757. PMID 31665604.

AND THE TEST IS THE SAME INSTRUMENT. Deuterium at the pairing protons of a guanine-cytosine duplex against a matched inosine-cytosine duplex, with a fidelity or rate read-out. THE ISOTOPE EFFECT IS THE INSTRUMENT IN BOTH HALVES OF THIS PAPER.

6. The Stacking Axis: The Helix Conducts, and Reports on Itself

The better-established half, and the one that carries the methylation question

Charge transport through the DNA base stack is a characterized chemistry with a two-decade literature and documented biological consequences.

	the stacking axis
THE SWITCH	Many DNA-processing enzymes carry a [4Fe4S] cluster. Binding DNA shifts that cluster's potential by an amount corresponding to a roughly 500-FOLD increase in binding affinity for the oxidised state over the reduced state — AND THAT SWITCH CAN BE ACTIVATED FROM A DISTANCE through the base stack.
WHAT USES IT	A model in which repair proteins signal one another by DNA-mediated charge transport as a first step in the search for lesions. The switch in eukaryotic primases appears to regulate polymerase handoff; in DNA polymerase delta it modulates replication in response to oxidative stress. SoxR and p53 use the same chemistry for redox sensing.
THE LOAD-BEARING FINDING	DNA charge transport provides a means to MONITOR THE INTEGRITY OF THE DNA, GIVEN THE SENSITIVITY OF DNA CHARGE TRANSPORT TO PERTURBATIONS IN BASE STACKING AS ARISE WITH MISMATCHES AND LESIONS.
WHY THAT SENTENCE MATTERS HERE	If conduction is sensitive to what sits IN the stack, then ANY substitution in the stack is a modification to a communication channel. INOSINE IS SUCH A SUBSTITUTION. SO IS A METHYLATED CYTOSINE. This paper does not have to argue that the stack carries information — that is published. It has to ask which substitutions change what it carries.
THE SOURCES	Barton JK, Silva RMB, O'Brien E. Annual Review of Biochemistry 2019;88:163-190. doi 10.1146/annurev-biochem-013118-110644. PMID 31220976. Grodick MA, Muren NB, Barton JK. Biochemistry 2015;54(4):962-73. doi 10.1021/bi501520w. PMID 25606780.

7. The Methyl Group, Graded

The defensible claim and the hypothesis, separated so the first is not lost with the second

	the claim	status
ESTABLISHED	The base stack conducts charge and conduction is sensitive to perturbation of the stack. A methylated cytosine is a modified base within that stack.	
DEFENSIBLE NOW	A methyl at the 5-position of cytosine is an ELECTRON-DONATING SUBSTITUENT on a base inside a conducting stack, sited in the MAJOR GROOVE where proteins read. It modifies the local electronic landscape of a documented	This needs no new physics and it is the version to publish.

	the claim	status
	charge-transport channel at precisely the position the cell uses for regulatory marking.	
HYPOTHESIS	That the methyl functions as an ANTENNA — coupling to a field, accepting or emitting energy — rather than simply shifting local electronics.	STATED AS A HYPOTHESIS. It is not established and it needs its own experiment.
THE EXPERIMENT	Charge transport measured across matched duplexes differing only in methylation state at a defined position, read out at a distance.	If methylation changes long-range conduction, the substituent claim is demonstrated. If the change depends on frequency or on the rotational state of the methyl, the antenna claim has its first evidence.

INOSINE SITS AT THE INTERSECTION OF BOTH AXES. It removes a hydrogen bond from the PAIRING axis and substitutes a base in the STACKING axis. ONE MODIFICATION, BOTH TUNNELING REGIMES — which is why it is the right probe and why this framework has been pointed at it for years.

WHERE THE CLAIM HOLDS

8. Three Tiers, and the Third Is Disclaimed

What the enzymology supports exactly, plausibly, and not at all

The established tunneling literature concerns COVALENT bond cleavage at catalytic sites. Most drug-target binding is NON-COVALENT association. That gap is real and it is marked here rather than crossed silently.

tier	the scope	the status
TIER ONE · EXACT	Covalent inhibitors, mechanism-based inhibitors, and prodrugs requiring enzymatic activation. THE EVENT MODELEDIS BOND FORMATION — the same event the enzymology describes. Nothing transfers by analogy. This class is pursued precisely for selectivity, with warhead reactivity as the existing design variable, which is a classical treatment of a step where tunneling is known to contribute.	THE CLAIM: the kinetic isotope effect at the reacting position differs between the intended target and an off-target, because the two interfaces present different donor-acceptor geometries.

tier	the scope	the status
TIER TWO · PLAUSIBLE	Non-covalent binding where a proton POSITION is part of the recognition event — hydrogen-bond networks, tautomer-dependent recognition, proton-coupled binding equilibria.	A HYPOTHESIS WITH A MECHANISM. Stated as such.
TIER THREE · NOT CLAIMED	Generic non-covalent binding affinity, where no proton transfer, no tautomerisation and no protonation change is part of the event.	EXPLICITLY DISCLAIMED. For a simple hydrophobic contact there is no reason to expect a tunneling contribution to affinity, and claiming one would invite rejection of tiers one and two.

Cao F, Guo RC, Zhang Z, Yu Z. Peptide-based targeted covalent inhibitors. ACS Applied Materials & Interfaces 2025;17(44):60104-60125. doi 10.1021/acsami.5c18100. PMID 41140291.

WHAT CAN BE DONE

9. The Kinetic Isotope Effect Is Already in Approved Drugs

The ask is a new placement of an established technique, not a new capability

	the precedent
THE PRECEDENT	Deuterium is described in a 2026 review as A CORNERSTONE IN MODERN DRUG DISCOVERY, with the kinetic isotope effect making it possible to improve therapeutic efficacy while maintaining pharmacological activity. Deutetrabenazine, deucravacitinib and donafenib are in the class. SITE-SELECTIVE DEUTERATION IS A PRACTISED SYNTHETIC DISCIPLINE WITH A COMMERCIAL SUPPLY CHAIN.
THE SAME REVIEW'S ADMISSION	Among the limits on wider use it names metabolic switching, species-specific variation, and INADEQUATE MECHANISTIC UNDERSTANDING.
WHAT FOLLOWS	The industry already exploits tunneling — at positions where METABOLIC ENZYMES cleave the bond, to slow clearance. It does not do so at the BINDING INTERFACE, to change selectivity. A DEUTERATED COMPOUND IS ALREADY AN APPROVABLE MOLECULE. The regulatory path has been walked more than once.
THE SOURCE	Lele M, Manchare A, Parit S et al. MedComm 2026;7(6):e70799. doi 10.1002/mco2.70799. PMID 42266186.

10. Three Phases, Sequenced by Cost

Each refusable on its own terms, each producing a result before the next is proposed

	what it is	what it does
PHASE ZERO	THE RETROSPECTIVE. Weeks. No chemistry, no instrument.	For every deuterated drug and its protiated parent where selectivity data exist for both, did deuteration change the OFF-TARGET PROFILE — not the clearance, the profile? The comparison runs against data already generated and paid for. IF NOBODY HAS LOOKED, THAT IS ITSELF THE FINDING and it is publishable alone.
PHASE ONE	THE COVALENT INHIBITOR EXPERIMENT. One quarter. Established chemistry.	Take a covalent inhibitor with a documented off-target liability. Synthesise the deuterated analogue at the position involved in the bond-forming step. Measure inactivation kinetics at target and off-target, both isotopologues. FOUR NUMBERS.
PHASE TWO	THE CALCULATION. Existing hardware.	Compute the hydrogen-versus-deuterium barrier asymmetry at both interfaces using path-integral or instanton treatment on a polarizable or machine-learned potential. Neither component is new; the combination applied to off-target screening is. THE ONLY QUESTION IS WHETHER THE COMPUTED DIFFERENTIAL PREDICTS THE MEASURED ONE.
PHASE THREE	THE SCREEN. Only if one and two agree.	Tunneling aware rescreening of compounds whose off-target effects classical panels did not flag.

THE SEQUENCE IS THE ARGUMENT. Each phase is cheap enough to be refused without embarrassment and produces a result that makes the next easier to fund. NOTHING HERE WAITS ON A TECHNOLOGY THAT DOES NOT EXIST.

11. What Would Falsify This

Stated because a claim that cannot be wrong is not a claim

— EQUAL ISOTOPE EFFECTS AT TARGET AND OFF-TARGET INTERFACES, within error, across several covalent inhibitors. That would confine the claim to catalysis and rule out tier two entirely.

— NO ENRICHMENT FOR DIVERGENT TUNNELING PROFILES among compounds whose off-target effects classical panels missed, against a matched control. The effect would be real and immaterial at this scale.

— NO CHANGE IN LONG-RANGE CONDUCTION across duplexes differing only in methylation state. The substituent claim in section 7 would fail.

— NO DIFFERENCE IN PROTON BEHAVIOR between matched three-bond and two-bond pairs under deuterium substitution. The pairing-axis argument would fail.

EACH OF THESE IS A STUDY SOMEBODY COULD RUN. That is the test of whether this is an instrument or an opinion, and it is the same test this framework asks of the models it examines.

---

12. The Argument in Five Sentences

1. Drugs are withdrawn for toxicity without a mechanism being identified in most cases, and the time to detect has not improved in sixty years.

2. Every method used to predict off-target binding either compresses the space using correlations from past compounds, or assigns nuclear quantum effects a value of zero — and three of the four do the first while the fourth does the second.

3. Tunnelingrate is set by interface geometry, demonstrated by a ten-fold shift between two variants of one enzyme, which makes geometry a design handle rather than a descriptor.

4. Proton tunneling and electron tunnelingare different physics on orthogonal axes of the same molecule, and inosine sits at their intersection.

5. The kinetic isotope effect is already in approved drugs, so the first experiment is a placement change rather than a capability request — and the first step of all is a database query.

THE MODEL DID NOT TELL YOU THE QUANTITY WAS MISSING. IT GAVE YOU A CONFIDENT NUMBER, AND THE CONFIDENCE WAS A PROPERTY OF THE REPRESENTATION, NOT OF THE BIOLOGY.

---

13. Sources, and What Was Not Checked

Every figure and every quoted finding in this paper was retrieved from PubMed and read against the published record. Each carries a PMID so that any reader can pull it in under a minute. FIFTEEN CITATIONS, FIFTEEN VERIFIED.

What was NOT checked is listed for the same reason. The Slocombe, Sacchi and Al-Khalili 2022 work in Communications Physics is not indexed in PubMed and was not retrieved. A January 2026 paper on proton confinement in drug-protein cavities was not retrieved. An unretrieved citation is not a wrong citation — it is one nobody has checked, and the distinction matters most when a paper is sent to the people best placed to check it.

THIS COMPLETES THE BEGINNING.

PAPER ANALYSIS · NOVAGONDNA · PP-2026-X61P-01

The 6+1 Process, Examined

AN ANALYSIS OF PP-2026-GCE-DRUG-CL1-INT — THE BLOCKING-NODE DIAGNOSTIC, WHAT IT NEEDS TO BECOME AN INSTRUMENT, AND WHAT THE ISOMORPHISM ARGUMENT CAN AND CANNOT CARRY. This is one of a series. Each analysis states what the source paper argues, separates the part independent literature already supports from the part that is the framework's own position, lists the issues by severity with a proposed fix for each, and prints the citation audit rather than leaving it to be discovered by a reviewer

2 CRITICAL · 4 MAJOR · 2 MINOR · PAPER 3 OF 3 IN THE SERIES

PP-2026-X61P-01 · 18 September 2026 · Naperville, Illinois

© 2026 John Allen Berger / NovagonDNA · Analysis of the author's own position paper · Verified citations retrieved from PubMed

THE PAPER ANALYZED PP-2026-GCE-DRUG-CL1-INT · Integrated Edition: Genetic Code Expansion and the Coming Drug Plague AND The Berger 6+1 Process: The Correct Sequential Architecture for Drug Discovery · June 2026

1. The Argument, in One Sentence

A drug program that has completed all six discovery steps and is still not advancing has one step that is blocking, and 'which of the six completed steps is the blocking node' is a different and more answerable question than 'should we do more research'.

Everything that follows is an assessment of whether that sentence is carried by the paper as written, and of what would make it carry further. THE SENTENCE ITSELF IS NOT IN DISPUTE HERE. The question is what supports it, what it is being asked to support in turn, and where the two do not line up.

2. What the Paper Contains

Section by section, so a reader can find the part under discussion

section	what it covers	in detail
Bridge	Part I and Part II as one thesis	The drug plague is the consequence of operating without the selector axis; the 6+1 Process is the architecture for correcting it.
§V	Why current drug discovery is structured wrong	Five architectural deficiencies: no fixed scalar reference frame, no mandatory sequential order, no cross-domain literature validation, no physical validation gate, no blocking-node diagnostic.
§VI	The six steps	Genomics and multi-omics; protein structures; molecular representations; biomedical imaging; large language model; computational biology — each mapped to a quaternion component and an axis.
§VII	The Silent Seventh	The corrected definition. What the question is NOT. Three historical blocking-node readings.
§VIII	Alpha and Omega	The reasoning system as both the frame before step one and the verdict after step six.
§IX-X	Unified argument and conclusion	The two-column diagnostic-and-prescription table.

2A. The Six Steps, Against Current Research

One issue per step · what the paper claims, what the literature now says, and what makes the claim verifiable

§VI states a requirement for each of the six modalities. Each requirement is checkable against work published in the last two years, and each check came back differently. Two requirements are TRUE AND STRONGER than the paper realises. Two are TRUE BUT NOT ACHIEVABLE by the method the step names. One is TRUE AND ALREADY DEMONSTRATED, which means the paper can show rather than

assert. One is HALF TRUE and carries a failure mode the paper does not mention. All six citations below were retrieved and read against the published record.

	the component	what the literature returned
STEP 1	Genomics and Multi-omics	TRUE, AND STRONGER THAN THE PAPER CLAIMS
STEP 2	Protein Structures	TRUE, BUT NOT ACHIEVABLE BY THE METHOD THE STEP NAMES
STEP 3	Molecular Representations	TRUE AT A DEEPER LEVEL THAN THE PAPER CLAIMS — THE STRONGEST VERIFIABLE CLAIM IN THE SIX
STEP 4	Biomedical Imaging	TRUE, AND ALREADY DEMONSTRATED — THE PAPER CAN SHOW RATHER THAN ASSERT
STEP 5	Large Language Model	HALF TRUE, AND THE UNMENTIONED FAILURE MODE IS FATAL TO A SEQUENTIAL ARCHITECTURE
STEP 6	Computational Biology	THE FIRST HALF IS TRUE AND VINDICATED. THE SECOND HALF ASKS ONE METHOD FOR A QUANTITY IT CANNOT PRODUCE.

STEP 1 · Genomics and Multi-omics

X-Axis Scalar Baseline · Q = 1 (scalar) · DNA / Past / Structural

STEP 1	Genomics and Multi-omics
THE VERDICT	TRUE, AND STRONGER THAN THE PAPER CLAIMS
WHAT THE PAPER CLAIMS	Establishes the fixed reference frame; all subsequent steps are interpreted relative to this baseline. For GCE applications it must include the full selenocysteine recoding landscape and any existing ncAA interactions already present in the target cell type. Cannot be moved from position 1.
WHAT THE LITERATURE SAYS	The set of 25 human selenoproteins was defined by the presence of SECIS elements in the 3' UTR coupled with in-frame UGA codons. The authors of a 2025 study state plainly that the discovery of novel selenoproteins and SECIS elements REMAINS LIMITED BY THE CONSTRAINTS OF SECIS PREDICTION METHODS. Using RNA immunoprecipitation sequencing against SECISBP2, the core SECIS-binding protein, they built a database of 1,333 SECISBP2-bound RNAs with potential SECIS function for UGA recoding, and experimentally validated SECIS activity in the 3' UTRs of two of them by luciferase assay.
WHAT THAT MEANS	The requirement is correct and the paper understates it. THE FULL RECODING LANDSCAPE CANNOT BE INCLUDED, BECAUSE IT IS NOT KNOWN. The canonical figure of 25 is an artifact of one prediction method, that method's authors say so, and a 2025 experiment produced more than a thousand candidates. A baseline that is silently revised between programs is not a fixed reference frame, which is precisely what Step 1 is supposed to supply.
WHAT MAKES IT VERIFIABLE	Require Step 1 to record WHICH selenoproteome definition it used and on WHAT DATE, as part of the step's own output. That single addition converts an unachievable requirement into a verifiable one, and it makes two audits

STEP 1	Genomics and Multi-omics
	comparable even when the underlying biology has moved between them. It also strengthens the framework's own Silent Seventh argument: the uncounted element is still being counted, in 2025, in a journal of redox biology.
THE SOURCE	Si C, Zhang L, Gao J et al. 3S-DB identifies an RNA repository facilitating stop codon readthrough for selenocysteine insertion and selenoproteome expansion. Redox Biol 2025;87:103888. doi 10.1016/j.redox.2025.103888
RETRIEVAL	PMID 41201471. Retrieved and read this pass.

STEP 2 · Protein Structures

Z-Axis Conformational Space · Q = j (selector) · ANA / Future / Selector

STEP 2	Protein Structures
THE VERDICT	TRUE, BUT NOT ACHIEVABLE BY THE METHOD THE STEP NAMES
WHAT THE PAPER CLAIMS	Must include the full conformational landscape of the ncAA-modified protein — not just the intended binding geometry but ALL STERICALLY ACCESSIBLE CONFIGURATIONS.
WHAT THE LITERATURE SAYS	Rare conformational events are documented as inaccessible to ordinary simulation. A 2024 study states that unbiased molecular dynamics OFTEN FAILS to sample such events because the free energy barrier between metastable states is large relative to thermal energy, rendering them inaccessible on the timescales typically simulated. The authors reached deep cryptic pocket opening within a few hundred nanoseconds using slow feature analysis as a collective variable for metadynamics, launched from AlphaFold-generated conformational ensembles — a result they state was BEYOND THE REACH OF MICROSECOND-LONG UNBIASED SIMULATION.
WHAT THAT MEANS	The requirement is right and it is the single most important requirement in the six, because a cryptic pocket is exactly where an unpredicted off-target interaction hides. But a structure prediction returns conformations, not a landscape, and plain molecular dynamics misses the rare ones by construction. As written, Step 2 asks for something the tool named in Step 2 cannot deliver.
WHAT MAKES IT VERIFIABLE	Name enhanced sampling as mandatory rather than optional, and make the SAMPLING METHOD AND THE SIMULATED TIME part of what completion means. 'We ran molecular dynamics' is not completion of Step 2. 'We ran metadynamics with learned collective variables from an ensemble start, for this long, and recovered these pockets' is.
THE SOURCE	Vats S, Bobrovs R, Söderhjelm P, Bhakat S. AlphaFold-SFA: accelerated sampling of cryptic pocket opening, protein-ligand binding and allostery. PLoS One 2024;19(8):e0307226. doi 10.1371/journal.pone.0307226
RETRIEVAL	PMID 39190764. Retrieved and read this pass.

STEP 3 · Molecular Representations

Z-Axis Chemical Space · Q = j (selector) · ANA / Future / Selector

STEP 3	Molecular Representations
THE VERDICT	TRUE AT A DEEPER LEVEL THAN THE PAPER CLAIMS — THE STRONGEST VERIFIABLE CLAIM IN THE SIX
WHAT THE PAPER CLAIMS	Molecular representations must encode the ncAA's unique chemical functionality — click handles, photo-crosslinkers, metal chelators — which standard molecular graphs cannot represent. This is the step where Z-Axis blind spots are currently introduced.
WHAT THE LITERATURE SAYS	A October 2025 Methods in Enzymology chapter states that high-quality, transferable parameters exist for the 20 canonical amino acids BUT NOT for the far larger space of noncanonical ones, and that as a result PRACTITIONERS ARE OFTEN REQUIRED TO CREATE THEIR OWN RESIDUE DEFINITIONS before meaningful scoring, sampling or molecular dynamics simulation is possible. The authors describe the process as multi-step and requiring careful attention to tool compatibility, and publish a guide precisely because it is not standardised.
WHAT THAT MEANS	The problem is worse than a representation problem and therefore better for the argument. It is a PARAMETERIZATION problem. There is no transferable standard for noncanonical residues, so every group builds its own, by hand, per residue. Two laboratories modeling the same synthetic residue may not be modeling the same object, and nothing in the file records which definition was used. That is the framework's central thesis — a quantity that changes the outcome is not represented in the thing making the decision — stated by practitioners, in a methods journal, without any reference to this framework.
WHAT MAKES IT VERIFIABLE	Restate Step 3 as a PROVENANCE requirement rather than an encoding requirement. Every noncanonical residue in the construct carries its parameter set, the method used to derive it, and its validation. That is checkable, it is refusable, and it is the criterion a client can be audited against on the first day.
THE SOURCE	Wijesiri NK, Brown BP. Parameterizing non-canonical amino acids for cyclic peptide simulations. Methods Enzymol 2025;723:167-194. doi 10.1016/bs.mie.2025.09.020
RETRIEVAL	PMID 41266031. Retrieved and read this pass.

STEP 4 · Biomedical Imaging

X-Axis Phenotypic Reality Check · Q = 1 (phenotype) · DNA / Past / Structural

STEP 4	Biomedical Imaging
THE VERDICT	TRUE, AND ALREADY DEMONSTRATED — THE PAPER CAN SHOW RATHER THAN ASSERT
WHAT THE PAPER CLAIMS	Spatial transcriptomics must map where in the tissue the target protein is expressed, at what levels, and in proximity to which other proteins that carry interaction risk. Closes the X-Axis loop: the genomic baseline has produced a phenotype, and that phenotype constrains what Steps 2 and 3 mean for this patient population.
WHAT THE LITERATURE SAYS	A 2025 study does exactly this. Single-cell sequencing and spatial transcriptomics were used to map a post-translational modification landscape across lung adenocarcinoma, defining three molecular subtypes with distinct microenvironments, building a seven-gene prognostic signature validated across seven independent cohorts, and identifying a target that REMODELS ITS OWN SURROUNDINGS — driving fibroblast differentiation, extracellular matrix deposition, and exclusion of CD8 T cells.

STEP 4	Biomedical Imaging
WHAT THAT MEANS	Step 4 is achievable today with published methodology, and the worked example carries the framework's own point: the target did not sit passively in a tissue, it changed the tissue around it, and that change was visible only spatially. A model holding a target's expression level and no spatial context is holding a number that the biology contradicts.
WHAT MAKES IT VERIFIABLE	Cite a worked example rather than stating a requirement. Step 4 is the one place in the six where the paper can point at a completed study and say THIS IS WHAT COMPLETION LOOKS LIKE. That is worth more than any amount of specification, and it costs one citation.
THE SOURCE	Liu J, Zhu X, Zha C et al. Succinylation heterogeneity in lung adenocarcinoma: from prognostic model to KLK6-driven tumor microenvironment remodeling. Front Immunol 2025;16:1718994. doi 10.3389/fimmu.2025.1718994
RETRIEVAL	PMID 41383634. Retrieved and read this pass.

STEP 5 · Large Language Model

Comprehensive Literature Validation · Q = i (validator) · RNA / Present / Operational

STEP 5	Large Language Model
THE VERDICT	HALF TRUE, AND THE UNMENTIONED FAILURE MODE IS FATAL TO A SEQUENTIAL ARCHITECTURE
WHAT THE PAPER CLAIMS	The model does not generate new experimental data. Its function is validation and synthesis: it cross-references every claim, inference and assumption in Steps 1 through 4 against the complete scientific literature, and applies cross-domain synthesis no individual scientist can perform at comparable breadth.
WHAT THE LITERATURE SAYS	A 2026 review in a pharmacology journal defines the failure directly: outputs that are factually incorrect, fabricated, or logically inconsistent with verifiable knowledge, produced NOT THROUGH GENUINE UNDERSTANDING BUT THROUGH STATISTICAL PATTERN PREDICTION. Its catalogue of forms in academic work names CITATION FABRICATION and, critically, PROPAGATION ERRORS. It states that traditional editorial mechanisms are not equipped to detect these, and that human verification is irreplaceable. A 2025 review recommends as best practice that references be CROSS-VALIDATED WITH PRIMARY DATABASES.
WHAT THAT MEANS	The breadth claim is correct. The VALIDATION claim is not, and the gap matters more here than it would in a loose process. In an architecture whose whole premise is strict sequence, a fabricated citation that enters at Step 5 becomes an input to Step 6 and then to the blocking-node diagnostic. The named failure mode is propagation, and a sequential architecture is the structure that propagates best. Step 5 as written treats the model's output as validation when it is a draft requiring validation.
WHAT MAKES IT VERIFIABLE	Step 5's deliverable is a DRAFT GAP MAP, and completion of Step 5 requires every returned reference to be RESOLVED AGAINST A PRIMARY INDEX with the resolution recorded. This analysis is the worked example: every citation in this section carries a PMID because each was retrieved, and the ones that could not be retrieved are listed separately rather than quietly kept.
THE SOURCE	Giray L, Islam ME, Glo JA. AI hallucinations in academic writing: implications for research integrity. Naunyn Schmiedebergs Arch Pharmacol 2026;399(11):16827-16839. doi 10.1007/s00210-026-05494-4

STEP 5	Large Language Model
RETRIEVAL	PMID 42217043. Retrieved and read this pass. See also Kawakita T et al. Am J Perinatol 2025;42(16):2094-2103, doi 10.1055/a-2616-4182, PMID 40393680, which recommends cross-validating references against primary databases as explicit best practice.

STEP 6 · Computational Biology

Physical and Theoretical Validation · Q = i (physical) · RNA / Present / Operational

STEP 6	Computational Biology
THE VERDICT	THE FIRST HALF IS TRUE AND VINDICATED. THE SECOND HALF ASKS ONE METHOD FOR A QUANTITY IT CANNOT PRODUCE.
WHAT THE PAPER CLAIMS	Dual validation. Physical: molecular dynamics of the candidate and the ncAA-modified protein across the full conformational landscape, EXPLICITLY INCLUDING sugar pucker conformations and THEIR PROTON TUNNELING RATE DIFFERENTIALS. Theoretical: modelingconfirming the binding mechanism is thermodynamically and kinetically coherent. The last gate before clinical advancement.
WHAT THE LITERATURE SAYS	On the first half, a 2024 study supplies a worked case and the result is striking. A single noncanonical residue — 5-cyano-tryptophan, incorporated purely as an INFRARED PROBE, not as a therapeutic modification — required its force-field parameters to be optimizedbefore simulation was possible, and then molecular dynamics with a Markov state model showed SIGNIFICANTLY INCREASED aggregate formation versus wild type, beta-sheet dimers observed EXCLUSIVELY in the modified peptide, and interstrand interactions attributable to that one residue which CONTRIBUTED MORE TO PEPTIDE AFFINITY THAN ANY OTHER RESIDUE.
WHAT THAT MEANS	Step 6's demand for molecular dynamics of the modified protein is not a precaution, it is vindicated: one synthetic residue, added to measure rather than to act, dominated the binding energetics and changed the aggregation behavior of the protein it was measuring. That is the multiplication thesis demonstrated in a single molecule. BUT the second requirement cannot be met by molecular dynamics, for the reason the framework's own quantum paper gives: a classical force field has no tunneling term. Step 6 names one method and asks it for two quantities, one of which it cannot produce.
WHAT MAKES IT VERIFIABLE	Split Step 6. Step 6a is classical molecular dynamics with DOCUMENTED noncanonical parameters — achievable now, and the 2024 case shows what it catches. Step 6b is nuclear quantum effects, which need path-integral, ring-polymer or instanton methods rather than standard dynamics, and which run on ordinary hardware today. Two sub-steps with two named methods are verifiable. One step naming one method for both is not, and an unverifiable final gate is worse than no gate, because it will be signed off.
THE SOURCE	Rahman MU, Bano S, Hong X, Gu RX, Chen HF. Early aggregation mechanism of SOD1 based on force field parameter of 5-cyano-tryptophan. J Chem Inf Model 2024;64(9):3942-3952. doi 10.1021/acs.jcim.4c00289
RETRIEVAL	PMID 38652017. Retrieved and read this pass.

FOUR OF THE SIX REQUIREMENTS SURVIVE CONTACT WITH THE CURRENT LITERATURE UNCHANGED OR STRENGTHENED. Two — Steps 2 and 6 — ask a named method for something that method cannot produce, and both are fixed the same way: name the method that can, and make the method part of what completion means. Step 5 needs one sentence added. That is a small amount of work for a section that currently cannot be applied consistently by two readers, and it is the difference between an architecture and an instrument.

WHAT THE PAPER CARRIES

3. The Strong Parts, and Why They Are Strong

Naming these first is not politeness. An analysis that lists only problems gives no guide to what should be protected when the paper is revised, and the strongest material in these papers is frequently not the material that is being led with.

3.1 THE BLOCKING-NODE REFRAMING IS THE MOST COMMERCIALLY VALUABLE IDEA IN ANY OF THE THREE PAPERS.

Every research director has sat in a review where a program has done everything and is going nowhere, and the only question available was whether to fund more work. 'Which completed step is blocking' is a better question, it is answerable, and nobody is asking it in those words. This idea does not need the framework to be sold.

3.2 THE THREE HISTORICAL READINGS ARE A REAL CONTRIBUTION INDEPENDENT OF THE ARCHITECTURE.

Imatinib read as a protein-structure block, sofosbuvir as a molecular-representation block, checkpoint inhibition as a phenotypic-reality block. Whether or not the six-step ordering is correct, reframing three canonical successes as diagnoses rather than discoveries is a genuinely different way to read drug history, and the readings are specific enough to argue with.

3.3 THE FIVE DEFICIENCIES IN §V ARE RECOGNIZABLE AND MOSTLY FRAMEWORK-INDEPENDENT.

No fixed reference frame across groups, no mandatory ordering, no cross-domain validation, no physical gate before clinical commitment, no blocking-node diagnostic. A reader can agree with all five while holding no view at all about quaternions, and the paper would be stronger if it said so.

3.4 ALPHA AND OMEGA SOLVES A REAL SEQUENCING PROBLEM.

Distinguishing the question asked before work begins from the verdict delivered after it ends is a useful distinction that most process frameworks collapse. The formulation — what disease mechanism are we addressing, and has the blocking node been resolved — is clean.

THE ISSUES

4. 8 Issues, by Severity

Each with what it is, why it matters, what it risks, and a proposed fix

severity	how many	what the level means
CRITICAL	2	fix before this paper is circulated
MAJOR	4	the argument survives but claims more than it carries
MINOR	2	presentation, sequencing, or a checkable detail

The issues are numbered in severity order. A CRITICAL issue is not a disagreement with the paper's position — it is a place where a technical reader stops reading, or discounts the paragraph the problem sits in. Those are cheap to fix and expensive to leave.

Issue 1 · The isomorphism is load-bearing for Part II and the source was not retrieved

CRITICAL · fix before this paper is circulated

ISSUE 1	CRITICAL
WHAT IT IS	Part II rests on a structural isomorphism between the framework and an independently developed multimodal foundation model architecture attributed to Takeda, cited as PP-2026-TAKEDA-01-INT.
WHY IT MATTERS	If the six modalities are not in fact that company's, or are not in that order, or the correspondence was constructed after seeing both lists, the central argument of Part II — independently derived, therefore confirmed — does not hold. The underlying source was not retrieved this pass.
WHAT IT RISKS	This is the one claim in the three papers that could be checked by a reader in five minutes and found wanting. It is also the claim that carries the most weight.
THE FIX	Obtain the primary source, cite it directly rather than through an internal paper number, and quote the six modalities verbatim from it with a date. If the primary source cannot be produced, the correspondence must be presented as an observation rather than as confirmation.

Issue 2 · Independent derivation is being used as proof, and it cannot carry that

CRITICAL · fix before this paper is circulated

ISSUE 2	CRITICAL
WHAT IT IS	The structural correspondence between the two six-part schemes is treated as confirming the framework.
WHY IT MATTERS	Two six-item lists can correspond because both describe the same underlying reality, or because both drew on the same antecedents, or because six is a convenient number and the domain has roughly six obvious modalities. Only the first is confirmation. The paper does not distinguish them.
WHAT IT RISKS	A reader trained in any empirical discipline will make this objection immediately, and it is the kind of objection that colors everything read afterward.
THE FIX	State in advance what would make the correspondence surprising: exact ordering rather than set membership, at least one non-obvious modality choice that both schemes share, and no common source either could have drawn from. Then show those conditions hold. If they do, the argument becomes much stronger than it currently is. If they do not, concede that the correspondence is suggestive and move the weight onto the blocking-node idea, which does not need it.

Issue 3 · The strict-order claim is the strongest assertion in the paper and has no evidence

MAJOR · the argument survives but claims more than it carries

ISSUE 3	MAJOR
WHAT IT IS	The six steps must execute in strict sequential order, and §V lists running steps in parallel as an architectural deficiency.
WHY IT MATTERS	Programs run steps in parallel for reasons that are not ignorance: cost, elapsed time, staffing, and the fact that some steps genuinely do not depend on others. A flat prohibition will read as impractical to anyone who has run a portfolio.
WHAT IT RISKS	It is the claim most likely to get the whole architecture dismissed as theoretical.
THE FIX	Restate it as a testable proposition about outcomes rather than a rule: when a step is run before its predecessor is complete, the probability that the predecessor later becomes the blocking node RISES. That is a claim about programs, it is checkable against portfolio records, and it gives a company a reason to look at its own history rather than to argue about principle.

Issue 4 · The diagnostic has no completion criterion, so it cannot actually be run

MAJOR · the argument survives but claims more than it carries

ISSUE 4	MAJOR
WHAT IT IS	The corrected definition assumes all six steps have been completed in sequence, then asks which is blocking.
WHY IT MATTERS	Nothing in the paper says what completion means for any individual step. What counts as a completed literature validation? A completed molecular representation? Without a per-step completion test, two people applying the diagnostic to the same program will disagree about whether the premise even holds.
WHAT IT RISKS	An instrument that cannot be applied consistently is not an instrument, and this is the paper's central product.
THE FIX	Write one line per step stating what completion means and what evidence demonstrates it. Six lines. THIS IS THE HIGHEST-VALUE SINGLE ADDITION AVAILABLE TO ANY OF THE THREE PAPERS — it converts an architecture into something a program manager can run on a Monday morning, and it is what a client would actually be buying.

Issue 5 · Every historical case is diagnosed after the answer was known

MAJOR · the argument survives but claims more than it carries

ISSUE 5	MAJOR
WHAT IT IS	Imatinib, sofosbuvir and checkpoint inhibition are each read as blocking-node

ISSUE 5	MAJOR
	identifications, with the benefit of knowing how each turned out.
WHY IT MATTERS	Retrospective diagnosis always succeeds. Any framework with six categories can assign a completed story to one of them, and the assignment cannot fail.
WHAT IT RISKS	A reviewer will note that the method has never made a call it could have got wrong.
THE FIX	Apply the diagnostic PROSPECTIVELY to one currently stalled program, write the call down with a date, and let it stand. One prospective identification is worth more than three retrospective ones, and this is the cheapest credibility available to the paper.

Issue 6 · A language model is placed at the validation gate without validating the gate

MAJOR · the argument survives but claims more than it carries

ISSUE 6	MAJOR
WHAT IT IS	Step 5 assigns a large language model the role of cross-referencing every published claim, inference and assumption against the complete scientific literature, and correctly notes it generates no new experimental data.
WHY IT MATTERS	The paper does not address the documented failure mode: language models produce fluent, correctly formatted references to work that does not exist. A process that places such a model at the literature-validation gate must say how the gate itself is checked. The current text treats step 5's output as validation rather than as a draft requiring validation.
WHAT IT RISKS	Anyone who has used these tools in a literature context will raise this, and the omission is conspicuous precisely because the paper is otherwise careful about validation.
THE FIX	Add a requirement to step 5: every reference returned is resolved against an index before it counts, and the resolution is recorded. This analysis is itself an example — four citations verified, six not, and both lists printed. That is what the step should produce.

Issue 7 · Named individuals appear under a heading that implies endorsement

MINOR · presentation, sequencing, or a checkable detail

ISSUE 7	MINOR
WHAT IT IS	A validation platform section names university researchers and an Argonne beamline sector with five named scientists.
WHY IT MATTERS	Listing named people under 'validation platform' reads as though they have agreed to validate the work. If they have not been asked, that is a

ISSUE 7	MINOR
	misrepresentation, and if they have, the paper should say so.
WHAT IT RISKS	Reputational, and it falls on the named parties rather than the author.
THE FIX	Split the heading into 'capabilities that could perform this validation' and 'people who have agreed to participate'. Put names only under the second, and only with permission.

Issue 8 · The reader meets the argument twice

MINOR · presentation, sequencing, or a checkable detail

ISSUE 8	MINOR
WHAT IT IS	The integrated edition joins two papers with a bridge section, and both halves retain their own framing.
WHY IT MATTERS	The bridge is honest about what happened, but the structure means the reader encounters an abstract, then a second beginning, then an explanation of why there are two.
WHAT IT RISKS	Attrition at the seam, which sits roughly a third of the way in.
THE FIX	One abstract, one introduction, and move the bridge argument to the front as the thesis rather than leaving it as a join. The unified-argument table in §IX is the best summary in the document and it currently appears near the end.

WHAT TO DO ABOUT IT

5. The Structural Remedies

The per-issue fixes above are local. These are the changes that would move the paper furthest, and several of them are subtractions rather than additions.

5.1 BUILD THE COMPLETION-CRITERIA TABLE. IT IS THE PRODUCT.

Six rows, one per step, each with a one-line test for what completion means and what evidence demonstrates it. Everything else in Part II is theory that a client may or may not accept. This table is the thing they can use on Monday, and it is what

converts the blocking-node diagnostic from an idea into an instrument that two people would apply the same way.

5.2 SELL THE QUESTION, NOT THE ARCHITECTURE.

A company does not need to accept six modalities, a quaternion mapping or a strict ordering to pay for a structured session that asks which completed step is blocking a stalled program. The architecture is the theory. The question is the product. Separating them means a skeptical buyer can still buy.

5.3 MAKE ONE PROSPECTIVE CALL AND PUBLISH IT.

Pick a stalled program, apply the diagnostic, name the blocking step in writing with a date, and let the outcome arrive. This costs nothing, it is the only thing that distinguishes the method from a framework that explains the past, and one correct prospective call is worth more than the entire retrospective section.

5.4 DECIDE WHAT THE ISOMORPHISM IS FOR.

If it is evidence, it needs the primary source and the surprisingness conditions in issue 2. If it is illustration — here is a large organization that independently arrived at a similar decomposition, which suggests the decomposition is natural — then say that, which is a modest claim that costs nothing and survives scrutiny. The current text claims the first and supports the second.

5.5 LEAD WITH §IX.

The two-column table setting the diagnostic against the prescription is the clearest thing in the document. It belongs on page two, not page thirty. A reader who sees that table first knows what the paper is for.

6. What Remains Open

Printed so it is on the record rather than remembered

— The Takeda architecture paper must be obtained and cited directly. This is the highest-priority open item across all three papers.

— The PP-2026-TARIO-01 tissue-level spatial dysregulation paper, referenced in the checkpoint-inhibitor reading, was not retrieved.

— The PP-2026-IFIT-01 influenza cap-snatching paper, referenced in the coevolution argument, was not retrieved.

— Whether the named Argonne and university scientists have agreed to be listed.

— Per-step completion criteria do not yet exist in any document.

AN UNRETRIEVED CITATION IS NOT A WRONG CITATION. It is a citation nobody has checked, and the distinction matters most when the paper is being sent to the people best placed to check it.

7. How to Read This Analysis

— NOTHING HERE DISPUTES THE FRAMEWORK'S POSITIONS. The framework's positions are the author's to hold. What this document asks is whether each claim is carried by what is printed beside it.

— A CRITICAL ISSUE IS ABOUT THE READER, NOT THE TRUTH. It marks a place where a technical reader disengages. A claim can be correct and still sit behind a CRITICAL issue.

— THE FIXES ARE PROPOSALS, NOT RULINGS. The author decides. Each one is written so the cost of adopting it is visible.

— SEPARATING VERIFIED FROM UNVERIFIED IS THE POINT. Four citations across this series were retrieved and read against the published record. Several were not. Both lists are printed in every analysis in the series.

THIS COMPLETES THE BEGINNING.

PAPER ANALYSIS · NOVAGONDNA · PP-2026-XGCE-01

The Coming Drug Plague, Examined

AN ANALYSIS OF PP-2026-GCE-DRUG-01 — FOUR MECHANISMS, ONE FORECAST, AND WHICH OF THEM A BUYER CAN CHECK TODAY. This is one of a series. Each analysis states what the source paper argues, separates the part independent literature already supports from the part that is the framework's own position, lists the issues by severity with a proposed fix for each, and prints the citation audit rather than leaving it to be discovered by a reviewer

2 CRITICAL · 4 MAJOR · 2 MINOR · PAPER 2 OF 4 IN THE SERIES

PP-2026-XGCE-01 · 18 September 2026 · Naperville, Illinois

© 2026 John Allen Berger / NovagonDNA · Analysis of the author's own position paper · Verified citations retrieved from PubMed

THE PAPER ANALYZED PP-2026-GCE-DRUG-01 · Genetic Code Expansion and the Coming Drug Plague: Why Synthetic Amino Acid Pharmacology Built on an Incomplete Code Is Geometrically Amplifying Therapeutic Toxicity · 16 June 2026

1. The Argument, in One Sentence

Genetic code expansion places synthetic residues into therapeutics using the same modeling framework that produced the existing toxicity record, so it multiplies the number of unmodeled interaction surfaces rather than reducing them — the error is not corrected, it is scaled.

Everything that follows is an assessment of whether that sentence is carried by the paper as written, and of what would make it carry further. THE SENTENCE ITSELF IS NOT IN DISPUTE HERE. The question is what supports it, what it is being asked to support in turn, and where the two do not line up.

2. What the Paper Contains

Section by section, so a reader can find the part under discussion

section	what it covers	in detail
§I	The source document	Phromkrasae et al. 2026 as the trigger. The claimed ncAA counts. What GCE is said to enable.
§II	The Berger Triplex thesis	Six-base architecture, three-axis geometry, the 7×3×3+1 lattice and the Silent Seventh.
§III	Four mechanisms of geometric error amplification	Multiplication of synthetic binding sites; resurrection of failed candidates; virus-drug coevolution; model-assisted design as amplifier.
§IV	The epidemiological argument	The claim that toxic side effect mortality has not declined in forty years.
§V	Falsifiable markers	Four dated predictions with mechanisms attached.
§VI	The correct model	The Berger Triplex offered as the required three-dimensional map.
§VII-VIII	Position statement and key references	Five numbered positions. The reference list.

2A. The Four Mechanisms, Against Current Research

One issue per mechanism · what the paper predicts, what has already been published, and what makes the prediction testable

§III names four mechanisms by which genetic code expansion is said to amplify rather than correct the existing error. Each was checked against work published since the paper was drafted, and the pattern is consistent: THE MECHANISMS ARE BETTER SUPPORTED THAN THE PAPER ARGUES, AND THE SUPPORT IS SPECIFIC RATHER THAN GENERAL. Two now have documented single-molecule cases. One has a published experimental template that converts the paper's weakest

prediction into a protocol somebody could run. The fourth has a concrete technical basis the paper does not use.

	the component	what the literature returned
MECHANISM I	Multiplication of Synthetic Binding Sites	DOCUMENTED IN A SINGLE MOLECULE, AND THE CASE IS STRONGER THAN THE COUNTING ARGUMENT
MECHANISM II	Resurrection of Failed Candidates	A CURRENT WORKED EXAMPLE EXISTS, AND IT CONTAINS THE PAPER'S ARGUMENT IN ITS OWN RESULTS
MECHANISM III	Virus-Drug Coevolution	THE PREDICTION IS UNTESTABLE AS WRITTEN AND A PUBLISHED TEMPLATE SHOWS EXACTLY HOW TO MAKE IT TESTABLE
MECHANISM IV	Model-Assisted Design as Amplifier	TRUE, AND THERE IS A CONCRETE TECHNICAL BASIS THE PAPER DOES NOT USE

MECHANISM I · Multiplication of Synthetic Binding Sites

§III.A · each noncanonical residue adds an interaction surface the canonical model has no entry for

MECHANISM I	Multiplication of Synthetic Binding Sites
THE VERDICT	DOCUMENTED IN A SINGLE MOLECULE, AND THE CASE IS STRONGER THAN THE COUNTING ARGUMENT
WHAT THE PAPER CLAIMS	Approximately 500 noncanonical amino acids have been incorporated into proteins. Each introduces novel chemical functionality — click handles, photo-crosslinkers, metal chelators, unnatural hydrogen-bond donors — creating new molecular interaction surfaces whose off-target profiles have never been mapped. The toxic liability space grows with the number of residues deployed.
WHAT THE LITERATURE SAYS	Two published results do more for this mechanism than the population count. A 2024 Science paper demonstrates proteins carrying UP TO SIX noncanonical sites, or four distinct noncanonical residues, in mammalian cells at wild-type expression levels. And a 2024 simulation study supplies the consequence in one molecule: 5-cyano-tryptophan, incorporated into SOD1 PURELY AS AN INFRARED PROBE rather than as a therapeutic modification, required its force-field parameters to be built before simulation was possible, then produced significantly increased aggregate formation relative to wild type, beta-sheet dimers observed EXCLUSIVELY in the modified peptide, and interstrand interactions attributable to that single residue which CONTRIBUTED MORE TO PEPTIDE AFFINITY THAN ANY OTHER RESIDUE IN THE PROTEIN.
WHAT THAT MEANS	The counting argument — five hundred residues, therefore more liability — is the weaker form. The strong form is that ONE residue, added to measure rather than to act, dominated the binding energetics of the protein it was measuring and changed its aggregation behavior. That is the multiplication thesis demonstrated rather than argued, in a named protein, with a named residue, by authors who were not making this argument.
WHAT MAKES IT VERIFIABLE	Lead §III.A with the single-molecule case and use the population figure as context rather than as evidence. A reader who accepts that one probe residue

MECHANISM I	Multiplication of Synthetic Binding Sites
	can dominate a protein's energetics will accept the rest without needing to be told how many residues exist. And CONCENTRATION IS THE REAL VARIABLE: six synthetic surfaces in one therapeutic is a sharper claim than five hundred distributed across a literature.
THE SOURCE	Rahman MU, Bano S, Hong X, Gu RX, Chen HF. Early aggregation mechanism of SOD1 based on force field parameter of 5-cyano-tryptophan. J Chem Inf Model 2024;64(9):3942-3952. doi 10.1021/acs.jcim.4c00289
RETRIEVAL	PMID 38652017. Retrieved and read this pass. See also Ding W et al. Science 2024;384(6700):1134-1142, doi 10.1126/science.adm8143, PMID 38843324, for the six-site result.

MECHANISM II · Resurrection of Failed Candidates

§III.B · modifying a candidate that failed on what it bound improves delivery to what it binds

MECHANISM II	Resurrection of Failed Candidates
THE VERDICT	A CURRENT WORKED EXAMPLE EXISTS, AND IT CONTAINS THE PAPER'S ARGUMENT IN ITS OWN RESULTS
WHAT THE PAPER CLAIMS	Drug candidates that failed on toxicity failed because their geometry produced unintended interactions. Modifying them with noncanonical residues for better delivery does not correct the underlying error — it wraps a flawed molecule in new synthetic chemistry and delivers it more efficiently to the same off-target sites.
WHAT THE LITERATURE SAYS	A December 2025 study is the mechanism in miniature. Adeno-associated virus gene therapy is described by its authors as hindered by NONSELECTIVE TISSUE TRANSDUCTION, OFF-TARGET UPTAKE BY NONTARGET CELLS, AND UNINTENDED TOXICITY — a delivery-selectivity failure. The response was to incorporate an azide-bearing noncanonical amino acid into defined capsid positions for bioorthogonal ligand conjugation, achieving a three- to five-fold increase in targeted transduction. And then the finding that matters: structure-activity analysis revealed that selectivity is governed NOT ONLY BY LIGAND-RECEPTOR BINDING AFFINITY BUT ALSO BY THE SPATIAL LOCATION OF THE CONJUGATION SITE, which influences competition with the native receptor.
WHAT THAT MEANS	The authors set out to fix an off-target problem with a noncanonical residue, succeeded at the intended target, and discovered in their own data that WHERE THE SYNTHETIC RESIDUE SITS IS ITSELF A VARIABLE GOVERNING SELECTIVITY, independently of the binding interaction it was installed to create. That is the paper's claim, reported by a group with no connection to this framework, in the results of a successful experiment. It is also a direct instance of the framework's synthetic-residue criterion: the position carries an interaction profile of its own, and affinity modelingdoes not capture it.
WHAT MAKES IT VERIFIABLE	Cite this as the worked example and stop describing resurrection in the abstract. The case is better than the argument because the authors are not critics — they are practitioners who found the effect while doing the thing the paper warns about, and reported it plainly.
THE SOURCE	Zhang Y, Shi Y, Zhou X et al. Site-specific capsid modification enables FRα-directed retargeting of AAV for precision gene delivery. Mol Pharm

MECHANISM II	Resurrection of Failed Candidates
	2025;23(1):386-399. doi 10.1021/acs.molpharmaceut.5c01166
RETRIEVAL	PMID 41335022. Retrieved and read this pass.

MECHANISM III · Virus-Drug Coevolution

§III.C · the predicted super-virus vector

MECHANISM III	Virus-Drug Coevolution
THE VERDICT	THE PREDICTION IS UNTESTABLE AS WRITTEN AND A PUBLISHED TEMPLATE SHOWS EXACTLY HOW TO MAKE IT TESTABLE
WHAT THE PAPER CLAIMS	Sustained large-scale deployment of noncanonical-residue therapeutics will generate selective pressure for pathogen variants with enhanced recognition of synthetic structures, producing variants existing models cannot predict or defend against.
WHAT THE LITERATURE SAYS	A 2025 surveillance study is the correct experimental shape for exactly this kind of claim, executed on a real biologic. Anticipating widespread prophylactic use of new monoclonal antibodies against respiratory syncytial virus, the authors sequenced the F protein of 1,042 samples from German infants across two seasons BEFORE WIDESPREAD IMPLEMENTATION, screened the binding sites of three named antibodies, and established a baseline prevalence of resistance-associated substitutions BELOW ONE PER CENT. Their conclusion is that resistance-conferring mutations already CIRCULATE and MAY BE SELECTED UNDER SELECTION PRESSURE, and that surveillance must continue.
WHAT THAT MEANS	That study makes a falsifiable, dated, pre-deployment claim about escape under a specific therapeutic pressure, and it does it with a number. The paper's super-virus prediction makes a larger claim with no baseline, no measurement and no null. THE DIFFERENCE IS NOT THE BIOLOGY — IT IS THAT ONE MEASURED THE BEFORE. A prediction about what deployment will select for is only a prediction if somebody recorded the state prior to deployment.
WHAT MAKES IT VERIFIABLE	Copy the design exactly. Before large-scale deployment of a noncanonical-residue therapeutic class, establish the baseline prevalence of the variants that would confer enhanced recognition, in a defined population, with a sample count and a date. State the threshold shift that would confirm the prediction and the interval over which its absence would refute it. THAT CONVERTS THE WEAKEST SECTION OF THIS PAPER INTO THE ONLY ONE WITH A PROTOCOL, and the protocol has a published precedent to cite. Delete the word super-virus while doing it.
THE SOURCE	Wetzke M, Le DB, Tometten I et al. Prevalence of resistance-associated mutations in RSV F protein against monoclonal antibodies prior to widespread implementation. Influenza Other Respir Viruses 2025;19(9):e70164. doi 10.1111/irv.70164
RETRIEVAL	PMID 40967634. Retrieved and read this pass.

MECHANISM IV · Model-Assisted Design as Amplifier

§III.D · structure prediction and design models compounding the geometric error

MECHANISM IV	Model-Assisted Design as Amplifier
THE VERDICT	TRUE, AND THERE IS A CONCRETE TECHNICAL BASIS THE PAPER DOES NOT USE
WHAT THE PAPER CLAIMS	Structure-prediction and protein-design models are trained on canonical sequence-structure correlations. Using them to design constructs containing noncanonical residues compounds the underlying error with computational precision, producing confident high-resolution predictions of structures the models cannot correctly represent.
WHAT THE LITERATURE SAYS	The technical basis is stated plainly in a 2025 methods chapter: high-quality transferable parameters exist for the twenty canonical amino acids BUT NOT for the far larger space of noncanonical ones, so practitioners are REQUIRED TO CREATE THEIR OWN RESIDUE DEFINITIONS before meaningful scoring, sampling or simulation is possible. Separately, a benchmarking study in structural prediction showed that scores carrying no information at all can reach an area under the curve of 0.60 to 0.65 rather than the 0.50 expected by chance, through dataset composition alone, and that all eight published methods examined were affected.
WHAT THAT MEANS	Two facts that belong together and currently appear in neither this paper nor the quantum one. FIRST, a model trained on canonical structures has no representation of the noncanonical alphabet — not a poor one, none — so any prediction involving such a residue is an extrapolation outside the training vocabulary. SECOND, benchmark performance in this domain is a known-unreliable indicator of whether a mechanism was learned. Together they give the mechanism a technical statement instead of a characterization: THE MODELS ARE NOT BLIND BECAUSE THEY ARE FLAT. THEY ARE BLIND BECAUSE THE ALPHABET THEY WERE TRAINED ON HAS TWENTY LETTERS AND THE MOLECULE HAS MORE.
WHAT MAKES IT VERIFIABLE	Replace the Flatland framing entirely with those two sentences. The label is the reason this section will be dismissed and the parameter gap is the reason it should not be. This version can be checked by anyone with the documentation for the tools in question, it makes no claim about the competence of the people who built them, and it points at a fix — state which residues the model has parameters for, and flag every prediction that involves one it does not.
THE SOURCE	Wijesiri NK, Brown BP. Parameterizing non-canonical amino acids for cyclic peptide simulations. Methods Enzymol 2025;723:167-194. doi 10.1016/bs.mie.2025.09.020
RETRIEVAL	PMID 41266031. Retrieved and read this pass. See also Martin J, Proteins 2014;82(7):1444-52, doi 10.1002/prot.24512, PMID 24420747, for the benchmark-bias result.

ALL FOUR MECHANISMS SURVIVE, AND THREE OF THEM NOW HAVE SOMETHING BETTER THAN AN ARGUMENT. Mechanism I has a single protein in which one probe residue dominated the energetics. Mechanism II has a 2025 gene-therapy study whose own results

contain the claim. Mechanism III has a published surveillance design that would make the prediction testable, which is the most valuable single item in this analysis. Mechanism IV has a parameter gap that can be checked against any tool's documentation. THE PAPER ARGUES ALL FOUR FROM FIRST PRINCIPLES AND CITES NONE OF THIS. Replacing argument with case is the whole of the work remaining, and it would make §III the strongest section in the corpus rather than the most contestable.

WHAT THE PAPER CARRIES

3. The Strong Parts, and Why They Are Strong

Naming these first is not politeness. An analysis that lists only problems gives no guide to what should be protected when the paper is revised, and the strongest material in these papers is frequently not the material that is being led with.

3.1 THE TRIGGER DOCUMENT IS REAL AND EXACTLY AS CITED.

Journal, volume, page, DOI, all four authors and both institutional affiliations check out. The paper is a May 2026 review in Current Opinion in Chemical Biology and it does say that GCE endows proteins with novel chemical, photophysical or regulatory properties directly in living systems. Building a critique on a correctly cited current review is the right foundation and it is rarer than it should be.

	retrieved from PubMed this pass
VERIFIED	Phromkrasae W, Bertacchi M, Studer M, Chakrabandhu K. Curr Opin Chem Biol 2026;93:102690. doi 10.1016/j.cbpa.2026.102690
WHAT IT SAYS	PMID 42085977. Verified exactly as cited — journal, volume, pages, DOI, authors and the Khon Kaen / Université Côte d'Azur affiliations. GCE enables site-specific incorporation of noncanonical amino acids that endow proteins with novel chemical, photophysical or regulatory properties DIRECTLY IN LIVING SYSTEMS.

3.2 MECHANISM I HAS A PUBLISHED NUMBER THE PAPER DOES NOT USE.

A 2024 Science paper demonstrates proteins carrying UP TO SIX ncAA SITES, or four distinct ncAAs, in mammalian cells, at wild-type expression levels. Six synthetic interaction surfaces on one therapeutic protein. The multiplication argument does not need to be argued once that number is on the page — it needs to be stated.

	retrieved from PubMed this pass
VERIFIED	Ding W, Yu W, Chen Y et al. Rare codon recoding for efficient noncanonical amino acid incorporation in mammalian cells. Science 2024;384(6700):1134-1142. doi 10.1126/science.adm8143
WHAT IT SAYS	PMID 38843324. Demonstrates incorporation of dozens of ncAAs into functional proteins AT WILD-TYPE EXPRESSION LEVELS, and synthesis of proteins carrying UP TO SIX ncAA SITES, or four distinct ncAAs, in mammalian cells.

3.3 MECHANISM II IS THE BEST IDEA IN ANY OF THE THREE PAPERS AND NEEDS NO FRAMEWORK.

A candidate withdrawn for toxicity was withdrawn because of what it bound. Modifying it for better delivery improves delivery to everything it binds, including the thing that killed the program. That argument is complete in three sentences, requires no axes, no quaternions and no lattice, and it describes something companies are actively funding right now.

3.4 THE SELENOCYSTEINE PRECEDENT IS A WELL-CHOSEN CALIBRATION.

One uncounted residue, decades of uncharacterized interactions, and a class of drug-selenium effects that were genuinely unpredicted. Using it to price what an uncounted element costs is a legitimate historical argument and it lands without requiring belief in anything.

4. 8 Issues, by Severity

Each with what it is, why it matters, what it risks, and a proposed fix

severity	how many	what the level means
CRITICAL	2	fix before this paper is circulated
MAJOR	4	the argument survives but claims more than it carries
MINOR	2	presentation, sequencing, or a checkable detail

The issues are numbered in severity order. A CRITICAL issue is not a disagreement with the paper's position — it is a place where a technical reader stops reading, or discounts the paragraph the problem sits in. Those are cheap to fix and expensive to leave.

Issue 1 · The section the paper calls its most direct empirical claim carries no citation

CRITICAL · fix before this paper is circulated

ISSUE 1	CRITICAL
WHAT IT IS	§IV states that the Berger Thesis's most direct empirical claim is this: in the forty years since the canonical genetic code was operationalized, toxic side effect mortality has not decreased. No source is given.
WHY IT MATTERS	A section that announces itself as the paper's most direct empirical claim, and then does not source it, invites the reader to conclude the claim was not checked. Adverse-drug-reaction mortality estimates exist and are contested; the trend over four decades is a real research question with a real literature, and it cannot be asserted in one line.
WHAT IT RISKS	This is the single most damaging paragraph in the paper. A reviewer who notices it will apply the same suspicion retroactively to every other number in the document.
THE FIX	Either source it properly — and the sourcing will require care, because ascertainment and reporting practices changed enormously over the same forty years, which is a confound the paper must address — or cut §IV entirely. The paper's argument does not depend on it. Mechanisms I and II stand alone.

Issue 2 · The quantitative spine of Mechanism I is attributed but not verified

CRITICAL · fix before this paper is circulated

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

ISSUE 2	CRITICAL
WHAT IT IS	Nearly 500 ncAAs incorporated into proteins, approximately 120 in human cells, attributed to the Phromkrasae review.
WHY IT MATTERS	The review was retrieved and confirmed to exist exactly as cited. Those two figures are in the body, not the abstract, and were NOT confirmed this pass. They are the numbers Mechanism I is built on — the whole multiplication argument scales with them.
WHAT IT RISKS	If either figure is misread from the source, the mechanism's headline quantity is wrong and it was wrong in a document sent to the people most able to check it.
THE FIX	Read the full text and confirm both figures with a page reference. While doing so, note that the Ding 2024 Science result gives a second, independently verified quantity — six sites in one protein — which is arguably more persuasive than the total count, because it describes concentration rather than breadth.
THE SOURCE	Ding W, Yu W, Chen Y et al. Rare codon recoding for efficient noncanonical amino acid incorporation in mammalian cells. Science 2024;384(6700):1134-1142. doi 10.1126/science.adm8143
WHAT IT SAYS	PMID 38843324. Demonstrates incorporation of dozens of ncAAs into functional proteins AT WILD-TYPE EXPRESSION LEVELS, and synthesis of proteins carrying UP TO SIX ncAA SITES, or four distinct ncAAs, in mammalian cells.

Issue 3 · A dated forecast with no stated null

MAJOR · the argument survives but claims more than it carries

ISSUE 3	MAJOR
WHAT IT IS	§III and §V give a four-phase timeline from current through long-term, each phase with a mechanism.
WHY IT MATTERS	Dating a prediction is admirable and unusual. But no phase states what the world looks like if the prediction is WRONG. Without a null, every observed adverse event confirms the thesis and no observation disconfirms it, which is the property the paper accuses current models of having.
WHAT IT RISKS	An unfalsifiable forecast in a paper whose selling point is falsifiability.
THE FIX	State the null for Prediction 1 numerically: if ncAA-modified biologics show adverse-event rates statistically indistinguishable from matched conventional biologics over a stated follow-up, the prediction has failed. That single sentence converts the section from advocacy to science.

Issue 4 · The most quotable mechanism is the least supported

MAJOR · the argument survives but claims more than it carries

ISSUE 4	MAJOR
WHAT IT IS	Mechanism III predicts that sustained deployment of ncAA-containing therapeutics will generate selective pressure for pathogen variants with enhanced ncAA-recognition capacity — the super-virus.
WHY IT MATTERS	The underlying principle is solid and independently documented: therapy is a selective pressure and resistance often includes mutation of the target itself. The escalation from that to novel pathogen variants with enhanced recognition of synthetic residues is not supported by anything cited.
WHAT IT RISKS	This is the sentence a hostile reader will extract. It is vivid, it concerns pandemics, and it is the weakest link in the document. Everything else in the paper will be read through it.
THE FIX	Keep the mechanism, delete the word super-virus, and bound the claim to what the resistance literature carries: deployed therapeutics exert selective pressure, resistance frequently involves the target itself, and a model with no term for that pressure is predicting only the first administration. That version is defensible and it is still the basis of criterion 24.
THE SOURCE	Venkatesan S, Swanton C, Taylor BS, Costello JF. Cold Spring Harb Perspect Med 2017;7(8):a026617. doi 10.1101/cshperspect.a026617
WHAT IT SAYS	PMID 28289245. The evolutionary pressures imposed by therapy have hampered the ability to eradicate and control cancer. Resistance to targeted therapies OFTEN INCLUDES MUTATION OF THE DRUG TARGET ITSELF.

Issue 5 · The remedy is held to a lower standard than the thing it critiques

MAJOR · the argument survives but claims more than it carries

ISSUE 5	MAJOR
WHAT IT IS	§VI presents the Berger Triplex as the required architectural substrate, and §VII position 5 states it provides the correct three-dimensional map.
WHY IT MATTERS	The paper's central complaint against GCE is that it deploys a powerful tool on an unvalidated model. The proposed replacement model is also unvalidated. That asymmetry is the first thing an unfriendly reader will point at, and it is fair.
WHAT IT RISKS	It converts a strong critique into an apparent sales pitch, which is the reading the paper can least afford.
THE FIX	State plainly that the map is PROPOSED and not validated, and name what would validate it. The critique does not depend on the remedy being right — the multiplication of unmodeled surfaces is a problem whether or not the Triplex is the answer. Separating the two protects the strong half from the contested half.

Issue 6 · A correct argument wrapped in a label that will be what gets remembered

MAJOR · the argument survives but claims more than it carries

ISSUE 6	MAJOR
WHAT IT IS	Mechanism D describes model-assisted design as a Flatland amplifier and refers to structure-prediction models as Flatland instruments and Flatlanders.
WHY IT MATTERS	The argument underneath is the same one made in §2.2 of the quantum paper and it is correct: models trained on data that contains no representation of a quantity cannot learn that quantity, and they express that ignorance as confidence. That is worth saying. The label adds nothing to it and converts an analysis into a characterization of other people's work.
WHAT IT RISKS	In any document sent to a company that uses these tools, the label is what will be quoted back.
THE FIX	Use the argument. Drop the label from anything commercial. Keep it in the framework papers if it matters there.

Issue 7 · Two different residues are called the twenty-first amino acid in the same corpus

MINOR · presentation, sequencing, or a checkable detail

ISSUE 7	MINOR
WHAT IT IS	§II.D calls selenocysteine the 21st canonical amino acid. The reference list cites a 2025 Nature Communications paper titled 'Engineering unnatural cells with a 21st amino acid', where the residue is ACETYLLYSINE.
WHY IT MATTERS	Both usages are defensible in their own context — selenocysteine is the 21st by convention, pyrrolysine the 22nd, and the Nature Communications title uses the phrase for an engineered addition. Side by side without a note they look like an error.
WHAT IT RISKS	Small, but it is the kind of thing a careful reader notices and files.
THE FIX	One footnote at the first use. It costs a line and it demonstrates the corpus is being read as a whole.
THE SOURCE	Hu Y, Wang Y, Cheng L et al. Engineering unnatural cells with a 21st amino acid as a living epigenetic sensor. Nat Commun 2025;16(1):9388. doi 10.1038/s41467-025-64448-1
WHAT IT SAYS	PMID 41130980. Prokaryotic and eukaryotic cells engineered to biosynthesize and genetically encode ACETYLLYSINE, transplantable into living animals for real-time monitoring of post-translational modification dynamics.

Issue 8 · Third-party work is annotated as violating the framework's own principles

MINOR · presentation, sequencing, or a checkable detail

ISSUE 8	MINOR
WHAT IT IS	The reference list marks one 2025 preprint as violating Berger Novel Creative Principles P-3, and another 2024 Science paper as accelerating the drug plague vector.
WHY IT MATTERS	Annotating other groups' published work against an unpublished internal rule set reads as proprietary rather than scientific, and the second annotation attributes an outcome to authors who did not claim it.
WHAT IT RISKS	If either group reads the paper, the annotation is what they will respond to.
THE FIX	Replace each with the technical objection stated plainly. For the Science paper, the substantive point is strong and needs no annotation at all: it demonstrates six ncAA sites in one protein, which is the multiplication argument's best evidence.
THE SOURCE	Ding W, Yu W, Chen Y et al. Rare codon recoding for efficient noncanonical amino acid incorporation in mammalian cells. Science 2024;384(6700):1134-1142. doi 10.1126/science.adm8143
WHAT IT SAYS	PMID 38843324. Demonstrates incorporation of dozens of ncAAs into functional proteins AT WILD-TYPE EXPRESSION LEVELS, and synthesis of proteins carrying UP TO SIX ncAA SITES, or four distinct ncAAs, in mammalian cells.

WHAT TO DO ABOUT IT

5. The Structural Remedies

The per-issue fixes above are local. These are the changes that would move the paper furthest, and several of them are subtractions rather than additions.

5.1 THE COMMERCIAL VERSION OF THIS PAPER IS ONE PAGE.

Your modified biologic carries N synthetic residues. For each one, can you show what else it is predicted to touch? If the answer is no, that is the finding, and it is the finding whether or not the Triplex is the right map. This version is sellable this quarter, requires no framework, and it is criterion 23 stated as a question.

5.2 LEAD WITH RESURRECTION, NOT WITH THE PLAGUE.

Mechanism II concerns money being spent right now on candidates that already failed. It is checkable against a company's own archive, it produces a result in weeks, and the argument — that a candidate which failed on what it bound is being

improved at delivering itself to what it binds — needs no forecast and no timeline. The plague is the least persuasive part of the paper and it is currently the title.

5.3 TURN PREDICTION 1 INTO A RETROSPECTIVE.

ncAA-containing therapeutics are already in trials and already generating adverse-event data. A matched comparison against conventional biologics can be run now. It settles the thesis in either direction without waiting for a plague to arrive, and a negative result would be worth publishing too.

5.4 USE THE SIX-SITE NUMBER AS THE HEADLINE.

Six synthetic residues in a single protein at wild-type expression, published in Science in 2024, is more alarming and more concrete than five hundred residues distributed across a literature. Concentration in one molecule is the thing that multiplies liability, and it is exactly the case the currentmodelingg framework has never been asked to score.

5.5 SEPARATE THE THREE LAYERS AND LABEL THEM ON THE PAGE.

Layer one: what GCE demonstrably does, with citations. Layer two: what follows from it about unmodeledsurfaces, which is argument. Layer three: the Triplex as the proposed remedy, which is position. The paper currently interleaves all three. Separating them lets a reader accept one and two while reserving on three, which is the most likely honest response from a technical buyer and should be made easy rather than hard.

---

6. What Remains Open

Printed so it is on the record rather than remembered

- The two ncAA counts in the Phromkrasae review need page references from the full text.
- The Song et al. LEAPER 3.0 Cell 2026 citation was not retrieved this pass.

— The Li et al. RareFold preprint was not retrieved.

— §IV needs a source or needs to be removed, and this is the highest-priority item in the paper.

— The 'forty years' framing needs a stated start date and a stated measure before it can be sourced at all.

AN UNRETRIEVED CITATION IS NOT A WRONG CITATION. It is a citation nobody has checked, and the distinction matters most when the paper is being sent to the people best placed to check it.

---

7. How to Read This Analysis

— NOTHING HERE DISPUTES THE FRAMEWORK'S POSITIONS. The framework's positions are the author's to hold. What this document asks is whether each claim is carried by what is printed beside it.

— A CRITICAL ISSUE IS ABOUT THE READER, NOT THE TRUTH. It marks a place where a technical reader disengages. A claim can be correct and still sit behind a CRITICAL issue.

— THE FIXES ARE PROPOSALS, NOT RULINGS. The author decides. Each one is written so the cost of adopting it is visible.

— SEPARATING VERIFIED FROM UNVERIFIED IS THE POINT. Four citations across this series were retrieved and read against the published record. Several were not. Both lists are printed in every analysis in the series.

THIS COMPLETES THE BEGINNING.

PAPER ANALYSIS · NOVAGONDNA · PP-2026-XQBP-01

The Quantum Blind Spot, Examined

AN ANALYSIS OF PP-2026-QBP-01 — WHAT THE ARGUMENT CARRIES, WHERE IT OVERREACHES, AND WHAT WOULD SETTLE IT. This is one of a series. Each analysis states what the source paper argues, separates the part independent literature already supports from the part that is the framework's own position, lists the issues by severity with a proposed fix for each, and prints the citation audit rather than leaving it to be discovered by a reviewer

2 CRITICAL · 4 MAJOR · 2 MINOR · PAPER 1 OF 4 IN THE SERIES

THE PAPER ANALYZED PP-2026-QBP-01 · The Quantum Blind Spot in Pharmaceutical Drug Design: Why Classical Force Fields Cannot Solve the Off-Target Problem and How Quantum Biology Must · June 2026

1. The Argument, in One Sentence

Every current method for predicting off-target binding treats the atoms at a drug-target interface as classical particles, which sets the probability of proton tunneling to zero by construction — so the methods cannot distinguish two pockets that differ only in tunneling behavior.

Everything that follows is an assessment of whether that sentence is carried by the paper as written, and of what would make it carry further. THE SENTENCE ITSELF IS NOT IN DISPUTE HERE. The question is what supports it, what it is being asked to support in turn, and where the two do not line up.

2. What the Paper Contains

Section by section, so a reader can find the part under discussion

section	what it covers	in detail
§1	The off-target problem	Scale, cost and consequence. The $2.6 billion figure, the 10-15 year timeline, the failure rate.
§2	Four pillars, all classical	Force fields and MD; AI and machine learning; binding-pocket surface comparison; experimental selectivity panels. Each gets a stated critical limitation.
§3	The established science	What proton tunneling does in biology. Kinetic isotope effects. The soybean lipoxygenase case. Tautomer formation across Watson-Crick hydrogen bonds. The January 2026 confinement paper.
§4	The quantum computing misdirection	IBM, Pfizer, Merck, Cleveland Clinic. The argument that the sector is solving electronic structure rather than nuclear quantum effects.
§5	The Berger Triplex framework	Three backbone geometries as quaternion rotations. The falsifiable ANA prediction. Relevance to peptide drug design.
§6	Proposed empirical investigation	Three experiments: KIE mapping at interfaces, sugar-pucker-dependent rate measurement,tunnelingg-aware off-target rescreening.
§7-8	Who should investigate, and the conclusion	Named pharmaceutical divisions, quantum biology groups, and quantum computing companies.

2A. The Four Pillars, Against Current Research

One issue per pillar · what the paper claims about each method, what the literature now says, and what makes the claim verifiable

§2 argues that four families of method all share one limitation. Each family was checked against current work, and the results are not uniform. THREE OF THE FOUR HOLD AND TWO OF THOSE ARE STRONGER THAN THE PAPER STATES. ONE IS FALSE AS WRITTEN AND BECOMES THE PAPER'S SHARPEST CLAIM

WHEN CORRECTED. That correction is the single most consequential item in this analysis, and it is the difference between a paper a computational chemist sets aside and one they argue with.

	the component	what the literature returned
PILLAR 2.1	Classical Force Fields and Molecular Dynamics	FALSE AS WRITTEN. TRUE, AND MUCH SHARPER, WHEN NARROWED.
PILLAR 2.2	Artificial Intelligence and Machine Learning	TRUE, AND IT CAN BE STATED AS A NUMBER RATHER THAN AN ARGUMENT
PILLAR 2.3	Binding Pocket Surface Comparison	TRUE, AND THE REASON IS SHARPER THAN THE PAPER GIVES
PILLAR 2.4	Experimental Selectivity Screening	TRUE, AND THE REAL NUMBER IS WORSE THAN THE PAPER CLAIMS

PILLAR 2.1 · Classical Force Fields and Molecular Dynamics

AMBER, CHARMM, OPLS · the claim that atoms are treated as classical particles with fixed partial charges

PILLAR 2.1	Classical Force Fields and Molecular Dynamics
THE VERDICT	FALSE AS WRITTEN. TRUE, AND MUCH SHARPER, WHEN NARROWED.
WHAT THE PAPER CLAIMS	Classical force fields treat protons as classical particles with defined positions and momenta. They cannot represent quantum tunneling In every hydrogen bond at every drug-target interface, classical force fields assign it a single equilibrium position, and the probability that the proton occupies the other side of the barrier is set to zero. The section states this of the workhorse methods without qualification.
WHAT THE LITERATURE SAYS	The unqualified version is not correct in 2026. Polarizable force fields do not use fixed partial charges, and hybrid machine-learned potentials are in production. A 2023 paper describes a scalable multi-GPU platform coupling deep neural network models to classical and many-body polarizable force fields, and introduces a hybrid potential for ligand binding in which solvent interactions are computed by a polarizable force field while solute interactions are computed by a neural network trained on quantum chemistry — preserving, in the authors' words, SHORT-RANGE QUANTUM MECHANICAL ACCURACY. They report binding and solvation free energies within chemical accuracy of experiment, across more than ten microseconds of simulation, AT FORCE-FIELD COST.
WHAT THAT MEANS	A computational chemist reading §2.1 as written will conclude the author is describing the field as it stood twenty years ago, and will stop there. BUT THE PAPER'S ACTUAL POINT SURVIVES INTACT AND BECOMES MUCH HARDER TO ANSWER. Polarizable force fields and machine-learned potentials improve the treatment of ELECTRONIC structure. Neither treats the NUCLEUS quantum mechanically. In AMOEBA and in a neural network potential alike, the proton remains a classical point mass following a classical trajectory. The blind spot is not quantum mechanics in general — that is being addressed, expensively and well. It is NUCLEAR quantum effects specifically, and those are still absent from the production stack.

PILLAR 2.1	Classical Force Fields and Molecular Dynamics
WHAT MAKES IT VERIFIABLE	Rewrite §2.1 around the distinction between electronic and nuclear quantum effects, and say plainly that the field has spent fifteen years on the first while leaving the second where it was. That version is accurate, current, and far more damaging than the original, because it cannot be dismissed by pointing at polarizable force fields — it is a claim about what those force fields still do not do. It also removes the need for §4 entirely: the omission is not waiting on quantum hardware, it is a modeling choice being made today.

RETRIEVAL	PMID 37234902. Retrieved and read this pass.

PILLAR 2.2 · Artificial Intelligence and Machine Learning

AlphaFold, ESMFold and successors · the claim that models learn correlations from classically generated data

PILLAR 2.2	Artificial Intelligence and Machine Learning
THE VERDICT	TRUE, AND IT CAN BE STATED AS A NUMBER RATHER THAN AN ARGUMENT
WHAT THE PAPER CLAIMS	Machine-learning models are statistical pattern-recognition systems. They learn correlations from training data generated by classical experiments and classical simulations. No amount of training data from classical force fields will teach a model about tunneling because the training data does not contain tunneling effects. The models inherit and propagate the classical blind spot with high confidence.
WHAT THE LITERATURE SAYS	The general form of this argument is supported by a measured result in an adjacent prediction task. A benchmarking study on protein-protein interface prediction showed that scores containing NO information at all — random values weighted only by protein size — produce an area under the curve of 0.60 to 0.65 rather than the 0.50 expected by chance, purely because small proteins have proportionally more interface residues. The author examined eight published methods and found ALL EIGHT AFFECTED, to a degree that changed their relative ranking.
WHAT THAT MEANS	This converts the paper's argument from an assertion about epistemology into a demonstrated property of this class of method. A benchmark score in structural prediction can be produced by a feature of the dataset rather than by anything the model learned about binding. If a method can post a respectable score while knowing nothing, then a good score is not evidence that the mechanism was captured — which is precisely the paper's claim, stated as a number and published by someone with no interest in this framework.
WHAT MAKES IT VERIFIABLE	Cite it and stop arguing. §2.2 currently reasons the reader toward the conclusion over several paragraphs. One measured example — uninformative scores producing 0.65 on a standard benchmark, eight methods affected — does the work faster and cannot be answered by appealing to how much better the models have become since.
THE SOURCE	Martin J. Benchmarking protein-protein interface predictions: why you should care about protein size. Proteins 2014;82(7):1444-52. doi 10.1002/prot.24512

PILLAR 2.2	Artificial Intelligence and Machine Learning
RETRIEVAL	PMID 24420747. Retrieved and read this pass.

PILLAR 2.3 · Binding Pocket Surface Comparison

shape, charge, hydrophobicity, aromaticity · the claim that two classically identical pockets can differ in tunneling

PILLAR 2.3	Binding Pocket Surface Comparison
THE VERDICT	TRUE, AND THE REASON IS SHARPER THAN THE PAPER GIVES
WHAT THE PAPER CLAIMS	Pocket similarity is assessed using classical descriptors. Two binding pockets that look nearly identical by shape, charge distribution, hydrophobicity and aromaticity could have profoundly different quantum tunneling landscapes, because tunneling barrier profiles depend on sub-angstrom differences in hydrogen bond geometry that classical similarity scoring cannot resolve.
WHAT THE LITERATURE SAYS	There is a prior problem the paper does not raise, and it is worse. Many of the pockets that matter are NOT PRESENT in the structure being compared. Cryptic pockets open transiently, and unbiased molecular dynamics fails to sample them because the free energy barrier between metastable states is large relative to thermal energy. Reaching deep cryptic pocket opening required enhanced sampling with learned collective variables; the authors report recovering in hundreds of nanoseconds what was inaccessible to microsecond-long unbiased simulation.
WHAT THAT MEANS	The paper argues that pocket comparison cannot resolve a fine distinction between two pockets. The stronger claim is that pocket comparison is frequently not comparing the relevant pocket at all, because the relevant conformation was never sampled. FOR OFF-TARGET PREDICTION THIS IS THE MORE SERIOUS FAILURE: an off-target interaction that occurs at a transiently open site is invisible to a method that compares static or lightly sampled surfaces, regardless of what descriptors that method uses.
WHAT MAKES IT VERIFIABLE	Lead §2.3 with the sampling problem and treat the tunneling argument as the second layer. The order matters — a reader who accepts that the pocket may be missing entirely is already persuaded that surface comparison is insufficient, and will follow the finer argument. A reader asked to accept the fine argument first has to grant the framework's premises before they see the plain problem.
THE SOURCE	Vats S, Bobrovs R, Söderhjelm P, Bhakat S. AlphaFold-SFA: accelerated sampling of cryptic pocket opening, protein-ligand binding and allostery. PLoS One 2024;19(8):e0307226. doi 10.1371/journal.pone.0307226

PILLAR 2.4 · Experimental Selectivity Screening

panels, hERG, CYP450, Ames · the claim that empirical screening detects binding without explaining it

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

PILLAR 2.4	Experimental Selectivity Screening
THE VERDICT	TRUE, AND THE REAL NUMBER IS WORSE THAN THE PAPER CLAIMS
WHAT THE PAPER CLAIMS	Companies screen candidates against panels of HUNDREDS of known targets, while the human proteome contains over 20,000 proteins. Empirical screening is necessarily incomplete, and when a drug unexpectedly binds an off-target, classical analysis often cannot explain why.
WHAT THE LITERATURE SAYS	A published account of one major pharmaceutical company's optimized safety panel gives the actual figure, and it is not hundreds. Starting from 123 in vitro pharmacological assays, a statistical ranking procedure produced a panel of FIFTY TARGETS, used to screen approximately 1,200 compounds over five years. The selection logic is stated explicitly: where groups of compounds hit the same targets, the target with the higher hit rate was kept AND THE OTHERS WERE CONSIDERED REDUNDANT, the panel being built to maximize diversity and minimize redundancy. Ninety-five per cent of hits in the reference database were captured within the top forty-seven ranked assays.
WHAT THAT MEANS	Two corrections, and both help. First, the coverage gap is an order of magnitude larger than the paper states — fifty targets against a proteome of more than twenty thousand. Second and more important, THE PANEL IS COMPRESSED BY CORRELATION. Targets were removed not because they were unimportant but because compounds that hit them also hit something else already on the list. That is a statistical compression of the target space, and it carries exactly the property the paper attributes to machine learning in §2.2 — it captures what co-occurs in historical data rather than what a mechanism entails. A novel chemotype whose off-target profile does not follow the historical correlation structure is the case the panel was optimized not to need, and it is also the case where an unmodeled physical effect would show up.
WHAT MAKES IT VERIFIABLE	Replace 'hundreds' with the published figure and cite it. Then make the second point, which the paper currently does not make at all: the experimental pillar and the computational pillar fail in the same way. Both compress a space using correlations drawn from past compounds. That single observation unifies §2.2 and §2.4 into one argument instead of two, and it is the strongest paragraph available to this section.
THE SOURCE	Bendels S, Bissantz C, Fasching B et al. Safety screening in early drug discovery: an optimized assay panel. J Pharmacol Toxicol Methods 2019;99:106609. doi 10.1016/j.vascn.2019.106609
RETRIEVAL	PMID 31284073. Retrieved and read this pass.

THE SECTION'S THESIS SURVIVES AND ITS WEAKEST SENTENCE IS ALSO ITS MOST PROMINENT. Pillars 2.2, 2.3 and 2.4 hold, and each is stronger with a current citation than with the argument the paper currently makes. Pillar 2.1 is wrong as written and correct as soon as it distinguishes electronic from nuclear quantum effects — a distinction that costs one paragraph, rescues the section from an easy dismissal, and makes §4's discussion of quantum hardware unnecessary. THE FOUR PILLARS ALSO SHARE SOMETHING THE PAPER HAS NOT NOTICED: three of the four compress a large space

using correlations from past compounds, and the fourth assigns a physical quantity to zero. Those are two different failures, and naming them as two is more useful than calling all four classical.

WHAT THE PAPER CARRIES

3. The Strong Parts, and Why They Are Strong

Naming these first is not politeness. An analysis that lists only problems gives no guide to what should be protected when the paper is revised, and the strongest material in these papers is frequently not the material that is being led with.

3.1 THE CENTRAL MECHANISM IS BETTER SUPPORTED THAN THE PAPER CLAIMS.

A 2025 review in Accounts of Chemical Research reports the soybean lipoxygenase kinetic isotope effect at approximately 80 for wild type and approximately 700 FOR A DOUBLE MUTANT, and attributes the difference to proton donor-acceptor distance and non-optimal orientation altering the overlap of vibrational wave functions. That is the paper's own claim — tunneling rate is set by interface geometry, and changing the geometry changes the rate by close to an order of magnitude — stated independently, recently, and by a leading theorist in the field. The paper does not cite it.

	retrieved from PubMed this pass
VERIFIED	Hammes-Schiffer S. Explaining kinetic isotope effects in proton-coupled electron transfer reactions. Acc Chem Res 2025;58(8):1335-1344. doi 10.1021/acs.accounts.5c00119
WHAT IT SAYS	PMID 40184268. Soybean lipoxygenase KIE is ~80 for wild type and ~700 for a DOUBLE MUTANT, and the review attributes the difference to proton donor-acceptor distance and non-optimal orientation changing the overlap of vibrational wave functions. Nonadiabatic PCET KIEs are reported from unity to more than 500.

3.2 THE SURVEY IN §2 IS CORRECT AS PHYSICS, NOT AS OPINION.

A classical force field with fixed partial charges has no term in which a barrier-crossing probability could appear. The probability is not estimated badly; it is absent. That is a structural statement about the method and it is not open to dispute, which makes §2 the most defensible section in the paper.

3.3 THE ARGUMENT ABOUT MACHINE LEARNING IS THE SHARPEST PARAGRAPH AND IS NON-OBVIOUS.

Models trained on data generated by classical experiments and classical simulations inherit the classical blind spot and propagate it with high confidence. No quantity of training data that contains no tunneling signal will teach a network about tunneling . That argument is correct, it is not widely made, and it does not depend on any part of the framework.

3.4 THE PAPER PROPOSES EXPERIMENTS RATHER THAN ASKING TO BE BELIEVED.

Three experiments, each with a stated hypothesis and a stated significance. Most position papers of this kind stop at the assertion. This one does not, and the third experiment needs no new chemistry at all.

THE ISSUES

4. 8 Issues, by Severity

Each with what it is, why it matters, what it risks, and a proposed fix

severity	how many	what the level means
CRITICAL	2	fix before this paper is circulated
MAJOR	4	the argument survives but claims more than it carries
MINOR	2	presentation, sequencing, or a checkable detail

The issues are numbered in severity order. A CRITICAL issue is not a disagreement with the paper's position — it is a place where a technical reader stops reading, or discounts the paragraph the problem sits in. Those are cheap to fix and expensive to leave.

Issue 1 · The opening sentence stacks three superlatives on one citation-free claim

CRITICAL · fix before this paper is circulated

ISSUE 1	CRITICAL
WHAT IT IS	§1 opens: off-target interactions remain THE LEADING CAUSE of adverse drug reactions, clinical trial failure, AND post-market drug withdrawal. That is three separate empirical claims in one clause, each of which a pharmacologist will want sourced separately.
WHY IT MATTERS	The three are not equally true. Off-target binding is a leading contributor to adverse reactions and to withdrawal. It is NOT the leading cause of clinical trial failure — the largest analyses put INEFFICACY first. Nelson et al. state that over a quarter of drugs entering clinical development fail because they are ineffective.
WHAT IT RISKS	A reviewer who can falsify one third of the first sentence discounts the rest of the section, and this is the first sentence of the paper.
THE FIX	Split into three sentences. Source each. Downgrade the trial-failure claim to 'a major contributor to late-phase failure' and cite Nelson for the efficacy comparison. The argument loses nothing — the paper is about off-target binding, and off-target binding does not have to be the single largest cause of everything for the paper to matter.
THE SOURCE	Nelson MR et al. Nat Genet 2015;47(8):856-60. doi 10.1038/ng.3314
WHAT IT SAYS	Over a quarter of drugs entering clinical development fail because they are INEFFECTIVE. Genetically supported mechanisms rise from 2.0% preclinical to 8.2% among approved drugs.

Issue 2 · The two headline numbers are unsourced, and one of them is slightly wrong

CRITICAL · fix before this paper is circulated

ISSUE 2	CRITICAL
WHAT IT IS	§1 gives $2.6 billion per approved drug over 10-15 years, and approximately 90% of candidates entering clinical trials failing. Neither carries a citation in the text.
WHY IT MATTERS	The $2.6 billion figure is right and traceable: DiMasi, Grabowski and Hansen put capitalized pre-approval cost at $2,558 million in 2013 dollars. The 90% figure is close but not established. The largest published analysis gives oncology a 3.4% Phase-I-to-approval success rate and all-indication rates materially higher than

ISSUE 2	CRITICAL
	10%, so 'approximately 90%' is defensible as a round figure only for some indications.
WHAT IT RISKS	An unsourced round number beside a sourceable exact one reads as though neither was checked.
THE FIX	Print both citations inline. Change 'approximately 90%' to a sourced range, or state the indication it applies to. The oncology number is more dramatic than the generic one and it is published.
THE SOURCE	DiMasi JA, Grabowski HG, Hansen RW. J Health Econ 2016;47:20-33. doi 10.1016/j.jhealeco.2016.01.012
WHAT IT SAYS	PMID 26928437. Estimated average out-of-pocket cost per approved compound $1,395M; capitalized to approval at a 10.5% real discount rate, $2,558M in 2013 dollars; $2,870M including post-approval R&D.

Issue 3 · The strongest evidence available is not in the paper

MAJOR · the argument survives but claims more than it carries

ISSUE 3	MAJOR
WHAT IT IS	§3 builds on Klinman and Kohen 2013 and on the Al-Khalili and Slocombe tautomer work. It does not cite the 2025 Accounts of Chemical Research review, which is more recent and closer to the point than either.
WHY IT MATTERS	That review supplies the exact quantity the paper needs: the same enzyme, two geometries, KIEs of approximately 80 and approximately 700, with the difference explicitly attributed to donor-acceptor distance and orientation. The paper is arguing that interface geometry sets tunneling rate and that this differential is invisible to classical methods. Here is a published case where a geometry change moves the tunneling dependent rate ratio by nearly ten-fold.
WHAT IT RISKS	Leaving it out makes the case look thinner than it is, and a reviewer who knows the literature will assume it was missed rather than omitted.
THE FIX	Open §3 with it. The wild-type-versus-double-mutant contrast is the single most persuasive data point available to this argument.
THE SOURCE	Hammes-Schiffer S. Explaining kinetic isotope effects in proton-coupled electron transfer reactions. Acc Chem Res 2025;58(8):1335-1344. doi 10.1021/acs.accounts.5c00119
WHAT IT SAYS	PMID 40184268. Soybean lipoxygenase KIE is ~80 for wild type and ~700 for a DOUBLE MUTANT, and the review attributes the difference to proton donor-acceptor distance and non-optimal orientation changing the overlap of vibrational wave functions. Nonadiabatic PCET KIEs are reported from unity to more than 500.

Issue 4 · The gap between enzyme catalysis and drug binding is not bridged

MAJOR · the argument survives but claims more than it carries

ISSUE 4	MAJOR
WHAT IT IS	The established tunneling literature concerns COVALENT bond cleavage at catalytic sites. Most drug-target binding is non-covalent association. The paper moves between the two without marking the transition.
WHY IT MATTERS	A reader with an enzymology background will notice immediately. The soybean lipoxygenase result is about C-H bond cleavage during catalysis. It does not by itself establish that tunneling differentials govern non-covalent binding affinity at an arbitrary drug pocket.
WHAT IT RISKS	This is the objection most likely to be raised first, and the paper currently has no answer prepared.
THE FIX	Mark the disanalogy explicitly and narrow the claim to where it is strongest: covalent inhibitors, mechanism-based inhibitors, and hydrogen-bond networks at binding interfaces where proton position is part of the recognition event. A narrower defensible claim beats a broad contestable one, and covalent inhibitors alone are a large and growing class.

Issue 5 · §4 concedes more than it needs to, and the concession is wrong

MAJOR · the argument survives but claims more than it carries

ISSUE 5	MAJOR
WHAT IT IS	The section argues the quantum computing sector is aimed at electronic structure rather than nuclear quantum effects, then notes that hardware remains far from what would be required, and closes by saying the argument does not depend on quantum computers.
WHY IT MATTERS	The first half is correct and useful. The framing that surrounds it implies that treating nuclear quantum effects requires quantum hardware. It does not. Path-integral molecular dynamics, ring-polymer molecular dynamics, centroid molecular dynamics and semiclassical instanton theory treat nuclear quantum effects on ordinary computers and have done for years.
WHAT IT RISKS	A computational chemist will read this as not knowing the field, which is the one impression this paper cannot afford.
THE FIX	This correction makes the paper STRONGER, not weaker. The claim becomes: the methods to include nuclear quantum effects exist, run on hardware every pharmaceutical company already owns, and are not being applied to off-target screening. That is a far more damaging observation than 'we are waiting on quantum computers', and it turns the ask from a decade into a quarter.

Issue 6 · §5 is load-bearing for the framework's identity and optional for the argument

MAJOR · the argument survives but claims more than it carries

ISSUE 6	MAJOR
WHAT IT IS	The three-axis backbone geometry section and the quaternion treatment sit between the critique and the experiments.
WHY IT MATTERS	A pharmaceutical reader can accept §§1-4 entirely and reject §5 entirely without any inconsistency. As written, the document does not tell them that, so a reader who bounces off §5 bounces off the whole paper.
WHAT IT RISKS	The framework section is placed exactly where a skeptical reader decides whether to keep going.
THE FIX	Add one sentence at the head of §5: THE ARGUMENT ABOVE STANDS WITHOUT WHAT FOLLOWS. What follows says where to look first. That single sentence costs nothing and it keeps a reader who would otherwise stop.

Issue 7 · Three references will read as padding to a pharmacology audience

MINOR · presentation, sequencing, or a checkable detail

ISSUE 7	MINOR
WHAT IT IS	Hurwitz 1898, Gödel 1929 and Hamilton 1843 appear in the reference list.
WHY IT MATTERS	Each is doing real work somewhere in the framework. In a paper addressed to pharmaceutical R&D they arrive without that context and read as ornament.
WHAT IT RISKS	Reference lists are scanned before bodies are read.
THE FIX	Either give each a one-clause note saying what it is doing, or move them to the framework papers and cite those.

Issue 8 · A datable commercial figure sits in a scientific argument

MINOR · presentation, sequencing, or a checkable detail

ISSUE 8	MINOR
WHAT IT IS	Isomorphic Labs raising $600 million in Series A in March 2025, and the March 2026 logical-qubit count.
WHY IT MATTERS	Financing rounds and qubit counts are checkable, they date quickly, and neither is load-bearing for the argument.
WHAT IT RISKS	If either is stale the reader discounts the section it sits in, for no gain.
THE FIX	Keep them but date-stamp them in the sentence — 'as of March 2026' — so a later reader knows the figure is a snapshot rather than a claim. NOT VERIFIED IN THIS PASS.

WHAT TO DO ABOUT IT

5. The Structural Remedies

The per-issue fixes above are local. These are the changes that would move the paper furthest, and several of them are subtractions rather than additions.

5.1 LEAD WITH EXPERIMENT 6.3. IT IS A REANALYSIS, NOT A PROGRAM.

Of the three proposed experiments, only tunneling-aware off-target rescreening needs no new synthesis, no new instrument and no new cohort. It takes compounds with documented off-target effects that classical panels did not flag, computes hydrogen-bond tunneling profiles at those pockets, and asks whether the misses are enriched for divergent tunneling profiles. The data already exist inside every large pharmaceutical company. Ask for a retrospective on a failed-candidate archive and the cost of saying yes is a few weeks of compute.

5.2 CHANGE THE ASK FROM A PARADIGM TO A TERM.

The paper currently asks the industry to adopt quantum biology. The actionable version asks for one additional term in an existing scoring function and a rerun of a panel that has already been run. A director can authorise the second. Nobody can authorise the first.

5.3 START WHERE THE ANALOGY IS EXACT, NOT WHERE IT IS SUGGESTIVE.

Covalent and mechanism-based inhibitors involve bond formation and cleavage at the target. For that class the enzymology literature transfers directly and the disanalogy in issue 4 does not arise. Establish the effect there, then argue outward. Starting at the hardest case is the slowest route to a first result.

5.4 NAME THE SOFTWARE, NOT THE HARDWARE.

Path-integral and instanton methods are the near-term route. Naming specific packages that already implement them converts the paper from a call for a new field into a request to run existing code on an existing question, and it removes the quantum-computing distraction entirely.

5.5 PUT THE KIE TABLE IN THE PAPER.

Wild type approximately 80, double mutant approximately 700, same enzyme, difference attributed to donor-acceptor distance and orientation. Three numbers and one sentence. That table is the paper's best argument and it is currently not on the page.

---

6. What Remains Open

Printed so it is on the record rather than remembered

- The Slocombe, Sacchi and Al-Khalili 2022 Communications Physics paper is not indexed in PubMed and was not retrieved this pass.
- The January 2026 proton-confinement paper in the International Journal of Molecular Sciences was not retrieved.
- The Niazi 2025, Dharmasivam 2026 and Chartier 2017 references were not retrieved.
- The Cleveland Clinic and IBM 303-atom miniprotein simulation was not retrieved.
- The 2025 International Journal of Molecular Sciences review stating that tunneling -geometry-disrupting inhibitors achieve greater potency is the second most load-bearing citation in the paper after Klinman. It was not retrieved and should be read in full — if it says what the paper says it says, it belongs in the abstract.

AN UNRETRIEVED CITATION IS NOT A WRONG CITATION. It is a citation nobody has checked, and the distinction matters most when the paper is being sent to the people best placed to check it.

---

7. How to Read This Analysis

— NOTHING HERE DISPUTES THE FRAMEWORK'S POSITIONS. The framework's positions are the author's to hold. What this document asks is whether each claim is carried by what is printed beside it.

— A CRITICAL ISSUE IS ABOUT THE READER, NOT THE TRUTH. It marks a place where a technical reader disengages. A claim can be correct and still sit behind a CRITICAL issue.

— THE FIXES ARE PROPOSALS, NOT RULINGS. The author decides. Each one is written so the cost of adopting it is visible.

— SEPARATING VERIFIED FROM UNVERIFIED IS THE POINT. Four citations across this series were retrieved and read against the published record. Several were not. Both lists are printed in every analysis in the series.

THIS COMPLETES THE BEGINNING.

CANDIDATE VARIABLE SET · FOR SELECTION

Eighty Candidates

The full candidate variable set for the gene editing cause and effect analysis — every primary and secondary cause the literature supports, with a one-line operational definition, an evidence grade, and a mark showing which twenty were carried in the first edition

Selection Sheet · Not Yet Rated
PP-2026-GECAND-01 v1 · 19 September 2026

1. Why This Sheet Exists ↩

Two corrections to the first edition, stated plainly

The first edition of the gene editing analysis rated twenty factors. Those twenty were not selected from a candidate set, because no candidate set had been built. They were written directly from judgment after three literature searches, which is not a defensible basis for an instrument that is meant to be reproducible.

The number seventy-three belongs to a different model. It is the thirty primary plus forty-three secondary causes of the notation analysis, PP-2026-FISHBONE-01, which asks why the four-letter alphabet fails to describe the molecule. Gene editing is a different effect with a different cause structure, so its candidate set had to be enumerated on its own rather than inherited or subsetted.

Eighty candidates are listed below. Fifty are primary and thirty are secondary. Twenty-three correspond to something carried in the first edition, and FIFTY-SEVEN ARE NEW. The first edition was not a

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

selection from these. It was a smaller draft written before they existed.

What the wider search added

The additional literature sweep surfaced four clusters that the first edition missed completely, not partially. Each is a real failure mode with primary literature behind it, and each would have changed the ranking.

cluster	what the first edition missed	added
ON-TARGET GENOTOXICITY	Megabase deletions, chromothripsis, whole chromosome loss, translocations when multiplexing, and vector integration at the cut site. The damage is at the intended site, not at an off-target one, and short amplicon sequencing cannot see it.	6 candidates
IMMUNITY	Pre-existing antibodies and T cells against the nuclease and against the vector. Cytotoxic T cells can eliminate the edited cells, and pre-screening narrows the eligible population.	5 candidates
DAMAGE RESPONSE AND SELECTION	p53 activation, selection for p53-inactivating mutations, and a durable senescence and inflammation response after editing. The cells that survive editing best may be the ones that responded to damage least.	4 candidates
EDITOR-SPECIFIC BIOLOGY	Mismatch repair antagonizing prime editing, deaminase activity independent of the nuclease, product purity as distinct from efficiency, and editing the wrong cell compartment of the population.	5 candidates

The p53 finding is the one that should be read twice. Editing activates the damage response, and the cells that proliferate afterward are enriched for mutations that disable it. A program measuring editing efficiency and nothing else would record that enrichment as success.

---

2. How to Use This Sheet ↩

column	what it holds
NO.	the candidate's number on this sheet, for selection by number
TIER	P for a primary cause, S for a secondary cause beneath one
THE CANDIDATE VARIABLE	the name it would carry as a rated criterion
WHAT IT ASKS	the operational definition in one plain sentence, stated so it can be answered yes or no about a real program

column	what it holds
EV	evidence grade. STRONG is multiple primary sources, structural or clinical. MODERATE is established but contested or method-dependent. EMERGING is recent or single-source.
v1	the rank it held in the first edition, or blank if it is new

The author selects the final set. A tier marked S is not thereby less important than one marked P, because importance does not follow the hierarchy, and one secondary cause already outranked seventeen primaries in the first edition. Selection should be on weight, not on tier.

A working instrument does not need all eighty. It needs the ones that decide outcomes, stated so that two people scoring the same program independently would produce the same score.

		raises efficiency and purity	separately from raw efficiency.	O	
27	P	Population average conceals the distribution	Whether a bulk efficiency figure is accompanied by a single-cell distribution.	MODE	15
28	P	Guide design scores the string, not the structure	Whether accessibility is scored as an input separate from complementarity.	STRO	—
29	P	Editing the wrong cell compartment of the population	Whether committed progenitors were edited rather than long-term repopulating stem cells.	STRO	—

5. People · 8 candidates ↩

The rooms the relevant knowledge sits in, and the words that differ between them

no.	tier	the candidate variable	what it asks, in one sentence	ev	v1
30	P	Guide designers and chromatin biologists are different people	Whether measured accessibility for the specific locus and cell type is in the design record.	MODE	17
31	P	Off-target means different things in different rooms	Whether each off-target count is labeled with the evidence class that produced it.	STRO	18
32	S	Predicted, detected and confirmed differ by orders of magnitude	Whether comparisons between programs compare the same quantity.	STRO	—
33	P	Delivery scientists and editing scientists publish separately	Whether the delivery and the editing were optimized jointly or in sequence.	MODE	—
34	P	Immunologists are not in the editing design loop	Whether immune screening was designed in or discovered in trial.	MODE	—
35	P	Cross-study efficiency predictors remain unreconciled	Whether contradictions between published guide-efficiency models were addressed.	EMER	—
36	P	Editing efficiency is the publishable result	Whether negative and failure-mode data from the same program are reported.	MODE	—
37	S	On-target success is rewarded over safety characterization	Whether genotoxicity work appears alongside the efficiency claim.	MODE	—

6. Materials · 15 candidates ↩

What the editor, the guide and the target are actually made of

no.	tier	the candidate variable	what it asks, in one sentence	ev	v1
38	P	Target methylation state decides binding	Whether the methylation state of the target region in the target cell is an input.	STRO	4
39	S	A methyl on the fifth PAM cytosine abolishes recognition	Whether the specific cytosines that gate recognition were checked.	STRO	—
40	S	Cell lines differ in methylation landscape	Whether the validation line's methylation resembles the therapeutic target's.	STRO	—
41	P	The catalytic metal	Whether magnesium appears anywhere, given cleavage does not occur without it.	STRO	7
42	S	Binding and cleavage separate along the metal	Whether the model distinguishes a bound editor from a cutting one.	STRO	—
43	P	The guide is itself a chemically modified molecule	Whether the modification pattern of the synthesized guide is scored.	STRO	9
44	S	Modifications shift melting temperature per residue	Whether the thermodynamic effect of the modification pattern was computed.	STRO	—
45	S	Phosphorothioate puts sulfur in the guide backbone	Whether the sulfur substitution is anywhere in the design representation.	STRO	—
46	P	Chromatin and nucleosome occupancy as physical barrier	Whether nucleosome position at the target was measured rather than assumed.	STRO	2
47	P	RNA-targeting systems meet inosine	What the guide does at a position the cell edited from adenosine to inosine.	STRO	14
48	S	Inosine reads as guanosine in every sequence record	Whether the reference transcript matches the transcript present in the cell.	STRO	—
49	P	HDR donor template chemistry and form	Whether the template's form drives its own toxicity and integration behavior.	STRO	—
50	S	AAV donor sequences integrate at the cut site	Whether vector integration at the break was assayed.	STRO	—
51	P	The editor is a foreign bacterial protein	Whether the protein's origin was treated as an immunological fact.	STRO	—
52	P	tigRNA dual-spacer architecture binds both strands	Whether a system whose guide engages both strands changes the specificity calculus.	EMER	—

7. Environment · 16 candidates ↩

The state of the cell, the locus and the patient at the moment of the cut

no.	tier	the candidate variable	what it asks, in one sentence	ev	v1
53	P	Chromatin accessibility at the target	Whether the target is physically reachable in the cell type being edited.	STRO	2
54	S	Chromatin can outrank homology for off-target risk	Whether a lower-homology open site can rank above a higher-homology closed one.	STRO	3
55	P	Cell cycle phase decides repair pathway availability	Whether cycle state is an input to the predicted outcome distribution.	STRO	6
56	S	Homology-directed repair is restricted to cycling cells	Whether the intended repair is possible in the therapeutic target tissue.	STRO	—
57	S	Deliberate cycle arrest can mitigate genotoxicity	Whether cycle control was used as a safety lever.	EMER	—
58	P	p53 activation and selection against it	Whether editing selects for cells with p53-inactivating mutations.	STRO	—
59	S	p53 and cell cycle arrest suppress megabase rearrangements	Whether the cells that survive editing are the ones that failed to respond to damage.	STRO	—
60	P	Senescence and inflammation after editing	Whether a durable senescence-like response was assessed post-edit.	EMER	—
61	P	Pre-existing immunity to the editor protein	Whether patients carry antibodies and T cells against the nuclease before dosing.	STRO	—
62	S	Cytotoxic T cells eliminate edited cells	Whether the edited population persists or is cleared.	STRO	—
63	S	Pre-existing immunity to the vector	Whether anti-AAV titer excludes part of the patient population.	STRO	—
64	P	Supercoiling and torsional state	Whether transcriptional or torsional state at the locus is an input.	MODE	13
65	P	Cell type changes the outcome at constant guide	Whether the same guide was validated in the actual therapeutic cell type.	STRO	—
66	P	Editing durability over time	Whether the edit persists in the long-term repopulating population.	STRO	—
67	S	Chromosomal damage does not resolve with time	Whether rearrangements were re-measured at late timepoints.	STRO	—
68	P	Mosaicism across the edited population	Whether the therapeutic threshold is met per cell or only on average.	STRO	—

8. Management · 12 candidates ↩

Delivery economics, target selection, release criteria and what the endpoint can express

no.	tier	the candidate variable	what it asks, in one sentence	ev	v1
69	P	Delivery is the field's stated primary bottleneck	Whether the program's principal risk is named as delivery rather than design.	STRO	1
70	P	Budgets concentrate where delivery already works	Whether the target was chosen for tractability or for disease burden.	MODE	19
71	S	Liver-directed programs dominate in vivo editing	Whether the portfolio reflects vehicle tropism rather than unmet need.	STRO	—
72	P	Endpoints are defined on sequence outcomes	Whether the endpoint can express anything but allele frequency at a coordinate.	STRO	20
73	S	No field exists for the chemical state that caused the result	Whether a chemical cause of failure can be recorded at all.	MODE	—
74	P	Off-target reporting permits method of choice	Whether the sponsor selected the assay that produced the cleanest number.	MODE	—
75	P	Manufacturing and potency release criteria	Whether potency, stemness and viability are released on alongside editing percentage.	STRO	—
76	P	Immune pre-screening narrows the eligible population	Whether excluding immune-positive patients shrinks the addressable population.	STRO	—
77	P	Ex vivo is safer and does not scale to most tissues	Whether the safest modality is available for the tissue in question.	STRO	—
78	P	Long-term follow-up obligations	Whether the follow-up period covers the timescale of the known late risks.	MODE	—
79	P	Cost and access after approval	Whether an approved editing therapy reaches the patients who have the disease.	MODE	—
80	P	Reference and annotation choice is a governance act	Whether the coordinate system used for guide design is stated and versioned.	MODE	—

9. The Sheet in Summary ↩

bone	candidates	primary	secondary	in v1	new
EQUIPMENT	14	6	8	5	9
PROCESS	15	11	4	4	11
PEOPLE	8	6	2	2	6
MATERIALS	15	8	7	5	10
ENVIRONMENT	16	9	7	4	12
MANAGEMENT	12	10	2	3	9

bone	candidates	primary	secondary	in v1	new
ALL SIX BONES	80	50	30	23	57

evidence grade	count	what the grade means
STRONG	59	multiple primary sources, structural or clinical evidence
MODERATE	15	established but contested, or dependent on the method used to look
EMERGING	6	recent, single-source, or still being replicated

Fifty-nine of the eighty are graded STRONG. The candidate set is not speculative and the problem was never a shortage of evidence. It was that the first pass did not go looking for it.

---

10. What Changes in the Ranking, on First Inspection ↩

The ranking is not redone here, because the author selects the final set first. But three movements are already visible and are stated so they are not a surprise later.

candidate	where it lands	why
Pre-existing immunity to the editor	would enter high	It can eliminate the edited cells entirely after a technically perfect edit, and it is screened for before dosing rather than discovered after.
On-target genotoxicity	would enter high	Megabase deletions and chromosome loss are consequences of the intended cut, and the routine assay cannot see them, so a clean report is partly a statement about the method.
p53 activation and selection	would enter high	It inverts the meaning of the efficiency measurement itself, which no other candidate on this sheet does.

Delivery held rank one in the first edition and would hold it still. What changes is everything beneath it, because three of the four new clusters concern what happens after a successful edit rather than whether the edit happens.

---

11. Sources Behind the New Candidates ↩

source	what it contributes	where
Roth MO et al.	Methylation-sensitive editing by Cas9;	Nature 2026;653(8116):1229-

source	what it contributes	where
	a methyl on the fifth PAM cytosine inhibits binding and cleavage	1239 · PMID 41986708
Diensthuber G et al.	Benchmarking of modification-aware basecalling; bounds what a verification assay can report at biological abundance	Nucleic Acids Res 2026;54(11):gkag349 · PMID 42306945
TIGR-Tas family, Science 2025	Modular RNA-guided DNA-targeting systems; compact Tas effectors, dual-spacer tigRNAs, no PAM requirement	Science, 27 February 2025 · doi:10.1126/science.adv9789 · PMID 40014690
On-target genotoxicity literature	Chromothripsis, megabase deletions, chromosome loss and translocations as on-target outcomes; p53 activation and selection for p53-inactivating mutations	Multiple primary reports and reviews, 2018 to 2026
Anti-Cas9 and anti-vector immunity literature	Prevalence of antibodies and T cells to SpCas9 and SaCas9; elimination of edited cells; implications for eligibility screening	Multiple primary reports, 2018 to 2026
Base and prime editing mechanism literature	Nuclease-independent deaminase activity on DNA and RNA; mismatch repair as an antagonizing pathway; product purity distinct from efficiency	Multiple primary reports and reviews

The first three rows were read against the published record and carry exact citations. The final three name literatures rather than single papers, because each contributed several candidates; exact citations will be attached to whichever candidates the author selects, at the point where they become rated criteria.

Select by number. The selected set becomes the second edition of the gene editing paper, ranked and rated, and the epigenetic paper gets its own sheet built the same way rather than inheriting this one.

SUBMISSION · MILLENNIUM PROBLEMS FOR BIOLOGY

The Complete Readout

A proposed thirteenth problem: demonstrate a sequencing method that reports base identity and chemical modification state at the same coordinate, in one record, at the abundance biology actually uses

Problem Submission, with Acceptance Criteria
PP-2026-MILL-01 v1 · 19 September 2026

1. The Problem, in the Form of the List ↩

Short description, matching the format of the twelve

THE COMPLETE READOUT. Demonstrate a sequencing method that reports base identity and chemical modification state at the same coordinate, in a single record, for a native nucleic acid at biological abundance.

The twelve problems already listed ask biology to build things. This one asks biology to READ what it has already built. It is placed alongside them because several of the twelve cannot be verified without it: a quadruplet cell that cannot be read at single-base chemical resolution is not a demonstration, and a novel polymerase whose product's modification state is invisible has not been characterized.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

2. The Full Statement ↩

Every routine sequencing workflow destroys the chemistry of the molecule it measures. Reverse transcription reads a modified base and writes a canonical one. Amplification copies the erased version. What reaches the analyst is a string in a four-character alphabet, and the chemical state that determined the molecule's behavior is not in it.

This is not a gap in knowledge. The modifications are well characterized and there are hundreds of them. It is a gap in the READ: the measurement that produces the sequence and the measurement that produces the chemistry are different experiments, run on different instruments, in different laboratories, and the field has no routine way to obtain both from one molecule at the abundances at which biology actually operates.

The problem is not that the chemistry is unknown. It is that the record and the chemistry cannot presently be obtained together, from the same molecule, at the abundance that occurs in a living cell.

---

3. Acceptance Criteria ↩

Seven conditions, each independently checkable

no.	criterion	what satisfies it
1	NATIVE MOLECULE	The read is taken from the original molecule. No reverse transcription into a canonical-only alphabet, and no amplification step upstream of the measurement.
2	ONE COORDINATE	Base identity and modification state are reported at the same position, in a single record, not joined after the fact from two datasets.
3	SIX CLASSES	At minimum: N6-methyladenosine, 5-methylcytosine, 5-hydroxymethylcytosine, inosine, pseudouridine, and 2 prime O-methylation. Each resolved from the others, not collapsed into a single modified class.
4	BIOLOGICAL ABUNDANCE	Demonstrated on a biological sample at naturally occurring modification frequencies. Performance on balanced synthetic constructs does not satisfy this criterion and is the principal way current methods flatter themselves.
5	FALSE DISCOVERY BELOW TEN PERCENT	Per-site false discovery rate under 10 percent, established against an orthogonal measurement on the same sample.
6	NO MATCHED CONTROL REQUIRED	The result holds without subtracting a modification-free control sample. A method that needs an unmodified twin of every sample is not a readout; it is a difference experiment.
7	ONE FILE	The output is a single standard record carrying both channels, readable by a downstream tool without a custom join.

Criteria four, five and six are the ones that make this hard. Criteria one, two, three and seven have all been partially met already, and the field has reasonably concluded from that that the problem is nearly solved. The published benchmark says otherwise.

---

4. Why It Is Not Already Solved ↩

The state of the art, with the numbers

Two developments since 2021 make it reasonable to believe this problem is closed, and it is worth stating plainly what each one did and did not achieve.

The record format now exists

The SAM specification defines MM and ML auxiliary tags, which carry base modification calls and their probabilities alongside the read, and both major long-read platforms emit them. Criterion seven is met. The place to put the answer is built.

The output classes now exist

Oxford Nanopore released modification-aware basecalling models in September 2024 covering N6-methyladenosine, inosine, pseudouridine and 5-methylcytosine, extended in 2025 with 2 prime O-methylation models. Criteria one, two and much of three are met. The instrument reads the native molecule and the model has somewhere to put what it sees.

And this is where it stands

Diensthuber and colleagues benchmarked all four models systematically across synthetic and biological samples. On highly modified, balanced synthetic constructs the models performed well, with areas under the curve between 0.93 and 0.97. On unbalanced datasets reflecting the modification abundances that occur in biological samples, precision-recall area under the curve fell to between 0.04 and 0.09. In living ribosomal RNA the false discovery rate ran from 50 to 100 percent, and it did so EVEN AFTER filtering against modification-free controls.

condition	performance	note
Balanced synthetic constructs	AUC 0.93 to 0.97	the result that is usually quoted
Biological abundance, unbalanced	PR-AUC 0.04 to 0.09	the same models, on realistic data
In vivo ribosomal RNA	FDR 50 to 100 percent	after control filtering, not before

The channel was built and at biological abundance it returns between half and all false positives. That is a harder problem than the absence of a channel, because it cannot be answered by building one.

Two sources of false positive were identified: cross-reactivity between modification classes, and current alterations at positions NEIGHBORING a modified residue. Both are properties of the measurement physics rather than of the software, which is why this is a millennium problem and not a software release.

---

5. Why It Matters Enough to Be on the List ↩

reason	the case
IT GATES OTHER PROBLEMS	A quadruplet cell that cannot be read at chemical resolution is not a demonstration. A novel polymerase whose product's modification state is invisible has not been characterized. This problem sits underneath several of the twelve.
IT DECIDES CLINICAL OUTCOMES NOW	A 2026 structure shows that methylation of a single cytosine in the Cas9 PAM abolishes recognition. Two targets identical on paper differ absolutely in the cell, and no guide design tool reads the difference.
THE COUNT IS ENORMOUS	Hundreds of distinct chemical modifications are catalogued across RNA species. The alphabet in which results are reported has four characters.
THE ERROR IS SILENT	Inosine is written as guanosine. Nothing downstream flags it. A made inosine and an inherited guanine are the same character, and the difference between them is the difference between an edit and a genotype.

An unreadable channel does not announce itself. It returns a clean four-letter string with no field for what was lost, and every instrument, pipeline, database and clinical report downstream is built to accept that string as the molecule.

---

6. What a Solution Would Unlock ↩

— Editing programs could screen targets on chemical state rather than on sequence alone, which is currently the largest unmodeled source of on-target failure.

— RNA editing could be measured as a rate rather than inferred from a mismatch to a reference, because a made inosine would be distinguishable from an inherited guanine in one read.

— Epigenetic readouts would stop conflating 5-methylcytosine with 5-hydroxymethylcytosine, which no bisulfite-based method can separate.

— Any engineered organism with an expanded alphabet would become verifiable at the level of the molecule rather than of the construct.

---

7. An Alternate, If a Second Is Wanted ↩

Offered as a companion, not a substitute

THE EIGHT-LETTER CELL. Produce a living cell in which inosine, xanthine or orotate is a distinct coding species with its own codon assignment, rather than a modification of one of the four.

This sits directly beside problem five, the quadruplet cell. Where that problem widens the CODON, this one widens the ALPHABET. Both test the same underlying question from different directions: whether the four-character representation is a fact about chemistry or a fact about what a laboratory could purify in 1953.

Acceptance would require that the organism be viable, that the added species be incorporated by the cell's own machinery rather than supplied as a modified feed, that it be read as a distinct codon by the ribosome, and that it be inherited through at least twenty divisions.

---

Submitted by Dr. John Allen Berger, NovagonDNA, Naperville, Illinois. The full evidence behind the framing is set out in the accompanying volume; the problem statement above stands on the four sources named here and does not require it.

The twelve problems ask biology to build. This one asks biology to read what it has built, in the alphabet the molecule is actually written in rather than the one the instrument can report.

SUBMISSION · MILLENNIUM PROBLEMS FOR BIOLOGY

The Non-Commuting Molecule

A proposed problem: demonstrate that a molecular operation carries non-commutative structure physically rather than notationally — that doing C then N leaves the system in a measurably different state than doing N then C, and that the two differ by sign in a defined observable

Problem Submission, with Acceptance Criteria
PP-2026-MILL-02 v1 · 19 September 2026

1. The Problem, in the Form of the List ↩

THE NON-COMMUTING MOLECULE. Demonstrate a physical molecular operation whose order of application is observable — where composing two operations in one sequence yields a state differing by sign, in a defined measurement, from the opposite sequence.

Chemistry is written almost entirely in commutative notation. A formula lists atoms, a sequence lists bases, a reaction lists reagents, and in none of these does the ORDER of two constituents change what the expression denotes. Yet rotation in three dimensions does not commute, molecular conformation is rotation, and the algebra that describes rotation without singularity is non-commutative.

The question is whether that non-commutativity is a property of our mathematics or a property of the molecule. It is asked here as a demonstration, because it can be settled by one.

 © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

2. Why the Problem Is Well Posed ↩

A worked assignment exists, its algebra has been verified, and exactly one thing is missing

A candidate assignment has been proposed and its algebra checked in full. Hydrogen is taken as the scalar — the proton, the unit against which every bond is measured, the part that commutes with everything. Carbon, nitrogen and oxygen take the three imaginary components. Under that assignment the following are verified statements, not conjectures.

what was checked	result
THE THREE SQUARES	C x C = -H, N x N = -H, O x O = -H
THE SIX PRODUCTS	C x N = O but N x C = -O. N x O = C but O x N = -C. O x C = N but C x O = -N.
THE TRIPLE PRODUCT	C x N x O = -H
THE IDENTITY	H commutes with all three from either side, which is what makes it the scalar and not a fourth direction.
CONJUGATION	Inverting the three while leaving the scalar fixed is an electronic reorganization around a stationary proton, which is the definition of a tautomeric shift.
THE NORM	A quantity times its conjugate returns a pure scalar equal to the sum of the four squared components, INCLUDING the hydrogen term. Magnitude without direction, which is what a bond energy is.

And here is what the check does not establish

Closure was never in doubt. Relabeling the three imaginary units with the names of three atoms produces a valid algebra for any three names, because renaming symbols cannot break an algebra. What the verification establishes is that the STATED CONSEQUENCES follow correctly — the conjugation reading and the norm reading are sound.

What it cannot establish is whether C x N = O denotes anything about matter. Carbon composed with nitrogen yielding oxygen is not, as written, a chemical statement. THE ASSIGNMENT IS PRESENTLY A LABELING, AND THE PROBLEM IS TO DETERMINE WHETHER IT IS MORE THAN ONE.

That is stated here plainly because the distinction is the entire problem. An assignment that closes formally and has no physical referent is notation. An

assignment whose products correspond to observable events is a discovery. Nothing published settles which this is.

3. Acceptance Criteria ↩

Six conditions. The fourth is the one that decides it.

no.	criterion	what satisfies it
1	A NAMED ASSIGNMENT	Four atoms, one taken as the scalar and three as the imaginaries, each assigned once and only once, fixed before any measurement.
2	A PHYSICAL OPERATION	Each imaginary corresponds to a specified, performable operation on a real molecule — not to a symbol standing for the atom, but to something done to the system.
3	CONJUGATION IS OBSERVED	The operation that inverts the three while leaving the scalar fixed is realized as a measured tautomeric shift, with the proton position shown to be unchanged across it.
4	ORDER IS OBSERVABLE	Applying operation C then N leaves the system in a state distinguishable by measurement from N then C, and the two differ by sign in a defined observable. THIS IS THE CRITERION THAT SEPARATES AN ALGEBRA FROM A RELABELING. If the physical system commutes, the assignment is notation.
5	THE NORM IS AN ENERGY	The scalar returned by a quantity times its conjugate corresponds to a measured bond energy, including the hydrogen term, within a stated tolerance.
6	THE DOUBLE COVER IS PHYSICAL	Two distinct states of the system map to one spatial configuration, and the distinction between them is measurable rather than formal — the 720-degree period is observed, not merely represented.

Criterion four is the problem. The other five can be satisfied by a careful assignment and a good argument. Only the fourth requires the world to agree, and it is the one no published work has attempted.

4. What Would Refute It ↩

— Show that every candidate molecular operation pair commutes under measurement, and the assignment is notation rather than structure. The problem is then closed in the negative, which is a result.

— Show that the conjugation-tautomer correspondence fails — that the proton position changes across the inversion — and criterion three falls with it.

— Show that a fifth independent component is required for some ordinary bonding operation, and the four-slot assignment is incomplete.

— Show that the scalar cannot be both the invariant and the site of proton motion, and that no second term repairs it. This tension is already printed in the source paper rather than hidden, and it is the author's own open question.

A problem whose author has published the objection that would sink it is a better problem than one that has not. The fourth bullet above is taken verbatim from the tension the source paper names in its own section five.

---

5. Why It Belongs Beside the Twelve ↩

reason	the case
IT IS A DEMONSTRATION	It asks for a measurement, not an argument. It can be settled, in either direction, by an experiment that does not yet exist.
IT DOES NOT REQUIRE THE FRAMEWORK TO BE ACCEPTED FIRST	Anyone who knows that rotations do not commute, and that conformation is rotation, can evaluate whether the answer is yes or no. The assignment offered here is a candidate, not a premise.
IT IS UNTOUCHED	The literature contains quaternions used to REPRESENT molecular rotation, in docking and in folding. It does not contain a test of whether the molecule itself carries the non-commutative structure.
IT IS CHEAP TO ATTEMPT	Unlike several of the twelve, a first attempt requires spectroscopy and a well-chosen tautomeric system rather than a new organism.

The distinction between a representation and a realization is the oldest question in mathematical physics and it is almost never posed as an experiment. Here it can be.

---

6. Provenance ↩

The assignment, the six letterforms, the double-cover treatment and the open tension are set out in Shape Is Function, PP-2026-QCH-01, 19 September 2026. The algebra was verified independently of that paper and the verification is reproduced in section two. The problem stated here is the gap the verification exposed, and it is offered in the form the list asks for: a thing to be demonstrated, with the conditions that would count as a demonstration and the results that would refute it.

Submitted by Dr. John Allen Berger, Independent Theoretical Researcher, NovagonDNA, Naperville, Illinois.

Chemistry is written in a notation where order does not matter, on molecules that rotate in a space where it does. Whether that is a limitation of the notation or a fact about the molecules has never been measured.

POSITION PAPER · NOVAGONDNA · PP-2026-ORD-01

Order Is Geometry

Rotating two backbone bonds in one sequence puts an atom 2.5 angstroms from where the opposite sequence puts it. The composition of orientations does not commute, the effect is larger than a carbon-carbon bond across most of the angle space, and no notation used in molecular biology has a field in which to write it

Companion to Shape Is Function · PP-2026-QCH-01

PP-2026-ORD-01 v1 · 19 September 2026

1. The Claim, Stated Narrowly on Purpose ↩

What is asserted, and what is deliberately not

FOR ORIENTATION, AND FOR HOW ORIENTATIONS COMPOSE, THE QUATERNIONS ARE THE RIGHT LANGUAGE — AND THE NOTATION OF MOLECULAR BIOLOGY CANNOT EXPRESS IT AT ALL.

That is narrower than it could be stated and it is narrow on purpose. This paper does not claim that quaternions are the only mathematics for chemistry, biology or genetics. They are not. Quantum chemistry runs on complex Hilbert spaces and produces the bond angles this paper depends on. Reaction kinetics runs on differential equations. Population genetics runs on probability. Geometric algebra is strictly more general than the quaternions, which sit inside it as the even subalgebra in three dimensions.

The claim here concerns one thing: THE COMPOSITION OF ORIENTATIONS. On that, the argument is not that the field uses a different adequate language. It is that

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

the field uses a notation with no slot for it, and that the quantity being dropped is large.

This is the same finding made elsewhere in this corpus about sulfur, about the methyl group and about magnesium, applied to shape. THE NOTATION LOSES WHAT THE MOLECULE HAS.

---

2. The Measurement ↩

Ideal backbone geometry, two rotations, two orders

Take one residue of a protein backbone with standard geometry. The nitrogen to alpha-carbon bond is 1.458 angstroms, the alpha-carbon to carbonyl-carbon bond is 1.525, the carbonyl carbon to the next nitrogen is 1.329, and the N-CA-C angle is 111 degrees. Two rotations are available: phi about the N-CA bond and psi about the CA-C bond.

quantity	value
The two rotation axes	69 degrees apart
Why that matters	Rotations about non-parallel axes do not commute. This is a fact about three-dimensional space, not about the molecule, and the molecule has no way to avoid it.

One case

Set phi to 60 degrees and psi to 60 degrees, and follow the next nitrogen in the chain.

order of application	where the atom ends up
phi first, then psi	(2.502, 0.662, 0.520)
psi first, then phi	(1.023, 1.341, 2.031)
SEPARATION	2.220 ANGSTROMS

And across the whole angle space

Sweeping phi and psi across the full range at five-degree steps gives 5,184 pairs.

measure	value
Mean separation	2.497 angstroms
Median separation	2.529 angstroms
Maximum separation	5.278 angstroms, at phi = -100, psi = -175

measure	value
Pairs exceeding 1.0 angstrom	76.9 percent
Pairs exceeding a carbon-carbon bond, 1.54 angstroms	67.5 PERCENT
Pairs that effectively commute, below 0.01 angstrom	2.8 percent

ACROSS TWO THIRDS OF THE ANGLE SPACE, THE ORDER OF TWO ROTATIONS MOVES AN ATOM FURTHER THAN THE LENGTH OF A CARBON-CARBON BOND. This is not a small correction. It is the size of the chemistry.

The pairs that do commute are not a counterexample and are worth naming precisely. Every exactly-commuting case in the sweep occurs where one of the two rotations is the identity — phi at zero or psi at zero. Two real rotations about these axes never commute. The exceptions are the cases where there is only one rotation.

---

3. What the Notation Cannot Write ↩

A protein is recorded as a sequence of letters. A molecule is recorded as a formula. A gene is recorded in a four-character alphabet. In none of these does the ORDER of two constituents change what the expression denotes, because all of them are commutative notations.

the record	what it holds, and what it drops
A sequence	Carries the identity of each residue and the order along the chain. No field for the orientation of any bond.
A formula	Carries the count of each atom. No field for arrangement, and none for the order in which arrangement was reached.
A reference genome	A consensus string. Cannot carry a fold, a metal, a charge state, a compartment, or a dihedral angle.
A structure file	Carries coordinates, which are the RESULT of a composition. It does not carry the composition, and two different orders that reach the same coordinates are indistinguishable in it.

The coordinates are the output. The composition is the process. A file that stores only the output cannot say that the process does not commute, and every downstream tool inherits that silence.

---

4. The Division of Labor ↩

Orbital theory gives the shapes. The quaternions give the composition.

The two are not rivals and this paper depends on both. Every bond angle used above is a result of quantum chemistry: the tetrahedral 109.5 degrees, the trigonal 120, the linear 180, the 111-degree N-CA-C angle, the nitrogen lone pair that makes the pyramid, the 104.5-degree bend in water. Those numbers come from linear algebra over a complex Hilbert space, and they are taken here as given.

the tool	the job it does
QUANTUM CHEMISTRY	Tells you that the axes exist and where they point. Hybridization, bond angles, lone pairs, the geometry of every center.
THE QUATERNIONS	Tell you what happens when you compose rotations about those axes, in which order, and by how much the answer differs.
NEITHER ALONE	Orbital theory does not tell you that phi-then-psi and psi-then-phi differ by 2.5 angstroms. Quaternion algebra does not tell you that the angle is 111 degrees.

A first-principles argument keeps every quantity that physics actually fixes, including the ones that arrive by a route one finds uncongenial. The 109.5 degrees is not an abstraction. It is in the figure.

---

5. The Double Cover, Concretely ↩

One further property of the representation is worth printing as a number rather than described, because it is routinely dismissed as bookkeeping.

rotation	quaternion scalar	the rotation itself
0 degrees	+1.000	identity
180 degrees	0.000	not identity
360 degrees	-1.000	IDENTITY
540 degrees	0.000	not identity
720 degrees	+1.000	identity

At 360 degrees the rotation has returned to the identity and the quaternion has returned to MINUS one. Two full turns are required to bring the representation back. The factor of two is not a redundancy to be engineered away; it is the structure, and in spin one-half systems it is measurable.

---

6. What This Paper Refuses ↩

the claim	the status
that quaternions are the only mathematics for biology	Refused. Quantum chemistry, kinetics and population genetics each run on something else, and each is correct in its domain.
that this replaces orbital theory	Refused. Every angle used here is an orbital-theory result and is taken as given.
that geometric algebra is not more general	Refused. The quaternions are its even subalgebra in three dimensions. The narrower tool is used here because the problem is rotation.
that the effect is small and correctable	Refused, on the numbers. The mean displacement exceeds a carbon-carbon bond across two thirds of the angle space.
that a structure file already captures this	Refused. A coordinate file stores the result of a composition, not the composition.

7. What Would Refute It ↩

— Show a pair of genuine rotations about these two axes that commute, other than the cases where one rotation is the identity, and the geometric claim fails.

— Show a standard molecular-biology record format with a field for the composition of orientations, rather than for its result, and the notation claim fails.

— Show that the ordering difference is never physically realized — that no synthesis, fold or conformational change ever traverses one order rather than the other — and the effect is formal rather than actual.

— Show that the 720-degree period has no observable consequence in any molecular system, and section five reduces to bookkeeping.

The third of these is the strongest objection and it is the one to take seriously. A molecule at equilibrium samples conformations; it does not necessarily execute an ordered sequence of two rotations. The claim survives wherever ORDER IS PHYSICALLY IMPOSED — in co-translational folding, where the chain folds as it is synthesized and the carboxyl end does not yet exist; in directed conformational change driven by a motor; and in any synthetic or computational procedure that applies rotations in sequence. Where order is imposed, the 2.5 angstroms is real.

8. The Experiment ↩

What would settle it, stated so that it could be run

Take a system in which two dihedral rotations can be driven independently and in a controlled sequence — a photoswitchable or otherwise triggerable backbone, or a designed peptide with two orthogonally addressable torsions. Drive phi then psi. Measure the end state. Reset. Drive psi then phi by the same angles. Measure again.

THE PREDICTION	The two end states differ, and the magnitude of the difference follows the composition computed in section two within experimental error.
THE NULL	The two end states are indistinguishable, and the ordering effect is an artifact of treating rotations as applied to a rigid frame.
WHAT MAKES IT CLEAN	The prediction is quantitative before the measurement is taken. The separation for any chosen pair of angles can be computed in advance and stated in the protocol.

The computation is four lines of arithmetic and it is printed in section two so that anyone can check it before running anything. That is the whole point of a first-principles claim: the number comes first, and the experiment is told what to look for.

---

9. Provenance ↩

The geometry in this paper was arrived at by drawing before it was arrived at by algebra. The four-color assignment, the six letterforms, the goalpost with a proton oscillating in the well, the up-vector that rises and curves back on itself, and oxygen as the closed loop are set out in Shape Is Function, PP-2026-QCH-01. The quaternion algebra under that assignment was verified independently and the verification held: the three squares, the six products, the triple product, the identity, the conjugation reading and the norm.

What the verification also showed is that closure alone proves nothing, because relabeling symbols cannot break an algebra. The physical content had to be found elsewhere, and it was found in the backbone rather than in the periodic table — in which bonds rotate and in what order, not in which atoms compose.

Hamilton spent years on rotation geometry before the expression came to him. The order of discovery here was the same, and the algebra is the receipt rather than the reason.

Dr. John Allen Berger, Independent Theoretical Researcher, NovagonDNA, Naperville, Illinois. The computation in section two is reproducible from the geometry stated there and uses only standard ideal backbone parameters.

FIELD INSTRUMENT · TWELVE WEEKS

Twelve Questions

A self-scoring gene editing instrument delivered one item per week as a LinkedIn poll — every question and option pre-counted against the platform limits, every answer mapped to a score, and the accumulated results designed to become a dataset rather than engagement

Poll Series, Scoring Card and Study Design

PP-2026-POLL-01 v1 · 19 September 2026

1. The Constraint That Designs This ↩

What a LinkedIn poll can and cannot be

the limit	what it means
Question length	140 characters maximum
Options	between 2 and 4, each 30 characters maximum
Duration	1 to 14 days, default 7
After publishing	CANNOT BE EDITED. A typo means delete and repost, and the impressions are lost with it
Who voted	the poll author can see each voter and the option they chose, natively
Scraper extensions	avoid. Accounts get restricted within about 48 hours, and they are not needed here

A poll cannot carry eighty items, or fifteen, or three. One poll is one question. That looks like a wall and it is not, because a three-point scale plus an honest way out is exactly four options, and four options is exactly what a poll allows.

The scale was already poll-shaped. Each question below asks one thing a practitioner can answer about their own program in ten seconds, and each answer converts to a 3, a 2 or a 1 on the instrument.

Why one per week beats eighty at once

what it buys	why
COMPLETION	Ten seconds and one tap. The eighty-item version would not be finished by anyone who was not paid to finish it.
REACH	Twelve polls are twelve impression events. One document is one. The audience that saves and does not comment will still tap a poll.
DATA	Each poll returns a distribution across the field on one criterion. Twelve weeks is twelve field-level distributions, which is a dataset and not a like count.
SAFETY	Nobody produces a document saying their program fails. They tap one anonymous option about one practice, and the aggregate is what gets published.

The last row is the one that decides adoption. An employee at a large company will not fill in a third-party form scoring their own program as deficient, because that form becomes a discoverable internal document. A single anonymous tap carries none of that weight.

---

2. The Twelve, Ready to Post ↩

Copy exactly as written. Every string below has been counted against the limits.

The character count for each question and each option is printed beside it. Nothing here exceeds the platform maximum, and the longest question used is 102 characters of the 140 available, which leaves room if you wish to sharpen the wording before posting. If you change a word, recount it. A poll cannot be edited once live.

Poll 1 · Delivery (rank 1)

QUESTION (99 of 140)	Your last in vivo edit: did you measure what fraction of TARGET cells actually received the editor?		
option · max 30 characters		**len**	**converts to**

Measured in the tissue	(22)	scores 3
Estimated, not measured	(23)	scores 2
Editing % only, no fraction	(27)	scores 1
Not my area	(11)	not scored

POST TEXT TO ACCOMPANY IT. Delivery is the field's own stated number one bottleneck, and it is not a sequence problem. Every in vivo program outside the liver is still solving it.

Poll 2 · p53 selection (new)

QUESTION (100 of 140)	After editing, do you check whether the surviving cells are enriched for p53-inactivating mutations?	
option · max 30 characters	**len**	**converts to**
Yes, routinely	(14)	scores 3
Once, not routinely	(19)	scores 2
No	(2)	scores 1
Had not considered it	(21)	scores 1

POST TEXT TO ACCOMPANY IT. Editing trips the damage response, and the cells that proliferate afterward are enriched for mutations that disable it. A program measuring efficiency alone records that as success.

Poll 3 · On-target genotoxicity (new)

QUESTION (89 of 140)	Do you assay for large on-target deletions with a method that could actually detect them?	
option · max 30 characters	**len**	**converts to**
Long-read or single-cell	(24)	scores 3
Short amplicon only	(19)	scores 1
Not assayed	(11)	scores 1
Not sure	(8)	not scored

POST TEXT TO ACCOMPANY IT. Megabase deletions, chromosome loss and chromothripsis are consequences of the INTENDED cut. Short amplicon sequencing cannot see any of them.

Poll 4 · Methylation state (rank 4)

QUESTION (76 of 140)	Does your guide design tool take the target's methylation state as an input?

option · max 30 characters	len	converts to
Yes, it changes output	(22)	scores 3
We check it separately	(22)	scores 2
No, sequence only	(17)	scores 1
Not sure	(8)	not scored

POST TEXT TO ACCOMPANY IT. A methyl group on the fifth cytosine of the PAM abolishes recognition. Shown at 2.8 angstroms in 2026, and absent from every guide design string. — Roth MO et al. Nature 2026;653:1229-1239. PMID 41986708

Poll 5 · Chromatin vs homology (rank 3)

QUESTION (95 of 140)	In your off-target ranking, can a lower-homology OPEN site outrank a better-matched closed one?

option · max 30 characters	len	converts to
Yes, accessibility scored	(25)	scores 3
Homology only	(13)	scores 1
I don't know our method	(23)	not scored

POST TEXT TO ACCOMPANY IT. A lower-homology site in open chromatin can carry more risk than a better-matched site in heterochromatin. A safety ranking built on the string is not conservative. It is wrong in an unknown direction.

Poll 6 · Pre-existing immunity (new)

QUESTION (98 of 140)	Do you screen for pre-existing immunity to the nuclease itself before dosing, not just the vector?

option · max 30 characters	len	converts to
Nuclease and vector	(19)	scores 3
Vector only	(11)	scores 2
Neither	(7)	scores 1
Ex vivo, not applicable	(23)	not scored

POST TEXT TO ACCOMPANY IT. Antibodies and T cells against SpCas9 and SaCas9 are common in people who have never been dosed. Cytotoxic T cells can clear the edited cells after a technically perfect edit.

Poll 7 · Guide chemistry (rank 9)

QUESTION (102 of 140)	Does your design tool score the guide's 2'-O-methyl and phosphorothioate pattern, or just the letters?

option · max 30 characters	len	converts to
Scores the modifications	(24)	scores 3
Letters only	(12)	scores 1
Vendor default, unchecked	(25)	scores 1
Not sure	(8)	not scored

POST TEXT TO ACCOMPANY IT. The guide every tool scores as four letters is manufactured with sulfur in its linkages, and each modification shifts the melting temperature that governs binding.

Poll 8 · The catalytic metal (rank 7)

QUESTION (99 of 140)	Cas9 does not cut without magnesium. Does any model in your pipeline carry magnesium as a quantity?

option · max 30 characters	len	converts to
Yes	(3)	scores 3
No	(2)	scores 1
Never thought about it	(22)	scores 1

POST TEXT TO ACCOMPANY IT. Binding and cleavage separate along the metal. The reaction every editing program depends on does not run without an atom that appears in no guide and no target string.

Poll 9 · Repair, not the nuclease (rank 5)

QUESTION (91 of 140)	Does your prediction output a distribution of repair outcomes, or a single intended allele?

option · max 30 characters	len	converts to
Outcome distribution	(20)	scores 3

Single intended allele	(22)	scores 1
We measure it after	(19)	scores 2
Not sure	(8)	not scored

POST TEXT TO ACCOMPANY IT. The nuclease makes a break. The cell decides what the break becomes.

Poll 10 · Mismatch repair (new)

QUESTION (92 of 140)	For prime editing: did you account for mismatch repair antagonizing the edit at your target?	
option · max 30 characters	**len**	**converts to**
Yes, MMR accounted for	(22)	scores 3
No	(2)	scores 1
We don't prime edit	(19)	not scored
Not sure	(8)	not scored

POST TEXT TO ACCOMPANY IT. Mismatch repair is a principal antagonist of prime editing, and product purity is not the same quantity as raw efficiency.

Poll 11 · Verification blind spot (rank 12)

QUESTION (91 of 140)	When an edit fails, can your data say WHICH failed: delivery, access, binding, or cleavage?	
option · max 30 characters	**len**	**converts to**
Yes, we can separate them	(25)	scores 3
We infer it	(11)	scores 2
No, one number	(14)	scores 1
Not sure	(8)	not scored

POST TEXT TO ACCOMPANY IT. A program that reports low efficiency and cannot say which of four upstream causes produced it will iterate on the guide, which is the one variable the data constrains and often not the one at fault.

Poll 12 · Cell type validation (new)

QUESTION (91 of 140)	Was your guide validated in the actual therapeutic cell type, or in a convenient cell line?

option · max 30 characters	len	converts to
Therapeutic cell type	(21)	scores 3
Cell line, then moved	(21)	scores 2
Cell line only	(14)	scores 1
Not sure	(8)	not scored

POST TEXT TO ACCOMPANY IT. A design validated in a dividing cell line carries no guarantee in the post-mitotic tissue that is the actual clinical target.

3. The Self-Scoring Card ↩

What the reader keeps, privately, and what you never see

The poll returns one answer. The card is what a reader fills in for themselves across all twelve, and it stays on their own machine. This is the part that has to be private by default, and saying so plainly in the post is what makes it usable inside a large company.

score	what it means
3	The quantity is in our model and we can set it independently. Changing it changes what the model predicts.
2	The quantity is present, but we cannot set it independently. We observe it rather than control it.
1	The quantity is not in our model at all. This is a failed criterion, stated plainly.
—	Not applicable or not known. Excluded from the total rather than scored as a 1.

total across twelve	the reading
Total of 36 to 30	Your program carries most of what decides the outcome. Publish how.
29 to 22	Solid on the quantities you control, thin on the ones you inherit.
21 to 14	The common profile. Strong sequence practice, weak on delivery, chromatin and chemical state.
13 to 12	Your pipeline is scoring a string and the outcome is being decided somewhere you are not looking.

Report the total alongside the count of items scored 1. Two programs with the same total are not in the same position if one has nine twos and the other has six threes and six ones.

The distinction that carries the whole exercise

A 1 is not an accusation of incompetence. It is a statement that a quantity is absent from the representation. If the quantity is not in the input, no amount of further training, more sequence or better models will put it there, and the failure is STRUCTURAL. If it is in the input and handled poorly, the failure is ENGINEERING, and engineering gets fixed.

A team told they have an engineering shortfall will go and fix it, and they should. A team told they have a structural absence learns something more useful: the thing they are missing cannot be trained in. It has to be added to the input or measured separately.

---

4. Turning Twelve Polls Into a Study ↩

The part that makes this a paper rather than a campaign

The polls give a field-level distribution on twelve criteria. That alone is publishable as a survey. The stronger design adds a small expert panel and the machine, scoring the same items, and measures where they disagree.

the three sources	what each contributes
THE FIELD	Whoever votes. An unselected, self-reporting sample. Its weakness is selection and its strength is size and honesty, because a single anonymous tap costs nothing to answer truthfully.
THE PANEL	Five raters recruited directly, each scoring the same twelve items against the same named program. Recruit them from the voters, whom the platform lets you see.
THE MACHINE	The same twelve items scored by an AI system given the same program description and the same operational definitions.
THE MEASUREMENT	Agreement among the five. Agreement between the panel and the machine. And, most usefully, the items where they disagree.

Disagreement is the result, not the noise. An item the five raters score differently is an item whose operational definition is not tight enough,

and tightening it is how the instrument gets validated. Publish the disagreement map and the instrument becomes a standard rather than an opinion.

Use a chance-corrected statistic rather than raw percent agreement, because with a three-point scale and skewed distributions raw agreement flatters badly. Report the count of complete responses beside every figure. If five raters produce one usable comparison, say so rather than reporting a coefficient that a reader will take as stable.

---

5. Cadence, and What to Watch ↩

when	what goes out
Weeks 1 to 3	Polls 1, 2 and 3. Delivery, p53 selection and on-target genotoxicity. The three heaviest, and the two newest.
Weeks 4 to 8	Polls 4 through 8. The chemical and physical quantities, where the color argument does its work.
Weeks 9 to 12	Polls 9 through 12. Process and validation practice.
Week 13	Publish the twelve distributions together, with the self-scoring card as the artifact.

Run each for seven days. Post the accompanying text with the poll, because the text is what makes it a scientific question rather than a marketing device, and the citation is what makes it checkable.

The three numbers that tell you whether this is working

watch	why
Votes per poll	The only real completion metric. Reactions and impressions do not measure participation and never did.
Comments, from zero	Your entire body of work has drawn zero comments against thirty-four saves. A poll that draws its first real comment thread has changed the relationship, and that is worth more than the vote count.
Repeat voters	Someone who votes on poll one and again on poll six is a panel candidate. The platform lets you see who they are.

The audience reading you is professors, postdocs and bioinformaticians inside large companies, and it is weighted more toward Bengaluru, Delhi and Hyderabad than toward the Bay Area and

Boston combined. Service and contract organizations have the strongest reason of anyone to adopt a published standard, because a standard is something they can show a client.

---

6. What This Instrument Refuses ↩

the claim	the status
that a poll can carry the full instrument	Refused. One poll is one item. The eighty remain the reference behind the twelve.
that vote counts measure quality of practice	Refused. They measure who answered. Selection is the known weakness and it should be printed beside every result.
that a low score impugns a team	Refused. A structural 1 is a property of the representation, not of the people using it.
that the twelve are the right twelve	Open. They are the heaviest twelve on current evidence, and the disagreement map is what would revise them.

Twelve taps over twelve weeks, and at the end a practitioner has scored their own program on the quantities that decide whether an edit happens. That is a smaller ask than eighty items and a larger result, because it finishes.

POSITION PAPER · SECOND EDITION · Q-1 AND Q-2 ANSWERED

Shape Is Function

A four-color quaternion architecture, with the two computational null hypotheses of the first edition now run. The algebra closes. The non-commutativity is real and it is not where the first edition looked for it — composing two backbone rotations in opposite orders displaces an atom by a mean of 2.5 angstroms, exceeding a carbon-carbon bond across two thirds of the angle space

H = 1 · C = i · N = j · O = k · P CARRIES THE SPIN · S CARRIES THE FOLD

PP-2026-QCH-02 v1 · 19 September 2026

1. What Is New in This Edition ↩

Two null hypotheses run, one question relocated, one claim narrowed

change	what it is
Q-1 IS ANSWERED	The assignment closes. All twelve statements verified — three squares, six products, the triple product. AND THE VERIFICATION CARRIES A FINDING THE FIRST EDITION DID NOT ANTICIPATE: closure alone proves nothing, because relabeling symbols cannot break an algebra.
Q-2 IS ANSWERED, AND REJECTED	The null was that order carries no chemical information. It is rejected on real backbone geometry with a mean separation of 2.497 angstroms. QUATERNIONS ARE JUSTIFIED OVER VECTORS, which is what Q-2 was built to decide.
THE QUESTION IS RELOCATED	The non-commutativity is not carbon-then-nitrogen as atoms composing. It is rotation about the carbon axis then the nitrogen axis. The atoms define the axes; the rotations do the composing.
ONE CLAIM IS NARROWED	This edition does not assert that quaternions are the only mathematics for chemistry, biology or genetics. The scope is stated in section 11 and it is deliberately smaller and harder to refute.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

The first edition said of Q-2 that it was THE CLAIM THE WHOLE DESIGN RESTS ON and THE HIGHEST-VALUE HOUR IN THE PROJECT. That hour has been spent and the result is in section 5.

PART ONE · THE ASSIGNMENT

2. The Argument, in One Sentence ↩

A QUATERNION HAS ONE SCALAR AND THREE IMAGINARIES, ORGANIC CHEMISTRY HAS ONE UNIT AND THREE HEAVY ATOMS, AND THE CORRESPONDENCE IS CLOSE ENOUGH TO BUILD ON PROVIDED EVERY SLOT IS ASSIGNED ONCE AND ONLY ONCE.

Hydrogen is the proton and the basis for bonding. It is the unit of acid and base, the particle the hydrogen bond is named for, and historically the unit of atomic mass. Everything else is counted against it. THAT MAKES IT THE IDENTITY, NOT ONE OF THE THREE. Carbon, nitrogen and oxygen take i, j and k, and the algebra then has no empty slot and no contested one.

3. Four Atoms, Four Components, Four Colors ↩

One slot each, stated so that no atom can claim two

slot	atom	color	what it is
1	HYDROGEN · H1	RED	THE IDENTITY. The scalar. The part that commutes with everything, carries the magnitude, and is unchanged by conjugation. A proton is the measure of every bond and is not itself a direction.
i	CARBON · C6	BLUE	THE FIRST IMAGINARY. The backbone atom, the one that makes chains and rings and therefore the one that defines extent.
j	NITROGEN · N7	GREEN	THE SECOND IMAGINARY. Three bonds and a lone pair. The atom that carries the exocyclic amine, and therefore the atom that distinguishes guanine from hypoxanthine.
k	OXYGEN · O8	ORANGE	THE THIRD IMAGINARY. And separately, in the ordinary sense of the word, the real process — oxidation, combustion, the energy that drives cellular machinery.

ONE PRECISION THAT COST AN HOUR AND WOULD HAVE COST A YEAR. IN QUATERNION ALGEBRA THE SCALAR PART AND THE REAL PART ARE THE SAME COMPONENT. Two atoms cannot both hold it. Oxygen is REAL in English — the actual, the process, the thing that happens — and it is k in the algebra. Hydrogen is the scalar. The collision is resolved by separating two senses of one word.

---

4. Both Sheets of the Double Cover ↩

SO(3) is 360 degrees, the quaternions are 720, and the sphere is neither

the object	what it is	the period, and the shape
SO(3)	All rotations of three-space about a point. Three parameters.	360 DEGREES and you are back to the identity, about any axis, without exception. This is what a physical object does when it turns. Topologically it is projective three-space — the solid ball of radius pi with opposite surface points identified. IT IS NOT A SPHERE.
THE UNIT QUATERNIONS	The three-sphere, also written SU(2) or Sp(1).	720 DEGREES. Two full turns to return to the same element, because a quaternion and its negative produce the identical rotation. This is the double cover, and it is where the quaternion itself lives.
THE TWO-SPHERE	Directions in space. Two parameters.	NEITHER OF THE ABOVE, and the object most often mistaken for SO(3). A qubit STATE lives here. A qubit GATE lives in the three-sphere.

And now as numbers rather than description

rotation	quaternion scalar	the rotation itself
0 degrees	+1.000	identity
180 degrees	0.000	not identity
360 degrees	-1.000	IDENTITY
540 degrees	0.000	not identity
720 degrees	+1.000	identity

At 360 degrees the ROTATION has returned to the identity and the QUATERNION has returned to minus one. The factor of two is not a redundancy to be engineered away. It is the structure, and in spin one-half systems it is measurable.

PART TWO · Q-1 ANSWERED · THE ALGEBRA

5. The Twelve Statements, Verified ↩

The null was that the assignment does not close. It closes.

what was checked	result
THE THREE SQUARES	C x C = -H, N x N = -H, O x O = -H
THE SIX PRODUCTS	C x N = O and N x C = -O. N x O = C and O x N = -C. O x C = N and C x O = -N.
THE TRIPLE PRODUCT	C x N x O = -H
THE IDENTITY	H commutes with all three from either side, which is what makes it the scalar and not a fourth direction.
CONJUGATION	Inverting the three while leaving the scalar fixed. The scalar is verified unchanged.
THE NORM	A quantity times its conjugate returns a pure scalar equal to the sum of the four squared components, INCLUDING the hydrogen term.

And the finding the first edition did not anticipate

Closure was never in doubt, and saying so is more useful than celebrating it. Relabeling the three imaginary units with the names of three atoms produces a valid algebra FOR ANY THREE NAMES, because renaming symbols cannot break an algebra. Q-1 could not have failed.

WHAT THE VERIFICATION ACTUALLY ESTABLISHES IS THAT THE STATED CONSEQUENCES FOLLOW. Conjugation leaves the proton fixed while carbon, nitrogen and oxygen invert, which is an electronic reorganization around a stationary hydrogen — the definition of a tautomeric shift. And the norm returns magnitude without direction, including the hydrogen term, which is what a bond energy is. Those two readings survive.

What it does not establish is that C x N = O denotes anything about matter. Carbon composed with nitrogen yielding oxygen is not, as written, a chemical statement, and atomic number does not supply one: six and seven do not produce eight under any product. That gap is what Q-2 had to close, and where it closed is not where the first edition looked.

PART THREE · Q-2 ANSWERED · ORDER IS GEOMETRY

6. Where the Non-Commutativity Actually Lives ↩

Not in which atoms compose. In which bonds rotate, and in what order.

The atoms do not multiply each other. THE ATOMS DEFINE THE AXES. Carbon gives the backbone axis, nitrogen brings the three-bond pyramid and its lone pair, oxygen the closure. Each contributes a direction about which a rotation can occur, those directions are not parallel, and rotations about non-parallel axes do not commute. That is a fact about three-dimensional space, and the molecule has no way to avoid it.

7. The Measurement ↩

Ideal backbone geometry, two rotations, two orders

Take one residue of a protein backbone with standard geometry: N-CA 1.458 angstroms, CA-C 1.525, C-N 1.329, and the N-CA-C angle 111 degrees. Two rotations are available — phi about the N-CA bond and psi about the CA-C bond.

quantity	value
The two rotation axes	69 degrees apart, therefore they cannot commute

One case

order of application, phi = psi = 60 degrees	where the next nitrogen ends up
phi first, then psi	(2.502, 0.662, 0.520)
psi first, then phi	(1.023, 1.341, 2.031)
SEPARATION	2.220 ANGSTROMS

Across the whole angle space, 5,184 pairs at five-degree steps

measure	value
Mean separation	2.497 angstroms

measure	value
Median separation	2.529 angstroms
Maximum separation	5.278 angstroms, at phi = -100, psi = -175
Pairs exceeding 1.0 angstrom	76.9 percent
Pairs exceeding a carbon-carbon bond, 1.54 angstroms	67.5 PERCENT
Pairs that effectively commute	2.8 percent, and every exactly-commuting case is one where a rotation is the identity

ACROSS TWO THIRDS OF THE ANGLE SPACE THE ORDER OF TWO ROTATIONS MOVES AN ATOM FURTHER THAN THE LENGTH OF A CARBON-CARBON BOND. Q-2 IS REJECTED. Order carries chemical information, and the quaternions are justified over vectors.

The commuting cases are not a counterexample and deserve naming precisely. All 143 of them occur where one of the two rotations is zero. TWO REAL ROTATIONS ABOUT THESE AXES NEVER COMMUTE. The exceptions are the cases where there is only one rotation.

---

8. What the Notation Cannot Write ↩

the record	what it holds, and what it drops
A sequence	Carries the identity of each residue and the order along the chain. No field for the orientation of any bond.
A formula	Carries the count of each atom. No field for arrangement, and none for the order in which arrangement was reached.
A reference genome	A consensus string. Cannot carry a fold, a metal, a charge state, a compartment or a dihedral angle.
A structure file	Carries coordinates, which are the RESULT of a composition. It does not carry the composition, and two orders reaching the same coordinates are indistinguishable in it.

The coordinates are the output. The composition is the process. A file that stores only the output cannot say that the process does not commute, and every tool downstream inherits that silence.

---

9. The Division of Labor ↩

Orbital theory gives the shapes. The quaternions give the composition.

The two are not rivals and this paper depends on both. Every bond angle used above is a result of quantum chemistry: the tetrahedral 109.5 degrees, the trigonal 120, the linear 180, the 111-degree N-CA-C angle, the nitrogen lone pair that makes the pyramid, the 104.5-degree bend in water. Those numbers come from linear algebra over a complex Hilbert space, and they are taken here as given.

the tool	the job it does
QUANTUM CHEMISTRY	Tells you that the axes exist and where they point.
THE QUATERNIONS	Tell you what happens when rotations about those axes compose, in which order, and by how much the answer differs.
NEITHER ALONE	Orbital theory does not tell you that phi-then-psi and psi-then-phi differ by 2.5 angstroms. Quaternion algebra does not tell you that the angle is 111 degrees.

A first-principles argument keeps every quantity that physics actually fixes, including the ones that arrive by a route one finds uncongenial. The 109.5 degrees is not an abstraction. It is in the figure.

PART FOUR · THE LETTERFORMS, THE SPIN AND THE FOLD

---

10. Six Letterforms, With Their Corrections ↩

atom	the stroke	what it maps to, and where it must be corrected
O OXYGEN	A closed circle. A zero, a cycle, 360 degrees returning to its start.	The closed loop is the right picture for a cycle, and oxidation is a cycle. Caution for layout: oxygen in water is BENT at 104.5 degrees, not round. The circle is the electron cloud and the closure, not the bond angle.
H HYDROGEN	A goalpost. Two uprights and a crossbar that moves back and forth.	The strongest item in the set, and it is NOT three covalent bonds — hydrogen forms one. Two uprights and a proton oscillating between them is a hydrogen bond: donor, acceptor, and the particle in the well. The crossbar going back and forth is proton tunneling drawn.
C CARBON	An open arc. A semicircle, 180 degrees.	True for sp — acetylene, carbon dioxide, the nitriles. But sp2 is 120 and sp3 is 109.5, and most biological carbon is one of those. THE ARC MUST BE A FAMILY OF THREE APERTURES, or the chip cannot represent a tetrahedral center.
N NITROGEN	Three vectors. Up, down the slope, up	HOLDS EXACTLY. Three bonds and a lone pair give trigonal pyramidal geometry near 107 degrees.

atom	the stroke	what it maps to, and where it must be corrected
	the slope.	
P PHOSPHORUS	An up vector that rises, peaks, bends sideways, curves back and reattaches to its own stem.	And the cell already draws this. The loop that rises, bends and reattaches is the cyclic nucleotide.
S SULFUR	The fold.	Sulfur is in no base, no sugar and no backbone, and performs every operation on them. It carries the disulfide that holds a protein in its working shape, which is why the fold is its slot.

11. Why Phosphorus Is on the Chip ↩

Not the electron cloud · the nucleus

THE CLAIM WITHDRAWN	A free phosphorus atom is paramagnetic. PHOSPHATE IS NOT. The earlier form of that claim is withdrawn and replaced with the nuclear spin, which is true and more useful.
THE PUBLISHED OCCUPANT	A first-principles study of calcium phosphate clusters of formula Ca9(PO4)6 — Posner molecules — reports an ideal environment for the six constituent phosphorus-31 nuclear spins to obtain very long spin coherence times. SIX SPINS PER CLUSTER.
ITS STATUS	PROPOSED AND CONTESTED, NOT ESTABLISHED. A 2026 review building on the same model describes it as speculative and sets out falsification routes including isotopically modified ligands and nitrogen-vacancy magnetometry. It de-emphasizes microtubule-centerd models in favor of the phosphate one.
WHY IT EARNS THE SLOT	Phosphorus-31. Nuclear spin one half, ONE HUNDRED PERCENT natural abundance, in a molecule the body already makes.

The rungs, so that two claims stop competing for one

the rung	what sits there
THE STAR	Phosphorus is forged in massive stars and is conspicuously scarce relative to carbon, nitrogen and oxygen. The scarcity is a standing problem in origin-of-life chemistry, not a detail.
THE DELIVERY	Reduced meteorites such as enstatite chondrites are enriched in phosphide minerals which, on reaction with water, release phosphorus in several oxidation states — and ultraviolet light acting on hydrogen sulfide oxidizes the rest of the way to phosphate. SULFUR IS THE ACTIVATING AGENT, and the reactions were monitored by phosphorus-31 NMR.
THE MINERAL	Apatite is where terrestrial phosphorus sits, and the clusters proposed as spin carriers were originally identified in hydroxyapatite. The mineral rung and the spin rung are the same material at different scales.
THE ATOM	Phosphorus-31. The qubit, if there is one, is here.
THE MOLECULE	GTP carries three phosphorus atoms — alpha, beta and gamma. Three spins per nucleotide in a fixed geometry.

the rung	what sits there
THE COMPLEX	A tubulin dimer binds two nucleotides. A dimer carrying GTP at both sites holds six phosphorus nuclei; hydrolysis leaves five. THE NUCLEAR SPIN INVENTORY OF THE LATTICE IS COUPLED, DISCRETELY, TO THE POLYMERIZATION STATE.

ONE NUMBER THAT IS PROBABLY A COINCIDENCE AND IS FLAGGED AS ONE. A calcium phosphate cluster of the proposed kind carries six phosphorus-31 spins. A fully loaded tubulin dimer also carries six. THERE IS NO MECHANISM CONNECTING THOSE TWO FACTS AND NONE IS CLAIMED. It is printed because a reader will notice it, and a coincidence named by the author is worth more than one found by a reviewer.

PART FIVE · WHAT REMAINS OPEN

---

12. The Tension That Q-2 Did Not Resolve ↩

The scalar is the part that DOES NOT ROTATE — invariant, conserved, the measure. But the goalpost has the proton MOVING. Both are true of hydrogen in the world; in the algebra they are different slots, and the invariant cannot also be the thing in motion.

EITHER THE TUNNELING LIVES IN THE NORM CHANGING RATHER THAN IN A COMPONENT MOVING, OR A SECOND TERM IS REQUIRED. Answering Q-2 did not touch this. It is the one structural question the design has not answered and it is printed again so it cannot be forgotten.

---

13. The Three Remaining Null Hypotheses ↩

test	the null and what settles it	cost
Q-3	Whether the conjugation reading survives a real tautomer. Encode both tautomers of a known pair, apply conjugation to one, compare to the encoding of the other. Failure to reject costs one paragraph and leaves the rest intact.	Computational chemistry. Modest cost.

test	the null and what settles it	cost
Q-4	Whether phosphorus-31 coherence survives outside the cluster. Relaxation times across free phosphate, cyclic nucleotide, nucleoside triphosphate and the cluster. THE LIKELIEST OUTCOME IS THAT THE EFFECT IS CLUSTER-SPECIFIC, and the design then narrows honestly before anything is fabricated.	Standard phosphorus NMR. Instrument time, no synthesis.
Q-5	Whether the letterform language predicts anything. A chemist given the six rules and no other training predicts the geometry of an unseen molecule. Better than chance makes it a design language; at chance it is a mnemonic, which is a respectable thing to be.	A blind trial. Small, and the one most likely to be skipped.

And one new test that Q-2 generates

test	the design	the outcome
Q-6	Whether the ordering effect is physically realized. Drive two dihedrals in a controlled sequence in a triggerable backbone — phi then psi, reset, psi then phi — and measure both end states. THE SEPARATION CAN BE COMPUTED IN ADVANCE FOR ANY CHOSEN PAIR OF ANGLES AND PUT IN THE PROTOCOL.	Rejected if the end states differ by the predicted magnitude. Not rejected if they are indistinguishable, in which case the ordering effect is formal rather than actual.

Q-6 is where the strongest objection lands and it should be stated rather than buried. A molecule at equilibrium samples conformations; it does not necessarily execute an ordered pair of rotations. The claim survives wherever ORDER IS PHYSICALLY IMPOSED — in co-translational folding, where the chain folds as it is synthesized and the carboxyl end does not yet exist; in motor-driven conformational change; and in any synthetic or computational procedure that applies rotations in sequence.

---

14. What This Paper Does Not Claim ↩

— It does not claim the brain is a quantum computer. The Posner proposal is cited as published and contested, its own authors call it speculative, and the 2026 treatment sets out how to falsify it.

— It does not claim microtubules are the quantum substrate, and does not claim they are irrelevant either. The spin is atomic and the lattice is cellular, so they occupy different rungs rather than competing for one.

— It does not claim phosphorus is paramagnetic in biology. The free atom is; phosphate is not. That claim is withdrawn and replaced with the nuclear spin.

— It does not claim quaternionic quantum mechanics. The algebra here is a representation for a design language, compatible with entirely standard physics.

— IT DOES NOT CLAIM THAT QUATERNIONS ARE THE ONLY MATHEMATICS FOR CHEMISTRY, BIOLOGY OR GENETICS. They are not. Quantum chemistry runs on complex Hilbert spaces and produces the bond angles this paper depends on. Reaction kinetics runs on differential equations. Population genetics runs on probability. Geometric algebra is strictly more general, with the quaternions sitting inside it as the even subalgebra in three dimensions.

— It does not claim that a structure file already captures the composition. A coordinate file stores the result of a composition, not the composition.

WHAT IT CLAIMS IS ONE THING. FOR ORIENTATION, AND FOR HOW ORIENTATIONS COMPOSE, THE QUATERNIONS ARE THE RIGHT LANGUAGE — AND THE NOTATION OF MOLECULAR BIOLOGY HAS NO SLOT FOR IT AT ALL. That is the same finding this corpus makes about sulfur, about the methyl group and about magnesium, applied to shape.

---

15. Provenance ↩

The geometry was arrived at by drawing before it was arrived at by algebra. The four-color assignment, the six letterforms, the goalpost with a proton oscillating in the well, the up-vector that rises and curves back on itself, and oxygen as the closed loop came first. The algebra arrived afterward and confirmed what the drawing already said.

The first edition posed five null hypotheses and said of the first two that they were pure computation and should be run before anything else. They have been run. Q-1 closed and taught that closure proves nothing. Q-2 was rejected, and in rejecting it the question moved from the periodic table to the backbone — from which atoms compose to which bonds rotate, and in what order.

Hamilton spent years on rotation geometry before the expression came to him. The order of discovery here was the same, and the algebra is the receipt rather than the reason.

A ROTATION AT 360, A REPRESENTATION AT 720, A SPIN-ONE-HALF NUCLEUS AT FULL ABUNDANCE IN EVERY PHOSPHATE IN THE BODY, A FOLD THAT CLOSES ON ITSELF LIKE A FIGURE EIGHT — AND NOW TWO AND A HALF ANGSTROMS THAT DEPEND ON NOTHING BUT THE ORDER YOU TURN IN.

THIS COMPLETES THE BEGINNING.

POSITION PAPER · NOVAGONDNA · PP-2026-QGE-03

Gene and Epigenetic Editing

GENE AND EPIGENETIC EDITING IN A 4-DNA (ATGC) AND 4-RNA (AUGC) GENETIC CODE ALPHABET. GENE AND EPIGENETIC EDITING NOW WRITE CHEMICAL SPECIES THAT ALPHABET HAS NO SYMBOL FOR. The MODOMICS database documents MORE THAN 330 RNA MODIFICATIONS. The readout has four symbols. Editors are now built to write and erase the species outside those four — and the instruments used to judge whether they worked were designed around the four. THE EDITORS HAVE OUTRUN THE ALPHABET. FIVE distinct failure modes — and two of them are not about a base at all, but about the sugar and the linkage, positions the notation never addressed. Nine issues, nine solutions taken from current work, and eight experiments each stated as a null hypothesis somebody can reject

4 LETTERS · 330+ SPECIES · 5 FAILURE MODES · 9 ISSUES · 8 NULL HYPOTHESES

PP-2026-QGE-03 · 19 September 2026 · Naperville, Illinois

Dr. John Allen Berger · Independent Theoretical Researcher · NovagonDNA · Naperville, Illinois

1. The Argument, in One Sentence

EVERY CLASS OF EDITOR NOW IN DEVELOPMENT WRITES A CHEMICAL SPECIES THE READOUT ALPHABET HAS NO SYMBOL FOR, AND IN THE EPIGENETIC CASE THE ASSAY CANNOT EVEN DISTINGUISH THE EDITOR'S PRODUCT FROM ITS SUBSTRATE.

An adenine base editor makes inosine; the sequencer prints guanosine. A targeted demethylase makes 5-hydroxymethylcytosine; bisulfite sequencing prints the same thing it printed before the edit. AND THE SECOND CASE IS WORSE THAN THE FIRST, because it is not a collapse of two distinct signals into one — IT IS AN ASSAY REPORTING THAT A SUCCESSFUL EDIT DID NOT HAPPEN.

THE CENSUS

2. Four Symbols Against Three Hundred and Thirty

The size of the gap, stated as a ratio rather than as a complaint

	the count	what it means
THE DNA ALPHABET	FOUR SYMBOLS — A, T, G, C.	And at least six chemical species occur in genomic DNA that are not among them: 5-methylcytosine, 5-hydroxymethylcytosine, 5-formylcytosine, 5-carboxylcytosine, N6-methyladenine, and deoxyinosine. EVERY ONE OF THOSE IS PRINTED AS ONE OF THE FOUR.
THE RNA ALPHABET	FOUR SYMBOLS — A, U, G, C.	MORE THAN 330 RNA MODIFICATIONS ARE NOW DOCUMENTED IN THE MODOMICS DATABASE, a count published in a 2025 review. The four canonical ribonucleosides are four entries in a catalogue of over three hundred.
THE RATIO	FOUR OF ROUGHLY THREE HUNDRED AND THIRTY-FOUR.	Slightly over one per cent of the documented chemical vocabulary has a symbol. THE REMAINING NINETY-NINE PER CENT IS NOT ABSENT FROM THE DATA — IT IS PRESENT, AND PRINTED AS ONE OF THE FOUR. That is the whole of the problem in one sentence.
AND THE CATALOGUE IS STILL GROWING	The 330 figure is from a 2025 review, and the detection methods for individual members of the class are an active 2025 and 2026 research front.	THE VOCABULARY IS NOT THE NEW THING. WHAT IS NEW IS THAT WE NOW BUILD MACHINES TO WRITE IN THE PART OF IT THE ALPHABET DOES NOT COVER — targeted methylation editors, targeted demethylases, epitranscriptomic editors — AND WE JUDGE THOSE MACHINES WITH INSTRUMENTS BUILT AROUND THE FOUR SYMBOLS. The gap is not old news. It opened when the editors arrived.

Azeem S, Aritonang IM, Peng C, Huang YS. The role of 2'-O-methylation in epitranscriptomic regulation. Wiley Interdiscip Rev RNA 2025;16(3):e70018. doi

10.1002/wrna.70018. PMID 40524419. Retrieved and read this pass — the 330 figure is from its opening, and the review itself is a 2025 survey of transcriptome-wide mapping for one member of the class.

3. Five Failure Modes, Which Are Not the Same Failure

Calling all of this invisibility loses the distinctions that determine what each one costs and how each one is fixed

A single word for five different defects produces a single remedy for five different problems. THESE ARE FIVE, THEY HAVE DIFFERENT SIGNATURES, AND FOUR OF THEM ARE ALREADY FIXABLE WITH PUBLISHED INSTRUMENTS. THE FIFTH IS NOT A BASE AT ALL, WHICH IS WHY IT WAS MISSED.

	the mode	what happens	the signature
MODE ONE	COLLAPSE	Two distinct molecules, one symbol. INOSINE IS PRINTED AS GUANOSINE — the published phrase is that inosines are identified indirectly as variants BECAUSE THEY ARE INTERPRETED AS GUANOSINES by cellular machineries.	THE SIGNATURE IS FALSE ATTRIBUTION. The signal is present and assigned to the wrong source. You cannot tell the editor's edit from the cell's own.
MODE TWO	ERASURE	The modification is present and prints as the unmodified parent. 5-METHYLCYTOSINE PRINTS AS C. N6-methyladenosine prints as A. 2'-O-methylation prints as nothing at all.	THE SIGNATURE IS A FALSE NEGATIVE. The information is not misattributed; it is gone. Standard sequencing of a methylated genome returns the unmethylated sequence and reports no anomaly.
MODE THREE	ISOMERISM	Same molecular formula, same mass, different connectivity. PSEUDOURIDINE IS AN ISOMER OF URIDINE — a carbon-carbon glycosidic bond where uridine has carbon-nitrogen. IT PRINTS AS U AND IT WEIGHS THE SAME AS U.	THE DEEPEST CASE. Mass spectrometry alone does not separate them either. This one is invisible to the obvious backup instrument as well as to the alphabet, and it requires specific chemistry or a signal-level method.
MODE FOUR	CONFLATION INSIDE THE ASSAY	The assay built specifically to see the modification cannot separate the modification from its own product. BISULFITE SEQUENCING CANNOT DISTINGUISH 5-METHYLCYTOSINE FROM 5-HYDROXYMETHYLCYTOSINE.	THE WORST FOR EDITING, AND THE SUBJECT OF §4. The instrument was chosen because it sees the mark. It sees the mark and the mark's oxidation product as the same thing — SO AN EDITOR THAT CONVERTS ONE INTO THE OTHER REGISTERS AS HAVING DONE NOTHING.
MODE	NO SYMBOL AT	The modification is not on a base.	THE ONE THAT WAS MISSED

	the mode	what happens	the signature
FIVE	ALL	It is on the LINKAGE between bases, or on the SUGAR that carries them. THE ALPHABET HAS FOUR LETTERS FOR BASES AND ZERO SYMBOLS FOR ANYTHING ELSE IN THE MOLECULE.	BECAUSE IT IS NOT A LETTER PROBLEM. Modes one to four are all arguments about which letter gets printed. This one concerns a position the notation does not address. A four-letter string can be WRONG about a base; it cannot be wrong about a linkage, BECAUSE IT NEVER MADE A CLAIM THERE. Set out in §4A.

AND NONE OF THE FIVE IS BLINDNESS. A blind instrument returns nothing and announces the fact. ALL FIVE OF THESE RETURN A CONFIDENT, WELL-FORMED, WRONG ANSWER AND ANNOUNCE NOTHING. That is why the right word is color blindness: distinct things collapsed into one perceived category, with no signal that a collapse occurred.

THE EPIGENETIC CASE

4. An Editor Whose Success Reads as Failure

The sharpest item in this paper, and every source under it is from the last eighteen months

	the conflation
THE EDITORS, IN 2025	CRISPR-based epigenetic editing fuses catalytically dead Cas9 to an enzyme that writes or erases a methyl mark: dCas9-DNMT3A FOR PRECISE HYPERMETHYLATION and dCas9-TET1 FOR TARGETED DEMETHYLATION, with SunTag amplification and KRAB-MeCP2 repression as further systems. A 2025 review describes this as a PARADIGM SHIFT IN CANCER THERAPY, aimed at reactivating tumor suppressor genes or silencing oncogenic pathways.
WHAT TET ACTUALLY DOES	TET enzymes do not remove a methyl group. THEY OXIDIZE IT, IN STEPS: 5-methylcytosine to 5-hydroxymethylcytosine to 5-formylcytosine to 5-carboxylcytosine. THE FIRST PRODUCT OF A dCas9-TET1 EDIT IS 5-HYDROXYMETHYLCYTOSINE.
WHAT THE ASSAY DOES	STANDARD BISULFITE SEQUENCING CANNOT DISTINGUISH 5-METHYLCYTOSINE FROM 5-HYDROXYMETHYLCYTOSINE. Both survive bisulfite treatment and both are read as cytosine — that is, as METHYLATED. This is a property of the chemistry rather than of any particular protocol, which is why it has not been fixed by better reagents or

	the conflation
	deeper coverage.
THE CONSEQUENCE, STATED PLAINLY	A TARGETED DEMETHYLASE THAT SUCCESSFULLY CONVERTS 5mC TO 5hmC AT ITS TARGET SITE IS SCORED BY THE STANDARD ASSAY AS HAVING CHANGED NOTHING. The editor worked. The readout says it did not. MORE READS DO NOT FIX IT.
AND THE CONVERSE	An editor writing 5mC, some of which the cell then oxidizes, still reads as fully methylated. THE ASSAY IS INSENSITIVE TO THE EDIT IN BOTH DIRECTIONS, and a demethylation efficiency reported by bisulfite is a lower bound of unknown tightness rather than a measurement.
WHY THIS IS A 2026 QUESTION AND NOT AN OLD ONE	BECAUSE 5hmC IS NOW A CLINICAL TARGET IN ITS OWN RIGHT AND ITS DETECTION IS AN ACTIVE 2025 RESEARCH FRONT. A 2025 review in Talanta describes 5hmC as a KEY EPIGENETIC BIOMARKER FOR TUMORIGENESIS, noting a marked reduction in 5hmC levels during progression of various malignant tumors, and surveys nanoparticle-based optical and electrochemical biosensors being built specifically because the established techniques — bisulfite sequencing, mass spectrometry, chromatography — are not adequate. PEOPLE ARE BUILDING NEW INSTRUMENTS FOR THIS RIGHT NOW. That is what makes it a live measurement question rather than a settled one.
AND ON THE NEWEST PLATFORM IT IS STILL OPEN	A January 2025 comparison of nanopore sequencing and optical genome mapping on a matched kidney tumor profiled both the tumor's methylome and its hydroxymethylome, and reported that while nanopore was SUPERIOR IN METHYLATION CALLING, HYDROXYMETHYLATION REPORTS CAN BE FURTHER OPTIMIZED. So the separation of the two marks is unfinished business on the current generation of instruments, in a cancer sample, this year.

Chen F, Chen L. CRISPR/Cas-mediated macromolecular DNA methylation editing. Int J Biol Macromol 2025;308(Pt 2):142401. doi 10.1016/j.ijbiomac.2025.142401. PMID 40132699. · Mahdipour F, Minaei P, Nasrollahi M, Mahmoudpour M, Karimzadeh Z. Advancing 5-hydroxymethylcytosine detection. Talanta 2025;297(Pt B):128698. doi 10.1016/j.talanta.2025.128698. PMID 40829303. · Margalit S, Tulpová Z, Detinis Zur T et al. Long-read structural and epigenetic profiling of a kidney tumor-matched sample. NAR Genom Bioinform 2025;7(1):lqae190. doi 10.1093/nargab/lqae190. PMID 39781516. · Huang Z, Meng Y, Szabó PE, Kohli RM, Pfeifer GP. High-resolution analysis of 5-hydroxymethylcytosine by TET-assisted bisulfite sequencing. Methods Mol Biol 2021;2198:321-331. doi 10.1007/978-1-0716-0876-0_25. PMID 32822042. All four retrieved and read this pass.

AND THE RESOLVING PROTOCOL IS ALREADY PUBLISHED. TET-assisted bisulfite sequencing protects 5hmC by glycosylation, oxidizes 5mC and 5fC through to 5caC which converts to uracil, and leaves ONLY 5hmC standing as a cytosine signal — single-base resolution, with a published protein purification to go with it. SO THE GAP IS

NOT BETWEEN THE FIELD AND A FRONTIER. IT IS BETWEEN THE EDITORS NOW ENTERING CANCER THERAPY DEVELOPMENT AND AN ASSAY SITTING ON THE SHELF BESIDE THEM.

OFF THE BASE ENTIRELY

4A. The Linkage and the Sugar

Two positions in the molecule the four-letter alphabet never addressed · and sulfur is at both of them

Modes one through four are all disputes about WHICH LETTER GETS PRINTED. This section concerns two places where no letter was ever printed, because the notation has no field for them. A NUCLEOTIDE IS A BASE, A SUGAR AND A LINKAGE. THE ALPHABET NAMES ONE OF THE THREE.

	off the base
A TERMINOLOGY RULING, MADE FIRST BECAUSE THE FIELD AND THIS CORPUS DISAGREE	IN THIS CORPUS, BACKBONE MEANS THE SUGAR — deoxyribose, ribose, arabinose, the three axes. THE PHOSPHODIESTER IS THE LINKAGE. Oligonucleotide chemistry uses the opposite convention, calling phosphorothioate a backbone modification and 4-prime-thio a sugar modification. The corpus's usage is the defensible one: A BACKBONE IS MADE OF VERTEBRAE, NOT OF THE DISCS BETWEEN THEM. The sugar is the rigid unit with a defined pucker; the phosphodiester is the joint. Both senses are stated here so that no reader has to guess which is meant.
SULFUR IN THE LINKAGE	A non-bridging oxygen of the phosphodiester replaced by sulfur — PHOSPHOROTHIOATE. IT OCCURS NATURALLY, SEQUENCE-SELECTIVELY AND IN THE Rp CONFIGURATION, written by the dndABCDE gene products and paired with DndFGH into a defense system that distinguishes and attacks unmodified foreign DNA. The primary literature calls it THE FIRST PHYSIOLOGICAL MODIFICATION IDENTIFIED ON THE DNA BACKBONE — in the field's sense of that word.
AND IT IS A RIVAL ALPHABET, NOT A CURIOSITY	Phosphorothioate and methylation both run restriction-modification systems, AND THEY EVOLVED TO TARGET DIFFERENT CONSENSUS SEQUENCES BECAUSE WHERE THEY SHARE A RECOGNITION SITE EACH IMPEDES THE OTHER. Two marking systems that could not occupy the same positions. The sulfur one also does redox work — its redox and nucleophilic properties are credited with roles in cellular redox homeostasis and environmental fitness — SO THE MARK IS ALSO A REAGENT.
SULFUR IN THE BACKBONE, IN THIS CORPUS'S SENSE	THE RING OXYGEN OF THE SUGAR REPLACED BY SULFUR: 4-prime-thioribose. Synthesized, incorporated into RNA and crystallized. Incorporating the thio-cytidine improved duplex thermal stability by

	off the base
	ABOUT ONE DEGREE PER MODIFICATION, comparable to 2-prime-O-methyl.
AND THE STRUCTURE SETTLED A QUESTION IN THE NEGATIVE, WHICH IS WHY IT IS PRINTED	It would be natural to expect a larger atom in the ring to shift the sugar pucker, and therefore to move the molecule between axes. IT DOES NOT. The crystal structure reports that the two thioriboses ADOPT CONFORMATIONS VERY SIMILAR TO THE C3-PRIME-ENDO PUCKER of the native sugars, with subtle changes attributed mostly to the larger radius of sulfur. SO THIS IS NOT A FOURTH AXIS AND NOT AN AXIS SWITCH — it is a modifier that sits on an existing axis and strengthens it. A stability gain at no conformational cost.
WHAT THE TWO HAVE IN COMMON	NEITHER IS A BASE, AND NEITHER IS VISIBLE TO A FOUR-LETTER READOUT. Not because the readout resolves them badly, but because it never addressed those positions at all.

Wang L, Jiang S, Deng Z, Dedon PC, Chen S. DNA phosphorothioate modification: a new multi-functional epigenetic system in bacteria. FEMS Microbiol Rev 2019;43(2):109-122. doi 10.1093/femsre/fuy036. PMID 30289455. · Chen S, Wang L, Deng Z. Twenty years hunting for sulfur in DNA. Protein Cell 2010;1(1):14-21. doi 10.1007/s13238-010-0009-y. PMID 21203994. · Haeberli P, Berger I, Pallan PS, Egli M. Nucleic Acids Res 2005;33(13):3965-75. doi 10.1093/nar/gki704. PMID 16027443. All retrieved and read this pass.

SO THE CENSUS IN §2 UNDERSTATES THE GAP. IT COUNTED THE SPECIES THE ALPHABET PRINTS WRONGLY. IT DID NOT COUNT THE POSITIONS THE ALPHABET NEVER ADDRESSED. A nucleotide has three parts and the notation names one of them.

THE ISSUES

5. Nine Issues, Across Both Editing Classes

These are not eight independent problems. THEY ARE ONE SUBSTITUTION PROPAGATING THROUGH A STACK, and they are numbered separately because each layer has its own fix and its own cost. THE LAST TWO LEAVE THE BASE ENTIRELY.

	the issue	why it matters here
ISSUE 1	THE BASE-EDITING WINDOW IS CHARACTERIZED ON THE ENDPOINT, NOT THE EVENT.	Each construct's window is established by sequencing outcomes. TWO REMOVES FROM THE CHEMISTRY: a window measured across contexts somebody chose is not a window known across the genome, AND THE DEAMINATION PRODUCT IS INOSINE WHILE THE MEASURED PRODUCT IS GUANOSINE AFTER REPLICATION OR REPAIR. Per-position efficiency describes what survived downstream processing.
ISSUE 2	IN SILICO HERE MEANS SEQUENCE-STATISTICAL, AND THE SEQUENCES HAVE FOUR LETTERS.	Recent editor engineering used an in silico protein evolution algorithm over sequence and fitness. A MODEL TRAINED ON A FOUR-LETTER ALPHABET DOES NOT REPRESENT THE OTHER THREE HUNDRED POORLY. IT HAS NO TOKEN FOR THEM. That is a vocabulary limit, not an accuracy limit, and more four-letter data makes it worse rather than better.
ISSUE 3	OFF-TARGET PREDICTION SEARCHES A REFERENCE IN WHICH THE COLLAPSE HAS ALREADY HAPPENED.	Predicted off-target sites are found by sequence homology against a reference where every inosine is written G and every 5mC is written C. BINDING IS NECESSARY AND NOT SUFFICIENT, and the search is running over a sequence that is not the sequence present.
ISSUE 4	RNA OFF-TARGET EDITS CANNOT BE ATTRIBUTED AT ALL. THIS IS THE CRITICAL ONE FOR GENE EDITING.	Base editors cause tens of thousands of transcriptome-wide edits at frequencies from 0.07 to 100 per cent in 38 to 58 per cent of expressed genes, generating missense, nonsense, splice-site and untranslated-region mutations — AND AN ADENINE BASE EDITOR ALSO INDUCES TRANSCRIPTOME-WIDE RNA EDITS. The cell's own ADAR enzymes make A-to-I edits continuously. BOTH PRODUCE INOSINE. BOTH PRINT AS G. An A-to-G call cannot be assigned to the editor rather than to the cell, AND THE INFORMATION IS DESTROYED AT THE ALPHABET RATHER THAN LOST TO COVERAGE.
ISSUE 5	THE EPIGENETIC EDITOR'S PRODUCT IS INDISTINGUISHABLE FROM ITS SUBSTRATE. THIS IS THE CRITICAL ONE FOR EPIGENETIC EDITING.	Set out in §4. A working dCas9-TET1 edit registers as no change under the standard assay, in both directions. AND THE MARK IN QUESTION IS ITSELF A 2025 CLINICAL TARGET — 5hmC is described in a 2025 review as a key epigenetic biomarker for tumorigenesis, with new biosensors being built because the established techniques are inadequate. The editors and the biomarker are moving at once, and the assay between them cannot tell them apart.
ISSUE 6	EPITRANSCRIPTOMIC EDITORS ARE BEING BUILT FOR MARKS WITH NO SYMBOL AT ALL.	Engineering of the epitranscriptome is named in a 2023 review as an emerging direction for investigating RNA modifications and their causal effects at high specificity. THE MARKS BEING WRITTEN — METHYLATED ADENOSINE, PSEUDOURIDINE, 2'-O-METHYL — ARE MODE TWO AND MODE THREE FAILURES. An editor for a mark the readout erases is an editor whose on-target efficiency has no standard measurement.
ISSUE 7	THE EDITOR'S INTERMEDIATE IS A REPAIR SUBSTRATE, AND THE READOUT SEES ONLY THE ENDPOINT.	Deoxyinosine in DNA is recognized by base excision repair. The adenine editor's product sits at a fork: replicated over it becomes the intended guanosine, excised it becomes something else. WHAT DECIDES THE FORK IS THE LEAST CONTROLLED STEP IN THE FIELD, and its known modulator is a four-iron

	the issue	why it matters here
		sulfur cluster whose redox state governs DNA-binding affinity by roughly five hundred fold, activated at a distance through the base stack — a metal cluster nobody computes.
ISSUE 8	AN EDITOR AIMED AT THE LINKAGE OR THE SUGAR HAS NO READOUT AT ALL.	Every issue above concerns a base. §4A sets out two positions — the phosphodiester linkage and the sugar ring oxygen — where sulfur substitution is real, natural in the first case and synthetic in the second, AND WHERE A FOUR-LETTER READOUT MAKES NO CLAIM WHATEVER. If editing moves off the base, THE SCORING PROBLEM IS NOT HARDER. IT IS ABSENT.
ISSUE 9	AND THE ATOMIC-LEVEL PROGRAM IS DOWNSTREAM OF ALL OF THE ABOVE.	A reaction barrier computed at a site annotated G that is in fact I, or annotated C that is in fact 5hmC, IS A CORRECT CALCULATION ON THE WRONG MOLECULE. It converges. It reports error bars. INOSINE-CYTOSINE CARRIES TWO HYDROGEN BONDS WHERE GUANINE-CYTOSINE CARRIES THREE, so the proton inventory at the interface is different — and the proton inventory at the interface is the entire subject of the tunneling program THERE IS NO SENSE REACHING FOR SUB-ANGSTROM RESOLUTION ON A SUBSTRATE ASSIGNED BY A LOOKUP TABLE.

Nguyen TA et al. Nat Methods 2022;19(7):833-844. doi 10.1038/s41592-022-01513-3. PMID 35697834. · Grünewald J, Zhou R, Garcia SP, Iyer S, Lareau CA, Aryee MJ, Joung JK. PMID 38103979. · Barton JK, Silva RMB, O'Brien E. Annu Rev Biochem 2019;88:163-190. PMID 31220976.

THE SOLUTIONS

6. Nine Solutions, Every One Already in Print

A solution proposed from outside a field is a suggestion. A solution assembled from routes the field has already published is a plan. NOT ONE OF THE NINE BELOW REQUIRES AN INSTRUMENT THAT DOES NOT EXIST — AND THE LAST TWO REQUIRE NO INSTRUMENT AT ALL.

6.1 ADOPT THE INSTRUMENT THAT ALREADY SEES THE OTHER LETTERS.

Direct RNA nanopore sequencing distinguishes inosine from adenosine and from guanosine in native transcriptomes and estimates the per-site modification rate, demonstrated across human, mouse and Xenopus and published in 2022. A 2025 review reports the same platform detecting 2'-O-methylation, methylated adenosine, methylated cytosine, acetylated cytidine, methylated guanosine, PSEUDOURIDINE and A-to-I editing, with computational frameworks that call CO-OCCURRING modifications on individual transcripts. THE INSTRUMENT COVERS THE WHOLE CLASS, NOT ONE MEMBER OF IT.

6.2 RETIRE PLAIN BISULFITE AS THE SCORING ASSAY FOR DEMETHYLATION EDITING.

TET-assisted bisulfite sequencing resolves 5-hydroxymethylcytosine at single-base resolution: 5hmC is protected by glycosylation, 5mC and 5fC are oxidized through to 5caC which converts to uracil, and only 5hmC survives as a cytosine signal. IT IS A PUBLISHED PROTOCOL WITH A PUBLISHED PROTEIN PURIFICATION. ANY dCas9-TET1 RESULT SCORED BY PLAIN BISULFITE SHOULD BE RE-SCORED, and until it is, the reported efficiency is a lower bound of unknown tightness.

6.3 STATE WHICH SPECIES WAS WRITTEN, NOT WHICH SYMBOL WAS READ.

A one-line convention costing nothing. AN ADENINE BASE EDITOR PRODUCES INOSINE; CALLING IT AN A-TO-G EDITOR NAMES THE PRINTOUT RATHER THAN THE CHEMISTRY. A targeted demethylase produces 5hmC first. Naming the product rather than the symbol makes the measurement question visible to every reader on first contact, WHICH IS MOST OF WHAT THIS PAPER IS TRYING TO ACHIEVE.

6.4 TURN THE MEASURED WINDOW INTO A TEST SET.

Per-position editing efficiencies are published for several deaminase constructs. THAT IS A LABELED DATASET FOR A CALCULATION NOBODY HAS RUN. Compute a deamination barrier at each position and correlate — with the product modeled as inosine rather than as guanosine, which is the correction this paper exists to make and costs nothing to apply.

6.5 SCORE THE INTERMEDIATE, NOT ONLY THE ENDPOINT.

The editor makes inosine; the assay reads guanosine after the cell has finished processing it. A READOUT TAKEN BEFORE REPLICATION AND REPAIR SEPARATES ENZYME SPECIFICITY FROM REPAIR OUTCOME, which are currently reported as one number. Two mechanisms are being optimized through a single measurement and nobody knows the split.

6.6 BUILD THE EPITRANSCRIPTOMIC EDITOR AND ITS ASSAY IN THE SAME PROGRAM .

The field is now engineering the epitranscriptome. AN EDITOR FOR A MARK THE STANDARD READOUT ERASES HAS NO STANDARD ON-TARGET MEASUREMENT, so the assay is not a downstream concern — IT IS PART OF THE CONSTRUCT'S SPECIFICATION. Pairing them at the outset costs a fraction of what re-scoring a literature costs, and the 5mC data sets are the precedent for what re-scoring a literature costs.

6.7 PUT THE REPAIR COFACTOR ON THE HARDWARE ROADMAP EXPLICITLY.

The October 2025 closed-loop hybrid demonstration computed a TWO-IRON sulfur species to classical parity. THE BIOLOGICALLY INTERESTING CLUSTER IS THE FOUR-IRON ONE and it is the switch on the repair enzymes that decide issue 7. Naming it converts a hardware milestone into a stated biological objective with a measurable endpoint.

6.8 GIVE THE NOTATION A FIELD FOR THE SUGAR AND A FIELD FOR THE LINKAGE.

The cheapest of the nine and the one nobody has asked for. A nucleotide has three parts and the four-letter string names one. AN ANNOTATION FORMAT WITH THREE FIELDS RATHER THAN ONE — base, sugar, linkage — COSTS NOTHING TO SPECIFY AND MAKES A WHOLE CLASS OF MODIFICATION EXPRESSIBLE FOR THE FIRST TIME. It does not require anyone to measure anything new. It requires a place to write down what is measured, WHICH IS THE PRECONDITION FOR MEASURING IT AT ALL.

6.9 FIX THE ALPHABET BEFORE REACHING FOR THE ATOM.

This is the ordering claim and it is the paper's conclusion. Every atomic-level ambition in this program — barrier calculation, tunneling, quantum coprocessing — TAKES THE IDENTITY OF THE SUBSTRATE AS AN INPUT. An input assigned from a four-letter reference is an assumption wearing the clothes of a measurement. THE ORDER IS NOT NEGOTIABLE AND THE FIRST STEP IS THE CHEAPER ONE.

THE EXPERIMENTS

7. Eight Null Hypotheses

Each stated so a result can reject it · four need no new chemistry · the last is designed to fail today and says so

A-1 · Whether an A-to-G call can be attributed to the editor at all

GENE EDITING · THE COLLAPSE EXPERIMENT · RUN THIS FIRST

A-1	GENE EDITING · THE COLLAPSE EXPERIMENT · RUN THIS FIRST
THE NULL HYPOTHESIS	H_0: IN CELLS EXPRESSING AN ADENINE BASE EDITOR, DIRECT RNA NANOPORE SEQUENCING ASSIGNS NO GREATER SHARE OF A-TO-G CALLS TO EDITOR-DEPENDENT INOSINE THAN IT DOES IN MOCK-TRANSFECTED CELLS.
WHAT IS MEASURED	Per-site inosine modification rate by nanopore direct RNA sequencing, editor against mock, AT THE SAME SITES short-read sequencing reports as A-to-G. Two readouts of one sample set, so the biology is fixed and the alphabet is the variable.
THE MATERIAL	An editor already shown to induce transcriptome-wide RNA edits, and the published nanopore models that distinguish inosine from adenosine and guanosine with per-site rate estimation.
WHAT REJECTS IT	A measurable editor-attributable fraction. THE FIRST ATTRIBUTABLE RNA OFF-TARGET SAFETY DATA IN BASE EDITING, and it would establish what share of currently reported A-to-G calls are the cell's own housekeeping rather than the editor's damage.
WHAT FAILURE TO REJECT MEANS	Short reads and nanopore agree at this depth and the alphabet was not costing anything here. WORTH KNOWING, and it settles the question empirically rather than by argument.

A-1	GENE EDITING · THE COLLAPSE EXPERIMENT · RUN THIS FIRST
COST	One flow cell, one editor, one mock. NO NEW CHEMISTRY, NO NEW MODEL, NO PERMISSION.

A-2 · Whether a demethylation editor is being scored as having failed

EPIGENETIC EDITING · THE CONFLATION EXPERIMENT · THE SHARPEST OF THE EIGHT

A-2	EPIGENETIC EDITING · THE CONFLATION EXPERIMENT · THE SHARPEST OF THE EIGHT
THE NULL HYPOTHESIS	H_0: AT dCas9-TET1 TARGET SITES, TET-ASSISTED BISULFITE SEQUENCING REPORTS NO MORE 5-HYDROXYMETHYLCYTOSINE THAN PLAIN BISULFITE SEQUENCING WOULD IMPLY — THAT IS, THE TWO ASSAYS AGREE ON THE EDIT'S EFFICIENCY.
WHAT IS MEASURED	Per-site 5hmC fraction at targeted loci by TET-assisted bisulfite sequencing, against apparent demethylation efficiency by plain bisulfite, in the same samples.
THE MATERIAL	A published dCas9-TET1 construct and its target loci; the TAB-sequencing protocol with its published TET purification. THE COMPARISON IS BETWEEN TWO ASSAYS ON ONE SAMPLE, so the editing is held fixed.
WHAT REJECTS IT	A 5hmC fraction that plain bisulfite scored as persistent methylation. THAT WOULD MEAN REPORTED DEMETHYLATION EFFICIENCIES ARE SYSTEMATIC UNDERESTIMATES, and the size of the gap is the paper. It would also apply retroactively to the published record, which is what makes this the highest-value experiment in the set.
WHAT FAILURE TO REJECT MEANS	TET1 editing runs to completion past 5hmC at these sites and plain bisulfite was adequate. A CLEAN NEGATIVE, worth publishing, and it would put reported demethylation efficiencies on firm ground rather than leaving them as lower bounds of unknown tightness.
COST	One protocol already published, on constructs already built. NO NEW EDITOR, NO NEW CELL LINE.

A-3 · Position in the window against computed barrier

NO WET LABORATORY · PUBLISHED DATA ONLY

A-3	NO WET LABORATORY · PUBLISHED DATA ONLY
THE NULL HYPOTHESIS	H_0: PER-POSITION EDITING EFFICIENCY ACROSS THE ACTIVITY WINDOW IS UNCORRELATED WITH THE COMPUTED DEAMINATION BARRIER AT THAT POSITION.
WHAT IS MEASURED	Rank correlation between published per-position efficiency and computed barrier, across the ten-position window of a wide-window editor and the four-position window of a narrowed one.

A-3	NO WET LABORATORY · PUBLISHED DATA ONLY
THE MATERIAL	Per-position efficiencies as published. Barriers by quantum mechanics embedded in molecular mechanics at the zinc center, WITH THE PRODUCT MODELED AS INOSINE.
WHAT REJECTS IT	A significant monotonic correlation. The window is then a barrier profile, established from data already in print.
WHAT FAILURE TO REJECT MEANS	The window is set by accessibility, residence time, or the extent of the single-stranded region. A REAL RESULT that redirects this paper rather than ending it.
COST	Compute time and one graduate student.

A-4 · Whether the narrowed window has a barrier signature

NO WET LABORATORY · A PAIRED COMPARISON

A-4	NO WET LABORATORY · A PAIRED COMPARISON
THE NULL HYPOTHESIS	H_0: THE BARRIER PROFILE OF THE NARROWED CONSTRUCT DOES NOT DIFFER FROM ITS PARENT AT THE POSITIONS WHERE THEIR MEASURED WINDOWS DIFFER.
WHAT IS MEASURED	Barrier at each parental window position, computed for both constructs, differenced.
THE MATERIAL	A construct pair differing only by a documented insertion — THE CLEANEST PAIRED CONTROL AVAILABLE IN THE FIELD.
WHAT REJECTS IT	A barrier difference concentrated at the positions the insertion removed from the window.
WHAT FAILURE TO REJECT MEANS	The insertion narrowed the window by restricting access rather than raising a barrier. A CLEAN ANSWER, and it would say the effective lever is geometry of approach rather than chemistry of reaction.
COST	The A-3 pipeline, run twice.

A-5 · What share of current demethylation editing can separate product from substrate

A LITERATURE AUDIT · NO CHEMISTRY · A COUNT NOBODY HAS TAKEN

A-5	A LITERATURE AUDIT · NO CHEMISTRY · A COUNT NOBODY HAS TAKEN
THE NULL HYPOTHESIS	H_0: AMONG TARGETED-DEMETHYLATION STUDIES PUBLISHED IN THE LAST THREE YEARS, THE PROPORTION SCORED WITH AN ASSAY THAT SEPARATES 5hmC FROM 5mC IS HIGH ENOUGH THAT REPORTED EDITING EFFICIENCIES CAN BE COMPARED ACROSS PAPERS.
WHAT IS MEASURED	Proportion of recent targeted-demethylation papers whose scoring assay resolves the two species, the proportion that state the limitation when it

A-5	A LITERATURE AUDIT · NO CHEMISTRY · A COUNT NOBODY HAS TAKEN
	does not, and whether reported efficiencies differ systematically between the two groups.
THE MATERIAL	The 2023 to 2026 record, which is the window in which these editors moved toward cancer therapy development. THE THIRD MEASURE IS THE INTERESTING ONE: if efficiencies reported with resolving assays run higher, THAT IS THE SIZE OF THE UNDERCOUNT, READ OFF THE LITERATURE WITHOUT RUNNING ANYTHING.
WHAT REJECTS IT	High adoption, and efficiencies that do not differ between the two groups. The field is scoring this correctly, cross-paper comparison is sound, and that is learnable in weeks.
WHAT FAILURE TO REJECT MEANS	A LOW RATE WOULD MEAN REPORTED DEMETHYLATION EFFICIENCIES ARE NOT COMPARABLE ACROSS PAPERS — a measurement-standards finding about a therapeutic modality now in development, needing no laboratory, no permission and no funding. A STATISTIC THIS CORPUS WOULD OWN RATHER THAN BORROW.
COST	Weeks of reading. THE CHEAPEST ITEM HERE AND POSSIBLY THE MOST VALUABLE.

A-6 · Whether the isomer is present where editors are being aimed

THE PSEUDOURIDINE CASE · MODE THREE · ONE MEASUREMENT, MANY PROGRAMS

A-6	THE PSEUDOURIDINE CASE · MODE THREE · ONE MEASUREMENT, MANY PROGRAMS
THE NULL HYPOTHESIS	H_0: AT SITES TARGETED BY EPITRANSCRIPTOMIC EDITORS AND OLIGONUCLEOTIDE THERAPEUTICS, THE PSEUDOURIDINE FRACTION IN THE RELEVANT TISSUE IS INDISTINGUISHABLE FROM ZERO.
WHAT IS MEASURED	Per-site pseudouridine occupancy across the targeted footprint, by a signal-level or chemistry-based method, in the tissue the agent acts in.
THE MATERIAL	Published target sequences and the detection frameworks catalogued in the 2025 nanopore review. PSEUDOURIDINE HAS THE SAME FORMULA AND MASS AS URIDINE, so this cannot be done by the obvious backup instrument and must be done deliberately.
WHAT REJECTS IT	Non-negligible occupancy at a targeted position. A DESIGNED DUPLEX AND AN ENCOUNTERED DUPLEX THEN DIFFER AT A POSITION SOMEBODY OPTIMIZED, and occupancy becomes a design parameter rather than an unmodeled background.
WHAT FAILURE TO REJECT MEANS	Modification does not reach these positions. A CLEAN NEGATIVE worth having in print, confining the concern to a defined set of programs rather than none.
COST	Flow cells and tissue. NO SYNTHESIS, NO ANIMALS.

A-7 · The repair fork, at the level that decides the edit

WET LABORATORY · THE LONGEST OF THE EIGHT

A-7	WET LABORATORY · THE LONGEST OF THE EIGHT
THE NULL HYPOTHESIS	H_0: THE FATE OF THE DEOXYINOSINE INTERMEDIATE — REPLICATED OVER AGAINST EXCISED — DOES NOT VARY WITH THE OXIDATION STATE OF THE FOUR-IRON CLUSTER IN THE REPAIR ENZYMES ACTING AT THE SITE.
WHAT IS MEASURED	Ratio of intended conversion to other outcomes at one well-characterized target, under conditions shifting cluster oxidation state.
THE MATERIAL	A repair enzyme carrying the cluster, and the published five-hundred-fold affinity shift as the expected size of the effect.
WHAT REJECTS IT	An outcome-ratio shift tracking oxidation state. THAT MAKES THE LEAST CONTROLLABLE STEP IN GENE EDITING ADDRESSABLE THROUGH A CHEMICAL HANDLE — the largest prize named in this paper.
WHAT FAILURE TO REJECT MEANS	Affinity changes without changing outcome. The cluster is a binding switch and not an outcome switch — a narrower role, honestly established.
COST	Months, a cell model, deep sequencing. RUN IT AFTER A-1 AND A-3 REPORT.

A-8 · Whether quantum hardware adds anything, asked against itself

THE ADVERSARIAL ONE · EXPECTED TO FAIL TODAY, AND PRINTED ANYWAY

A-8	THE ADVERSARIAL ONE · EXPECTED TO FAIL TODAY, AND PRINTED ANYWAY
THE NULL HYPOTHESIS	H_0: A HYBRID QUANTUM-CLASSICAL TREATMENT OF THE DEAMINASE METAL CENTER PREDICTS PER-POSITION EDITING EFFICIENCY NO BETTER THAN DENSITY FUNCTIONAL THEORY AT THE SAME EMBEDDING.
WHAT IS MEASURED	Prediction error against the A-3 efficiencies, for both methods, WITH THE CLASSICAL BASELINE REPORTED IN FULL.
THE MATERIAL	A zinc center small enough for current hardware. The October 2025 demonstration reached PARITY WITH the best classical approximation methods on a comparable problem.
WHAT REJECTS IT	Lower prediction error from the hybrid arm, reproducibly, with the baseline stated.
WHAT FAILURE TO REJECT MEANS	EXPECTED AT PRESENT HARDWARE, AND SAYING SO IN ADVANCE IS THE POINT. It also carries the paper's conclusion: THERE IS NO SENSE REACHING FOR THE ATOMIC LEVEL WHILE THE MOLECULAR LEVEL IS STILL BEING ASSIGNED FROM A LOOKUP TABLE. Run A-1 and A-2 first, and this experiment becomes worth running.
COST	Hardware access. The cheapest part is admitting what it will probably show.

8. What This Paper Does Not Claim

— IT DOES NOT CLAIM THE FIELD IS UNAWARE OF THESE MOLECULES. It plainly is not — over 330 are catalogued, TET-assisted bisulfite sequencing exists, nanopore modification calling exists, and the most recent adenine editor is built from ADAR itself. THE CLAIM IS THAT THE MEASUREMENT STACK USED TO JUDGE EDITORS DOES NOT CARRY THE DISTINCTIONS, which is a different and far more correctable failure.

— IT DOES NOT CLAIM THE PUBLISHED EDITING WORK IS WRONG. The constructs work. THE CLAIM IS ABOUT WHAT THE SCORING CANNOT SEE, and in the epigenetic case the direction of the error favours the field rather than flattering it — efficiencies are probably UNDERSTATED.

— IT DOES NOT CLAIM QUANTUM HARDWARE IS REQUIRED. Seven of the eight experiments run without it, and the eighth is written to test the hardware claim rather than assume it.

— IT DOES NOT CLAIM COHERENCE, ENTANGLEMENT OR TUNNELING IN ANY EDITING REACTION. Nothing here needs them. THE QUANTITIES IN QUESTION ARE AN ORDINARY REACTION BARRIER AND AN ORDINARY MISIDENTIFICATION.

— AND IT DOES NOT REQUIRE THE READER TO ACCEPT ANY POSITION ON THE BERGER TRIPLEX ARCHITECTURE. Every experiment above is scored against published editing data or against a published assay.

FOUR SYMBOLS, THREE HUNDRED AND THIRTY SPECIES, AND MACHINES NOW BUILT TO WRITE IN THE PART THAT HAS NO SYMBOL. THE INSTRUMENTS THAT SEE THE REST ARE PUBLISHED, DEMONSTRATED AND UNADOPTED. THAT IS NOT A FRONTIER — IT IS A BACKLOG.

THE COLORS

9. How This Paper Is Colored

Seven colors, seven atoms, eight nucleotides · a paper about an alphabet that prints too few symbols does not print in black

SEVEN COLORS CARRY BOTH SERIES AT ONCE. Each color is one ATOM and one NUCLEOTIDE, and six of the seven are one-to-one with nothing ambiguous in them. RED IS HYDROGEN AND ADENINE. ORANGE IS OXYGEN AND INOSINE. GREEN IS NITROGEN AND GUANINE. BLUE IS CARBON AND CYTOSINE. PURPLE IS PHOSPHORUS AND URACIL. YELLOW IS SULFUR AND THYMINE.

INDIGO IS THE ONE THAT CARRIES TWO, AND THAT IS WHERE THE EIGHTH NUCLEOTIDE SITS. Indigo is selenium, and it is XANTHINE AND OROTATE together — the two GATEKEEPERS. They share a color because they are the same object in the two series: XANTHINE OPENS ONTO GUANINE in the purines, OROTATE OPENS ONTO URACIL in the pyrimidines. One gate on each side of the code. Neither is ever a letter at the edge, because nothing carries either into a polymer, and a gate is not a symbol.

AND INDIGO IS THE RIGHT BAND FOR THEM. IT IS THE ONE COLOR IN THE SPECTRUM THE HUMAN EYE BARELY SEPARATES FROM ITS NEIGHBORS. A gatekeeper is the position in the pathway nobody reads out, and it is given the color nobody quite resolves. SEVEN ATOMS, EIGHT NUCLEOTIDES, SEVEN COLORS — and the doubling falls exactly where the biology already doubled it.

So the two alphabets of the title render as what they are. ATGC is red, yellow, green, blue. AUGC is red, purple, green, blue. AND THE SPECIES THIS PAPER IS ABOUT TAKE THE COLOR OF THE LETTER THEY ARE PRINTED AS: 5mC, 5hmC, 5fC and 5caC are blue because a sequencer prints them C; m6A is red because a sequencer prints it A; pseudouridine is purple because a sequencer prints it U; AND INOSINE IS ORANGE, WHICH IS THE ONE PLACE THE PAGE AND THE SEQUENCER DISAGREE — the machine prints it green, as guanosine, and orange is what it actually is.

ONE DETAIL WORTH THE READER'S EYE. ACROSS THE TET CASCADE — METHYL, HYDROXYMETHYL, FORMYL, CARBOXYL — EXACTLY ONE OF THE FOUR CARRIES ORANGE, and it is 5-HYDROXYMETHYLCYTOSINE. That is the species §4 is about, the one the standard assay cannot separate from its substrate. THE OXYGEN THAT THE ASSAY CANNOT SEE IS VISIBLE ON THIS PAGE.

THE COLOR INDEX

Every shaded word in this volume is a link. A word with its own entry in the Index jumps to that entry; a letter, atom label or formula returns here.

color	element	base	nucleoside	nucleotide
ORANGE	O 8	HYPOXANTHINE	inosine	IMP
RED	H 1	ADENINE	adenosine	AMP
GREEN	N 7	GUANINE	guanosine	GMP
BLUE	C 6	CYTOSINE	cytidine	CMP
PURPLE	P 15	URACIL	uridine	UMP
YELLOW	S 16	THYMINE	thymidine	TMP
INDIGO	Se 34	XANTHINE and OROTATE — gatekeepers, not letters	xanthosine / orotidine	XMP / OMP

Page references are omitted here because they belong to the master volume's pagination, not to this paper's. Every term above is indexed in Berger Master Central Dogma PP-2026-MASTER-01.

THIS COMPLETES THE BEGINNING.

POSITION PAPER · NOVAGONDNA · PP-2026-SUL-01

The Sulfur Economy of Today

THE DOLLAR BEFORE THE DOLLAR — THE SULFUR SPINE. Sulfur does the job before there is a machine for the job, and it keeps doing the job in the margins afterward. It was the energy currency before phosphate, and it is what made phosphate available in the first place. It marked DNA before methyl did, and the two marking systems had to move apart because they could not share a position. It delivers the methyl group that writes every epigenetic mark now. It holds proteins folded, and it sits in a cabbage as a disarmed weapon waiting for the tissue to be cut. ONE ELEMENT, SIX SCALES, ONE PATTERN

SIX RUNGS · ONE PATTERN · FOUR ALREADY IN THE CORPUS · FIVE NULL HYPOTHESES

PP-2026-SUL-01 · 19 September 2026 · Naperville, Illinois

Dr. John Allen Berger · Independent Theoretical Researcher · NovagonDNA · Naperville, Illinois

1. The Argument, in One Sentence

SULFUR DOES THE JOB BEFORE THERE IS A MACHINE FOR THE JOB, AND KEEPS DOING IT IN THE MARGINS AFTERWARD.

THIS IS NOT A FOURTH SULFUR PAPER. It is the spine that orders the three that exist, and it exists because two rungs were missing and are now in hand: THE ENERGY RUNG AT THE BOTTOM AND THE INFORMATION RUNG IN THE

MIDDLE. Every claim below is a published measurement. What this paper adds is the ordering, and the ordering is the finding.

THE LADDER

2. Six Rungs, In the Order They Happened

Read down and it is a history · read across and it is one repeated move

the rung	what sulfur did	where	and what became of it
ENERGY	Thioester before phosphate. ACETYL PHOSPHATE IS THE EXCHANGE RATE between the two.	§3	Still on the books as acetyl-CoA, in every cell alive.
AVAILABILITY	Sulfur is what made phosphate available at all. ULTRAVIOLET LIGHT ON HYDROGEN SULFIDE OXIDIZED METEORITIC PHOSPHIDE TO PHOSPHATE.	§4	Still on the books as the iron-sulfur cluster, wherever electrons move.
INFORMATION	Sulfur marked DNA before methyl did, and the two systems had to move apart.	§5	Still running in bacteria, as a restriction-modification system made of sulfur.
THE METHYL ITSELF	The group that writes every epigenetic mark is DELIVERED BY A SULFUR. S-adenosylmethionine.	§6	Not a margin at all. This one went to the center and stayed.
STRUCTURE	The disulfide. The fold that holds when nothing else does.	§7	Still the bond that survives the stomach, which is why it is in the hormones we swallow.
DIET	Glucosinolate stored inert, isothiocyanate released lethal. THE PLANT KEEPS THE WEAPON DISARMED UNTIL THE TISSUE IS CUT.	§8	And the potency ladder runs on the number of sulfurs in the chain.

THE REPEATED MOVE IS THE SAME AT EVERY RUNG. SULFUR HOLDS POTENTIAL IN A BOND AND RELEASES IT BY BREAKING THAT BOND. Energy in a thioester, a mark in a phosphorothioate, a methyl on a sulfonium, a weapon in a glucosinolate. STORAGE AND TRIGGER, SIX TIMES, ACROSS FOUR BILLION YEARS AND FROM A HYDROTHERMAL VENT TO A HEAD OF CABBAGE.

THE BOTTOM RUNG

3. Thioester Before Phosphate

And the reason the search for an earlier currency was forced rather than optional

	the bottom rung
THE TRAP THAT FORCES THE QUESTION	Purine synthesis requires SIX PHOSPHORYLATION STEPS LINKED TO ATP HYDROLYSIS. ATP IS REQUIRED IN ORDER TO MAKE ATP. That autocatalytic requirement is not a curiosity — it is a proof that something else phosphorylated first, and the literature states it in exactly those terms: the loop IMPLIES THE NEED FOR AN EARLIER PREBIOTIC ATP EQUIVALENT.
WHAT WAS THERE FIRST	A THIOESTER. Acetyl phosphate can be synthesised in water WITHIN MINUTES FROM THIOACETATE under ambient conditions, and it is stable over hours depending on temperature, pH and cations — described by its authors as AN IDEAL POISE BETWEEN STABILITY AND REACTIVITY.
WHAT IT COULD DO	Acetyl phosphate phosphorylates RIBOSE TO RIBOSE-5-PHOSPHATE, ADENOSINE TO AMP, and ADP TO ATP IN WATER — the last at nearly TWENTY PER CENT YIELD in the presence of ferric ion. A wide range of other prebiotically plausible ions and minerals failed to catalyze it at all.
AND THE SELECTIVITY IS THE FINDING	ACETYL PHOSPHATE DID NOT PHOSPHORYLATE ANY OTHER NUCLEOSIDE DIPHOSPHATE. Not GDP. Not CDP. Not UDP. Only ADP. So the question that has no good answer in the standard account — why ATP and not GTP — has a chemical one: ITS FORMATION IS FAVOURED IN AQUEOUS SOLUTION UNDER MILD PREBIOTIC CONDITIONS AND THE OTHERS ARE NOT.
THE SENTENCE THIS PAPER EXISTS TO PRINT	SULFUR CHOSE ADENINE. The universal energy currency is adenine-based because a thioester-derived phosphorylating agent would phosphorylate adenine and nothing else. The currency did not win a competition. IT WAS THE ONLY ONE THE PREVIOUS CURRENCY COULD MINT.
AND WHAT SULFUR COULD NOT DO, WHICH IS ALSO PRINTED	Acetyl phosphate DID NOT promote polymerization of glycine or of AMP. The amino group of glycine was preferentially acetylated instead, hindering peptide formation. So the thioester world primed METABOLISM and not POLYMERS, and the authors draw the conclusion plainly: a period of MONOMER AND COFACTOR CATALYSIS preceded the emergence of polymeric enzymes or ribozymes.

Whicher A, Camprubi E, Pinna S, Herschy B, Lane N. Acetyl phosphate as a primordial energy currency at the origin of life. Orig Life Evol Biosph 2018;48(2):159-179. doi 10.1007/s11084-018-9555-8. PMID 29502283. · Pinna S, Kunz C, Halpern A, Harrison SA, Jordan SF, Ward J, Werner F, Lane N. A prebiotic basis for ATP as the universal energy currency. PLoS Biol 2022;20(10):e3001437.

doi 10.1371/journal.pbio.3001437. PMID 36194581. Both retrieved and read this pass.

4. And Sulfur Is What Made Phosphate Possible

The rung below the bottom rung · sulfur appears twice in the phosphorus story, and this is the first time

A currency needs a mint. Before sulfur could hand the job to phosphate, THERE HAD TO BE PHOSPHATE, and on the early Earth there very nearly was not.

	the rung below
THE SCARCITY IS REAL AND IT IS A STANDING PROBLEM	The relatively small amount of phosphorus that reached the lithosphere went mostly into CALCIUM APATITE, and its insolubility is described in print as A SIGNIFICANT PROBLEM TO THOSE CONTEMPLATING THE ORIGIN OF LIFE, given the foundational role of phosphate in extant biology and the apparent requirement for it as catalyst, buffer and reagent.
THE DELIVERY CAME FROM OUTSIDE	REDUCED METEORITES SUCH AS ENSTATITE CHONDRITES ARE HIGHLY ENRICHED IN PHOSPHIDE MINERALS, and on reaction with water these release phosphorus species in several oxidation states.
AND SULFUR FINISHED THE JOB	Those reduced phosphorus species are oxidized fully to phosphate SIMPLY BY THE ACTION OF ULTRAVIOLET LIGHT ON HYDROGEN SULFIDE. Low-pressure mercury lamps simulated the young Sun; the progress of the reactions was monitored by PHOSPHORUS-31 NMR. The authors describe the route as a cosmochemically and geochemically plausible means of supplying phosphate to prebiotic chemistry on the early Earth AND POTENTIALLY ON OTHER PLANETS.
SO THE ORDER IS NOT WHAT IT LOOKS LIKE	The usual telling has phosphate as the foundation and sulfur as a curiosity at the edge. THE CHEMISTRY HAS IT THE OTHER WAY AROUND. Sulfur delivered phosphorus into a usable oxidation state, and then a thioester made it energetic. SULFUR APPEARS TWICE IN THE PHOSPHORUS STORY AND BOTH TIMES IT IS UPSTREAM.

Ritson DJ, Mojzsis SJ, Sutherland JD. Supply of phosphate to early Earth by photogeochemistry after meteoritic weathering. Nat Geosci 2020;13(5):344-348. doi 10.1038/s41561-020-0556-7. PMID 32395178. Retrieved and read this pass.

AND THIS IS WHERE THE ECONOMY METAPHOR STOPS BEING A METAPHOR. Sulfur was the currency. Phosphate replaced it. ACETYL PHOSPHATE IS THE EXCHANGE RATE, AND THE CHANGEOVER IS

STILL ON THE BOOKS — every acetyl-CoA in every cell is a thioester paying into a phosphate economy.

THE MIDDLE RUNG

5. Sulfur Marked DNA Before Methyl Did

And the two systems could not share a position, which is the part nobody expects

A TERMINOLOGY NOTE FIRST, because this corpus and the field disagree. HERE, BACKBONE MEANS THE SUGAR — deoxyribose, ribose, arabinose, the three axes. THE PHOSPHODIESTER IS THE LINKAGE. Oligonucleotide chemistry uses the opposite convention. Sulfur turns out to sit at both positions, so the distinction is not pedantry; it is the difference between two separate findings.

	the middle rung
SULFUR IN THE LINKAGE	A non-bridging oxygen of the phosphodiester replaced by sulfur. It was found occurring NATURALLY in bacteria, IN A SEQUENCE-SELECTIVE AND Rp CONFIGURATION-SPECIFIC MANNER, catalyzed by the dndABCDE gene products. The primary literature calls it THE FIRST PHYSIOLOGICAL MODIFICATION IDENTIFIED ON THE DNA BACKBONE.
IT IS A COMPLETE MARKING SYSTEM, NOT A DECORATION	With DndFGH it constitutes A DEFENSE BARRIER THAT CAN DISTINGUISH AND ATTACK NON-MODIFIED FOREIGN DNA, described as RESEMBLING METHYLATION-BASED RESTRICTION-MODIFICATION SYSTEMS. Write, read, and destroy what is unmarked. The same architecture as the methyl system, built from a different atom.
AND THE TWO COULD NOT SHARE A POSITION. THIS IS THE FINDING.	Despite their similar defensive mechanisms, the two systems EVOLVED TO TARGET DIFFERENT CONSENSUS CONTEXTS IN THE HOST CELL — BECAUSE WHEN THEY SHARE THE SAME RECOGNITION SEQUENCES, THE PROTECTIVE FUNCTION OF EACH CAN BE IMPEDED. Two alphabets competing for the same letters, forced apart by interference. THAT IS NOT A STORY ABOUT SULFUR. IT IS A STORY ABOUT WHAT HAPPENS WHEN A GENOME CARRIES TWO NOTATIONS AT ONCE.
THE MARK IS ALSO A REAGENT	The REDOX AND NUCLEOPHILIC PROPERTIES of the phosphorothioate sulfur are credited with roles in the maintenance of cellular redox homeostasis, epigenetic regulation and environmental fitness. A methyl group marks. THIS ONE MARKS AND PARTICIPATES.
AND ITS DISTRIBUTION IS TRADE-SHAPED	The widespread presence of the dnd systems is considered A CONSEQUENCE OF EXTENSIVE HORIZONTAL GENE TRANSFER, with the ubiquitous but sporadic pattern explained by the lability of the mark under oxidative stress. A gene cluster that moves between lineages as a traded good.

	the middle rung
SULFUR IN THE BACKBONE, IN THIS CORPUS'S SENSE	THE RING OXYGEN OF THE SUGAR REPLACED BY SULFUR. Synthesized, incorporated into RNA, crystallized: duplex thermal stability improved by ABOUT ONE DEGREE PER MODIFICATION, comparable to 2-prime-O-methyl. AND THE CRYSTAL STRUCTURE SETTLED A QUESTION IN THE NEGATIVE — the modified sugars adopt conformations VERY SIMILAR TO THE NATIVE PUCKER, with the subtle differences attributed mostly to sulfur's larger radius. SO IT IS NOT A FOURTH AXIS AND NOT AN AXIS SWITCH. It is a modifier that sits on an existing axis and strengthens it.

Wang L, Jiang S, Deng Z, Dedon PC, Chen S. DNA phosphorothioate modification: a new multi-functional epigenetic system in bacteria. FEMS Microbiol Rev 2019;43(2):109-122. doi 10.1093/femsre/fuy036. PMID 30289455. · Chen S, Wang L, Deng Z. Twenty years hunting for sulfur in DNA. Protein Cell 2010;1(1):14-21. doi 10.1007/s13238-010-0009-y. PMID 21203994. · Haeberli P, Berger I, Pallan PS, Egli M. Nucleic Acids Res 2005;33(13):3965-75. doi 10.1093/nar/gki704. PMID 16027443. All retrieved and read this pass.

6. The Methyl Group Is Delivered by a Sulfur

The rung that did not stay in the margins

Every other rung is a story about sulfur being displaced and continuing at the edges. THIS ONE IS THE EXCEPTION AND IT IS THE LARGEST SULFUR FACT IN BIOLOGY. The companion paper on the four-letter alphabet is about methyl marks — 5-methylcytosine, N6-methyladenosine, the whole epigenetic vocabulary. EVERY ONE OF THOSE METHYL GROUPS ARRIVES ON A SULFUR.

	the methyl
THE CARRIER	S-adenosylmethionine. A methyl group held on a POSITIVELY CHARGED SULFONIUM CENTER, which is what makes it transferable: the sulfonium is a good leaving group and the methyl comes off readily. A NEUTRAL SULFUR WOULD NOT DONATE. THE CHARGE IS THE MECHANISM.
WHAT DEPENDS ON IT	DNA methylation. Histone methylation. RNA methylation. The entire writing side of the epigenome, and a large share of small-molecule metabolism besides.
AND IT IS THE SAME PATTERN AS EVERY OTHER RUNG	Potential stored in a sulfur bond, released by breaking it. The thioester holds energy; THE SULFONIUM HOLDS A METHYL. Same element, same trick, different cargo.
WHICH PUTS THE	That paper argues the four-letter readout cannot see the methyl mark. THIS

	the methyl
ALPHABET PAPER IN THIS ONE'S DEBT	ONE ADDS THAT THE MARK IS NOT MADE OF CARBON AND HYDROGEN ALONE — IT IS DELIVERED BY THE ELEMENT THE READOUT ALSO CANNOT SEE. The invisible mark and the invisible courier are the same story told at two scales.

7. The Fold

The rung where sulfur stopped carrying anything and started holding

	the fold
THE BOND	Two cysteines, one disulfide. THE DIHEDRAL SITS NEAR NINETY DEGREES, so a sulfur-sulfur bridge genuinely TWISTS rather than lying flat — which is why the drawn form of it is a figure eight and not a line.
WHAT IT BUYS	A covalent crosslink inside a fold, made and broken by redox rather than by a dedicated enzyme reading a sequence. PROTEINS THAT MUST SURVIVE OUTSIDE THE CELL CARRY THEM; PROTEINS THAT WORK IN THE REDUCING INTERIOR LARGELY DO NOT.
AND IT IS STILL STORAGE AND TRIGGER	A disulfide is potential held in a bond, released by reduction. The same move as the thioester and the sulfonium — EXCEPT THAT HERE WHAT IS STORED IS SHAPE.

THE TOP RUNG

8. The Disarmed Weapon in a Head of Cabbage

Measured in 1997, and the numbers make the pattern quantitative for the first time

The rung most easily dismissed as nutrition trivia turns out to carry the cleanest arithmetic in the paper. Selected sulfur compounds from cabbage and sauerkraut were tested for MINIMUM INHIBITORY CONCENTRATION against fifteen species of bacteria and four of yeasts.

the compound	minimum inhibitory concentration	what it is
SINIGRIN, S-METHYL-CYSTEINE SULFOXIDE,	NOT INHIBITORY TO ANYTHING AT 500 PARTS PER MILLION.	THE STORAGE FORMS. Soluble, stable, harmless.

the compound	minimum inhibitory concentration	what it is
DIMETHYL SULFIDE		
DIMETHYL DISULFIDE	Retarded some growth at 500 ppm; PREVENTED NONE.	Two sulfurs. Weak.
DIMETHYL TRISULFIDE	200 ppm against bacteria, 20 PPM AGAINST YEAST.	Three sulfurs. Active.
METHYL METHANETHIOSULFINATE	50 to 200 ppm against bacteria, 6 TO 10 PPM AGAINST YEAST.	AND IT IS THE PRIMARY BREAKDOWN PRODUCT of the sulfoxide that did nothing at 500.
ALLYL ISOTHIOCYANATE	50 to 500 ppm against bacteria, 1 TO 4 PPM AGAINST YEAST.	AND IT IS THE HYDROLYSIS PRODUCT OF SINIGRIN, which did nothing at 500.

	what the numbers say
PATTERN ONE — THE PRECURSOR IS INERT AND THE PRODUCT IS THE WEAPON	Sinigrin does nothing at 500 ppm; its hydrolysis product works at 1 to 4. The sulfoxide does nothing at 500; its breakdown product works at 6 to 10. TWO ORDERS OF MAGNITUDE, UNLOCKED BY BREAKING ONE BOND. The plant stores sulfur in a soluble, harmless reservoir and weaponizes it only when the tissue is cut. STORAGE AND TRIGGER, AGAIN, AT THE TOP OF THE LADDER.
PATTERN TWO — POTENCY TRACKS CATENATION, NOT CONCENTRATION	One sulfur: nothing at 500. Two: weak. Three: 20 ppm. THE DOSE-RESPONSE IS IN THE NUMBER OF SULFURS IN THE CHAIN. That is a structural variable, not a dosing one, and it is the polysulfide argument appearing as a clean ladder in a food-microbiology table.
AND ONE PRACTICAL NUMBER WORTH KEEPING	Methyl methanethiosulfinate was 10 TO 100 TIMES MORE INHIBITORY against Listeria monocytogenes at pH 5, 6 and 7, and was MUCH LESS INFLUENCED BY pH than sodium benzoate. Which makes this a preservation result as well as a chemistry one.

Kyung KH, Fleming HP. Antimicrobial activity of sulfur compounds derived from cabbage. Journal of Food Protection 1997;60(1):67-71. Read this pass from the full text. THE MEASUREMENTS ARE PRIMARY AND DO NOT EXPIRE; the glucosinolate and Nrf2 biology around them is an active field and current sources should sit beside this table wherever the biology rather than the number is at issue.

THE TESTS

9. Five Null Hypotheses

Each stated so a result can reject it · the first two need no laboratory

S-1 · Whether the ladder is one pattern or six coincidences

A STRUCTURED AUDIT · NO LABORATORY · THE TEST OF THIS PAPER'S OWN THESIS

S-1	A STRUCTURED AUDIT · NO LABORATORY · THE TEST OF THIS PAPER'S OWN THESIS
THE NULL HYPOTHESIS	H₀: THE SIX RUNGS DO NOT SHARE A COMMON MECHANISM — STORAGE OF POTENTIAL IN A SULFUR BOND AND RELEASE BY CLEAVING IT — BEYOND WHAT WOULD BE EXPECTED OF ANY REACTIVE ELEMENT.
WHAT IS MEASURED	For each rung, state the bond, the stored quantity, the trigger, and the released species. Then do the same for a CONTROL ELEMENT — nitrogen or oxygen — across a comparable set of biological roles, and compare how many rungs fit.
THE MATERIAL	The six sections above, and an honestly chosen comparison element. THE CONTROL IS THE WHOLE EXPERIMENT: if oxygen fits the same frame equally well, the pattern is a property of the frame and not of sulfur.
WHAT REJECTS IT	Sulfur fits at all six rungs and the control fits at materially fewer. THE SPINE IS THEN A MECHANISM RATHER THAN A NARRATIVE.
WHAT FAILURE TO REJECT MEANS	THE FRAME IS TOO ACCOMMODATING AND THE PAPER IS A LIST, NOT AN ARGUMENT. That is worth discovering before the paper is circulated, which is why this is first.
COST	Days of careful writing. No reagents, no permission, and it is the only experiment here that can falsify the title.

S-2 · Whether the selectivity of acetyl phosphate has been tested against the full set

A LITERATURE CHECK, THEN ONE BENCH DAY IF IT HAS NOT

S-2	A LITERATURE CHECK, THEN ONE BENCH DAY IF IT HAS NOT
THE NULL HYPOTHESIS	H₀: ACETYL PHOSPHATE PHOSPHORYLATES NUCLEOSIDE DIPHOSPHATES OTHER THAN ADP UNDER SOME PREBIOTICALLY PLAUSIBLE CONDITION NOT YET TESTED.
WHAT IS MEASURED	Yield of the triphosphate from each of ADP, GDP, CDP, UDP and IDP, across a matrix of cation, pH and temperature wider than the published one.
THE MATERIAL	Commercial nucleotides and acetyl phosphate. THE PUBLISHED RESULT IS THAT ONLY ADP WAS PHOSPHORYLATED; the question is how wide the conditions were.
WHAT REJECTS IT	Any other diphosphate phosphorylated at comparable yield. THE SENTENCE SULFUR CHOSE ADENINE WOULD THEN NEED WITHDRAWING, and this paper should be the place it is withdrawn.
WHAT FAILURE TO	THE SELECTIVITY HOLDS ACROSS A WIDER MATRIX AND BECOMES

S-2	A LITERATURE CHECK, THEN ONE BENCH DAY IF IT HAS NOT
REJECT MEANS	MUCH STRONGER THAN A SINGLE PAPER'S RESULT. Note the inclusion of IDP: inosine sits between adenine and guanine, and nobody has asked where it falls.
COST	A literature afternoon, then one bench day.

S-3 · Whether the two marking systems still interfere where they meet

COMPARATIVE GENOMICS · PUBLISHED SEQUENCE DATA ONLY

S-3	COMPARATIVE GENOMICS · PUBLISHED SEQUENCE DATA ONLY
THE NULL HYPOTHESIS	H_0: IN GENOMES CARRYING BOTH A dnd CLUSTER AND METHYLATION-BASED RESTRICTION-MODIFICATION, THE RECOGNITION SEQUENCES OF THE TWO SYSTEMS OVERLAP NO LESS THAN CHANCE WOULD PREDICT.
WHAT IS MEASURED	Overlap between phosphorothioate and methylation consensus contexts in genomes carrying both, against a null model preserving base composition and motif length.
THE MATERIAL	Sequenced bacterial genomes with annotated dnd clusters. NO NEW SEQUENCING.
WHAT REJECTS IT	Significant avoidance. THAT WOULD TURN A STATED MECHANISM INTO A MEASURED ONE, and it would show two notations negotiating for space inside one genome — the strongest available evidence that an alphabet has a carrying capacity.
WHAT FAILURE TO REJECT MEANS	The contexts are independent, the interference is local rather than genomic, and §5's strongest claim narrows accordingly.
COST	Compute time. The data are public.

S-4 · Whether catenation predicts potency outside cabbage

WET LABORATORY · THE SMALLEST NEW MEASUREMENT IN THE PAPER

S-4	WET LABORATORY · THE SMALLEST NEW MEASUREMENT IN THE PAPER
THE NULL HYPOTHESIS	H_0: ANTIMICROBIAL POTENCY DOES NOT SCALE WITH THE NUMBER OF CATENATED SULFURS ACROSS COMPOUND SERIES DRAWN FROM OTHER PLANT FAMILIES.
WHAT IS MEASURED	Minimum inhibitory concentration against a fixed panel, across mono-, di-, tri- and tetrasulfides from allium as well as brassica sources.
THE MATERIAL	Commercially available polysulfides and a standard MIC protocol. THE 1997 TABLE GIVES ONE SERIES; this asks whether the ladder is general or particular to one plant.

S-4	WET LABORATORY · THE SMALLEST NEW MEASUREMENT IN THE PAPER
WHAT REJECTS IT	A monotonic relationship across families. CATENATION BECOMES A DESIGN VARIABLE rather than an observation.
WHAT FAILURE TO REJECT MEANS	The trend is specific to the cabbage series and probably reflects those particular structures. HONEST AND USEFUL, and it bounds the claim to where it was measured.
COST	Reagents and plates. Weeks, not months.

S-5 · Whether the sulfur mark is visible to anything the field currently runs

THE INSTRUMENT QUESTION · SHARED WITH THE ALPHABET PAPER

S-5	THE INSTRUMENT QUESTION · SHARED WITH THE ALPHABET PAPER
THE NULL HYPOTHESIS	H_0: STANDARD SEQUENCING PIPELINES REPORT PHOSPHOROTHIOATE-MODIFIED POSITIONS NO DIFFERENTLY FROM UNMODIFIED ONES, AND NO CURRENTLY DEPLOYED PIPELINE FLAGS THEM.
WHAT IS MEASURED	Proportion of bacterial genome pipelines that flag, annotate, or even have a field for a linkage modification. Then run a dnd-positive genome through the standard stack and count what is reported.
THE MATERIAL	Published pipelines and a dnd-positive strain. THE ALPHABET HAS FOUR LETTERS FOR BASES AND NO SYMBOL FOR THE LINKAGE BETWEEN THEM — this measures what that costs in practice rather than in principle.
WHAT REJECTS IT	Some pipeline reports it. The gap is narrower than claimed and this paper says so.
WHAT FAILURE TO REJECT MEANS	NOTHING REPORTS IT, WHICH IS THE EXPECTED RESULT AND IS A COUNT RATHER THAN AN IMPRESSION. A natural, stereospecific, enzymatically written epigenetic mark, invisible to every instrument aimed at the genome it sits in.
COST	Reading and one pipeline run.

10. What This Paper Does Not Claim

— IT DOES NOT CLAIM SULFUR IS MORE IMPORTANT THAN CARBON, PHOSPHORUS OR NITROGEN. It claims sulfur arrives EARLIER and persists at the EDGES, which is a claim about sequence and position, not about rank.

— IT DOES NOT CLAIM THE THIOESTER WORLD IS ESTABLISHED. It is a serious, experimentally supported hypothesis with named authors and

reproducible yields. THAT IS NOT THE SAME AS SETTLED, and S-2 is written to test the part this paper leans on hardest.

— IT DOES NOT CLAIM THE SIX RUNGS ARE CAUSALLY LINKED. They are one element doing one kind of thing at six scales. WHETHER THAT IS A MECHANISM OR A FRAME IS EXACTLY WHAT S-1 ASKS, and the control element is the whole point of that experiment.

— IT DOES NOT SUPERSEDE THE THREE EXISTING SULFUR PAPERS. It orders them. They carry the detail this one cites.

— AND IT DOES NOT CLAIM THE CABBAGE NUMBERS ARE CURRENT BIOLOGY. They are primary measurements from 1997 and measurements do not expire; THE BIOLOGY AROUND THEM HAS MOVED AND CURRENT SOURCES BELONG BESIDE THEM.

SULFUR WAS THE CURRENCY. PHOSPHATE REPLACED IT. ACETYL PHOSPHATE IS THE EXCHANGE RATE, AND THE CHANGEOVER IS STILL ON THE BOOKS IN EVERY CELL ALIVE.

THIS COMPLETES THE BEGINNING.

POSITION PAPER · NOVAGONDNA · PP-2026-TUB-01

The Amine Tubulin Can See

INOSINE, GUANINE, AND THE ONE ATOM THAT DECIDES. Guanine carries an exocyclic amine at the two position. Hypoxanthine does not. THAT SINGLE NITROGEN IS WORTH A THREE-HUNDRED-FOLD BINDING PREFERENCE AT THE TUBULIN NUCLEOTIDE SITE, and it is worth nothing at all to a sequencing machine, which prints both as G. This paper takes the narrow case first — what tubulin adds to gene and epigenetic editing — and then follows the same atom outward into GTP and ATP signaling and into the microtubules of the brain

ONE ATOM · FIVE READERS · TWO OF THEM DISCRIMINATE · SIX NULL HYPOTHESES

PP-2026-TUB-01 · 19 September 2026 · Naperville, Illinois

Dr. John Allen Berger · Independent Theoretical Researcher · NovagonDNA · Naperville, Illinois

1. The Argument, in One Sentence

TUBULIN IS A BETTER READER OF INOSINE AGAINST GUANINE THAN THE SEQUENCING MACHINE IS, AND IT READS BY THE ONE ATOM THE MACHINE THROWS AWAY.

The companion paper argued that the four-letter alphabet collapses inosine onto guanosine before any calculation begins. THIS PAPER SHOWS WHAT THE CELL

DOES WITH THE SAME DISTINCTION, and the contrast is not close. Tubulin discriminates three hundred fold. A dedicated enzyme exists whose entire function is to destroy the inosine form before it can be used. LOSING THAT ENZYME IS A LETHAL PEDIATRIC BRAIN DISEASE. The cell takes this difference more seriously than our instruments do.

THE ATOM

2. One Exocyclic Amine, Five Readers

The same chemical difference put to five different machines · two of them resolve it, three do not

GUANINE CARRIES AN EXOCYCLIC AMINE AT THE TWO POSITION. HYPOXANTHINE, THE BASE OF INOSINE, DOES NOT. That is the entire chemical difference between the two, and it is one hydrogen-bond donor. Every claim below turns on it.

the reader	discrimination of I against G	the basis
THE SEQUENCER	NONE.	Inosines are identified indirectly as variants BECAUSE THEY ARE INTERPRETED AS GUANOSINES. The alphabet has no symbol for the fifth species, so the amine is not measured badly — it is not measured.
THE RIBOSOME	NONE, AND DELIBERATELY SO.	Inosine in a codon is decoded as guanosine. This is not a defect: it is how recoding works. An edited CAG is read CGG, glutamine becomes arginine, and the protein changes. THE CELL USES THE COLLAPSE AS A MECHANISM.
TUBULIN	THREE HUNDRED FOLD.	Measured at the exchangeable nucleotide site with relative binding affinities of GTP 3000, ITP 10, XTP 2, ATP 1. The authors attribute the specificity directly: THE 2-EXOCYCLIC AMINO GROUP IN GTP IS IMPORTANT IN DETERMINING THE NUCLEOTIDE SPECIFICITY OF TUBULIN, and may interact with a hydrogen bond acceptor group in the protein. The 6-oxo group makes a further contribution.
ITPA	ABSOLUTE, AND IT IS THE CELL'S PROOFREADER FOR THIS EXACT CONFUSION.	Inosine triphosphate pyrophosphatase hydrolyzes ITP and other deaminated purine nucleotides back to the monophosphate. ITS ENTIRE JOB IS TO KEEP THE INOSINE FORM OUT OF THE TRIPHOSPHATE POOL. A dedicated enzyme for one letter.
GUK1	IT FAILS, AND THE	Guanylate kinase phosphorylates GMP. A 2026 study

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

the reader	discrimination of I against G	the basis
	FAILURE IS THE SOURCE.	identifies it as the enzyme responsible for inosine accumulation, showing that recombinant human GUK1 PHOSPHORYLATES IMP INTO INOSINE DIPHOSPHATE. THE ENZYME NAMED FOR GUANYLATE IS HOW INOSINE ENTERS THE POOL AT ALL.

Chakrabarti G, Mejillano MR, Park YH, Vander Velde DG, Himes RH. Nucleoside triphosphate specificity of tubulin. Biochemistry 2000;39(33):10269-74. doi 10.1021/bi000966n. PMID 10956016. · Tsuchimoto D, Takiguchi Y, Nakabeppu Y. Guanylate kinase 1 is an enzyme responsible for inosine accumulation in RNA of mammalian cells deficient in inosine triphosphatase. Proc Natl Acad Sci U S A 2026;123(31):e2606968123. doi 10.1073/pnas.2606968123. PMID 42531025. · Nguyen TA et al. Nat Methods 2022;19(7):833-844. PMID 35697834. All retrieved and read this pass.

THE ORDER IS THE FINDING. A PROTEIN THAT EVOLVED TO BUILD A CYTOSKELETON RESOLVES THIS DIFFERENCE THREE HUNDRED FOLD. AN INSTRUMENT BUILT IN THE LAST TWENTY YEARS TO READ NUCLEIC ACIDS RESOLVES IT NOT AT ALL.

THE NARROW CASE

3. What Tubulin Adds to Gene and Epigenetic Editing

Taken first and kept small, because the wide claim in §5 is only worth making if this one holds

The companion paper listed eight issues in editing, all of them versions of one substitution. TUBULIN SUPPLIES SOMETHING NONE OF THE EIGHT HAD: A CALIBRATED NUMBER FOR WHAT THE SUBSTITUTION COSTS.

	what it adds
THE MISSING QUANTITY	How much does it matter that inosine is not guanosine? The editing literature cannot answer, because its readout does not separate them. A

	what it adds
	PROTEIN ANSWERS: THREE HUNDRED FOLD, at one site, measured.
AND THE AMINE IS THE SAME ATOM THE EDITING PAPER NAMED	That paper observed that inosine-cytosine carries two hydrogen bonds where guanine-cytosine carries three, and that the missing donor is the 2-exocyclic amine. THE TUBULIN MEASUREMENT IS AN INDEPENDENT ASSAY OF THAT EXACT ATOM, in a protein with no connection to nucleic acid recognition at all.
THE POINT THAT MAKES IT AN EDITING ISSUE	An adenine base editor produces INOSINE. An epitranscriptomic editor built from ADAR produces INOSINE. The product is not a guanosine that the cell will treat as a guanosine — IT IS A MOLECULE THAT SOME READERS TREAT AS GUANOSINE AND OTHERS DO NOT. Scoring an editor in a readout that collapses them measures the agreement of one reader and reports it as the identity of the molecule.
WHERE THE EDITING PRODUCT IS NOT INTERCHANGEABLE	In DNA, the deoxyinosine intermediate is replicated over or excised, and either way the endpoint is a letter. IN RNA, THE PRODUCT STAYS. An edited transcript carries inosine for its whole life, and every protein that binds that transcript sees an amine that is not there.
THE NARROW CLAIM, STATED AND BOUNDED	Editing outcomes should be reported as the species produced, not the symbol printed, BECAUSE AT LEAST ONE CLASS OF CELLULAR READER DISTINGUISHES THEM BY TWO AND A HALF ORDERS OF MAGNITUDE. That claim needs no framework and no new experiment. It follows from a measurement published in Biochemistry.

AND THE NARROW CASE STOPS HERE, DELIBERATELY. Tubulin binding does not show that editing changes microtubules. It shows that the difference editing creates is a difference some proteins measure. EVERYTHING IN §5 AND §6 IS A LONGER REACH AND IS LABELED AS ONE.

4. Three Axes, Not One

Inosine reaches biology by three independent routes — one regulated, one hazardous, one mutagenic — and the corpus has been treating them as one subject

	the route	what the collapse means there
THE CODING AXIS	ADAR deaminates adenosine to inosine IN RNA, and the ribosome reads that inosine as guanosine.	THE COLLAPSE IS THE MECHANISM. At the GluA2 Q/R site a glutamine codon is recoded to arginine, and abnormally low editing at this site LEADS TO EXCESSIVE CALCIUM INFLUX AND CELL DEATH. Editing here is not damage; UNDER-EDITING IS.
THE METABOLIC AXIS	Inosine enters the free nucleotide pool as IMP, is phosphorylated to IDP and ITP, and competes with guanine nucleotides at every site	THE COLLAPSE IS THE HAZARD. Here nothing is recoded and nothing is intended. A nucleotide that is nearly the right shape arrives at a site built for a different one, AND

	the route	what the collapse means there
	that binds them.	THE CELL MAINTAINS A DEDICATED ENZYME TO PREVENT IT.
THE GENOMIC AXIS	The DEOXY form, dITP, is incorporated into DNA by polymerase, leaving deoxyinosine in the genome.	THE COLLAPSE IS MUTAGENIC, AND THIS IS THE ONE THAT REACHES THE ARCHIVE. Deoxyinosine is described as a HIGHLY MUTAGENIC LESION: in DNA it PREFERABLY PAIRS WITH CYTOSINE RATHER THAN THYMINE AND RESULTS IN A:T TO G:C TRANSITION MUTATIONS after replication. The letter is not merely misread — AT THE NEXT ROUND OF REPLICATION IT IS REWRITTEN AS THE LETTER IT WAS MISREAD AS.
WHY THE DISTINCTIONS MATTER	One axis is regulated, site-specific and reversible. One is a pool concentration acting on proteins. ONE IS HERITABLE.	AN EDITOR ACTS ON THE FIRST. A METABOLIC DEFECT ACTS ON THE SECOND AND THIRD. THEY CONVERGE ON THE SAME MOLECULE AND THEY ARE NOT THE SAME PROBLEM, and a paper that runs them together will be corrected by the first biochemist who reads it.

THE WIDER CASE

5. The Proofreader, and What Happens Without It

The cell's own verdict on how much the amine matters, read off a disease

IF INOSINE AND GUANOSINE WERE INTERCHANGEABLE, NO ENZYME WOULD EXIST TO SEPARATE THEM. One does, and its loss is catastrophic.

	the proofreader
THE ENZYME	ITPA hydrolyzes inosine triphosphate and other deaminated purine nucleotides to the corresponding nucleoside monophosphates. IT IS DESCRIBED AS AN ESSENTIAL ENZYME IN PURINE METABOLISM whose function is removal, not synthesis.
LOSING IT	Biallelic ITPA variants cause DEVELOPMENTAL AND EPILEPTIC ENCEPHALOPATHY 35. Across a characterized cohort of 40 subjects with

	the proofreader
	18 distinct pathogenic variants, ALL SUBJECTS SHOWED PROFOUND DEVELOPMENTAL DELAY, MICROCEPHALY, AND REFRACTORY EPILEPSY FOLLOWED BY NEURODEVELOPMENTAL REGRESSION. Brain imaging showed a recurrent pattern of DELAYED MYELINATION AND RESTRICTED DIFFUSION OF EARLY MYELINATING STRUCTURES. Congenital microcephaly and cardiac involvement were predictors of adverse outcome.
AND IN THE NERVOUS SYSTEM SPECIFICALLY	Neural-stem-cell-specific ITPA knockout mice showed growth retardation and died within three weeks of birth, with spontaneous and audiogenic seizure. Patch-clamp recording from entorhinal cortex neurons found A DEPOLARIZED RESTING MEMBRANE POTENTIAL AND INCREASED FIRING. The authors propose that accumulated ITP or its metabolites, OR RNA CONTAINING INOSINES, cause the depolarization and hyperexcitability.
THE SOURCE OF THE PROBLEM, NAMED IN 2026	GUK1 — guanylate kinase — was identified as the enzyme responsible for inosine accumulation in RNA in ITPA-deficient cells. Recombinant human GUK1 phosphorylates IMP into inosine diphosphate. THE ENZYME NAMED FOR GUANYLATE IS THE ONE THAT CANNOT TELL THE TWO APART.
AND THE RESCUE, WHICH IS THE STRONGEST ITEM HERE	In brain-specific ITPA-knockout mice, GUK1 HAPLOINSUFFICIENCY PRODUCED A SIGNIFICANT REDUCTION IN INOSINE IN CORTICAL RNA AND AN EXTENDED LIFESPAN. Halving the enzyme that confuses the two letters lengthens life in a brain disease. THAT IS A CAUSAL CHAIN FROM ONE MISSING AMINE TO SURVIVAL, DEMONSTRATED IN AN ANIMAL.

6. Microtubules, and Why the Brain Pays First

The longest reach in this paper, and the one most carefully bounded

Tubulins are globular GTP-BINDING PROTEINS. The superfamily contains six families from a single ancestral protein near the emergence of the last eukaryotic common ancestor, and the alpha, beta and gamma tubulins are universal and essential in all eukaryotes. THEY ARE HIGHLY CONSERVED BECAUSE THEY MUST MAINTAIN INTERACTIONS WITH GTP.

	the reach
WHY THE NUCLEOTIDE IS THE MECHANISM, NOT A COFACTOR	Microtubules cycle stochastically between polymerization and depolymerization — DYNAMIC INSTABILITY — and the cycle is driven by nucleotide binding and hydrolysis at the exchangeable site. THE NUCLEOTIDE IS NOT FUEL ALONGSIDE THE STRUCTURE. IT IS THE SWITCH THE STRUCTURE IS MADE OF.
WHAT THE MEASUREMENT ACTUALLY SHOWED, INCLUDING THE PART THAT CUTS AGAINST A SIMPLE STORY	Affinity is three hundred fold in favor of GTP. BUT ONCE THE SITE IS SATURATED, THE DISCRIMINATION LARGELY DISAPPEARS: with the site saturated there was LITTLE DIFFERENCE IN THE ABILITY OF THE FOUR NUCLEOTIDES TO STIMULATE ASSEMBLY, critical protein concentration was essentially identical, ALL FOUR WERE HYDROLYZED DURING ASSEMBLY, AND THE DIPHOSPHATES WERE INCORPORATED INTO THE MICROTUBULE. So tubulin is a filter at the door and not a guard inside the room.
WHICH IS PRECISELY WHY A POOL CHANGE IS THE INTERESTING VARIABLE	A three-hundred-fold preference is overcome by concentration. IN A CELL WITH NORMAL ITPA THE INOSINE FORM NEVER REACHES A CONCENTRATION WHERE THAT MATTERS. In a cell without it, ITP accumulates — and the filter, being a ratio rather than an absolute, admits a proportionate share.
AND THE BRAIN IS THE TISSUE THAT WOULD SHOW IT FIRST	Neurons are the most microtubule-dependent cells in the body: axonal transport, growth cone steering, neuronal migration and myelination all run on microtubule dynamics. A NUCLEOTIDE-POOL PERTURBATION THAT BARELY TROUBLES A FIBROBLAST IS A DEVELOPMENTAL CATASTROPHE IN A CORTEX BEING BUILT.
THE PHENOTYPE OVERLAP, STATED AS AN OBSERVATION AND NOT AS A MECHANISM	Tubulinopathies — caused by variants in TUBA1A, TUBA8, TUBB2B, TUBB3 and TUBB5 — produce lissencephaly, dysmorphic or hypertrophic basal ganglia, cerebellar hypoplasia, and clinically MOTOR AND COGNITIVE IMPAIRMENT AS WELL AS EPILEPSY. ITPA deficiency produces microcephaly, delayed myelination, refractory epilepsy and developmental regression. TWO DIFFERENT GENETIC LESIONS, ONE ARRIVING AT THE PROTEIN AND ONE AT THE NUCLEOTIDE THAT PROTEIN BINDS, AND THE CLINICAL PICTURES RHYME.

THAT RHYME IS A HYPOTHESIS AND IT IS PRINTED HERE AS ONE. NOBODY HAS SHOWN THAT MICROTUBULE DYNAMICS ARE DISTURBED IN ITPA DEFICIENCY. The published mechanism on offer is membrane depolarization and hyperexcitability, which is a different and well-evidenced proposal. WHAT THIS PAPER CLAIMS IS THAT THE MICROTUBULE QUESTION HAS NOT BEEN ASKED, that the reagents to ask it are ordinary, and that §8 states how.

7. The Genomic Axis, and Two Proofreaders for One Letter

The route that does not stop at protein function · and the strongest single argument in this paper

Everything to this point concerns molecules being USED. This section concerns a molecule being FILED. If the inosine form reaches DNA, the confusion stops being a transient misreading and becomes a permanent entry in the record.

	the genomic axis
THE LESION	Deamination of adenine occurs spontaneously under physiological conditions to generate DEOXYINOSINE, described in the primary literature as a HIGHLY MUTAGENIC LESION. The same species arrives by a second route: dITP from the nucleotide pool, incorporated by polymerase.
WHY IT IS MUTAGENIC, IN ONE LINE	In DNA, deoxyinosine PREFERABLY PAIRS WITH CYTOSINE RATHER THAN THYMINE, AND RESULTS IN A:T TO G:C TRANSITION MUTATIONS AFTER DNA REPLICATION. The polymerase reads the hypoxanthine face, finds no 2-exocyclic amine to object to, and lays down a cytosine. NEXT ROUND, THE CYTOSINE SPECIFIES A GUANINE. THE MISREADING HAS BECOME THE SEQUENCE.
AND ADENINE DEAMINATION IS NOT RARE	It is ENHANCED BY REACTIVE OXYGEN SPECIES from ionizing radiation, ultraviolet light, nitrous acid, or heat. This is a background process that every cell runs against continuously.
SO THE CELL KEEPS TWO PROOFREADERS, NOT ONE	UPSTREAM: ITPA hydrolyzes the triphosphate before it can be incorporated — sanitizing the POOL. DOWNSTREAM: ENDONUCLEASE V initiates excision of the lesion once it is in the DNA, with DNA polymerase proofreading exonuclease completing the removal. TWO INDEPENDENT ENZYME SYSTEMS, AT TWO DIFFERENT STAGES, FOR ONE MISSING NITROGEN.
AND THE SECOND ONE IS LOAD-BEARING	In an endonuclease V mutant the repair level fell to 11 PER CENT AGAINST 87 PER CENT in wild type — nearly eight fold. Remove the downstream proofreader and the lesion stays.
THE ARGUMENT THIS MAKES, AND IT IS THE STRONGEST HERE	EVOLUTION SPENT TWO SEPARATE REPAIR SYSTEMS ON DISTINGUISHING THIS ONE LETTER FROM ITS NEIGHBOR. A sequencing pipeline spends no bits on it at all and reports no anomaly. THE DISCREPANCY BETWEEN WHAT THE CELL INVESTS IN THIS DISTINCTION AND WHAT OUR INSTRUMENTS INVEST IN IT IS THE WHOLE OF THE COMPANION PAPER, STATED AS ENZYMOLOGY RATHER THAN AS COMPLAINT.
AND BIOTECHNOLOGY ALREADY RELIES ON THE DISTINCTION BEING REAL	A 2026 assay deliberately incorporates dITP during amplification so that amplicons carry hypoxanthine, THEN USES ENDONUCLEASE V TO DESTROY THEM SELECTIVELY while the template, lacking hypoxanthine, is untouched. The method works because inosine and guanosine are chemically distinguishable. THE SAME LABORATORY WOULD THEN SEQUENCE THE PRODUCT ON AN INSTRUMENT THAT PRINTS THEM AS ONE LETTER.

Su KY, Lin LI, Goodman SD et al. DNA polymerase I proofreading exonuclease activity is required for endonuclease V repair pathway both in vitro and in vivo. DNA Repair (Amst) 2018;64:59-67. doi 10.1016/j.dnarep.2018.02.005. PMID 29522920. · Liu X, Zhang J, Hu W, Zhou H, Jia J, Yan J. Elimination of carryover contamination for DNA methylation analysis based on isothermal amplification and lateral flow assay. Anal Chim Acta 2026;1406:345502. doi 10.1016/j.aca.2026.345502. PMID 42067293. Both retrieved and read this pass.

ONE PRECISION THAT MATTERS AND IS EASY TO LOSE. IT IS ITP THAT MEETS TUBULIN AND THE OTHER GUANINE-NUCLEOTIDE PROTEINS — A SIGNALING AND CYTOSKELETAL PROBLEM. IT IS dITP THAT REACHES DNA — A MUTATIONAL ONE. Same base, same missing amine, two different sugars and two entirely different consequences. A CLAIM THAT ITP DAMAGES DNA WOULD BE WRONG BY ONE OXYGEN, and the corrected version is the more serious of the two.

8. The ATP Side, Which Is Weaker and Is Said So

	the adenine arm
THE SYMMETRY IS TEMPTING	Adenosine deaminates to inosine. So does adenine in ATP, giving ITP by oxidative deamination — one of the two proposed routes into the ITP pool, the other being phosphorylation of IMP.
BUT THE ARITHMETIC DOES NOT FAVOR IT	At the tubulin site ATP binds three thousand fold more weakly than GTP and ten fold more weakly than ITP. ATP IS THE WORST OF THE FOUR AT THIS SITE. The amine that matters here is on the two position of a purine that also carries a six-oxo group, and adenine has neither arrangement.
WHERE THE ATP CONNECTION IS REAL	Not at the tubulin nucleotide site but at the POOL. Purine salvage and de novo synthesis feed one pool; IMP is the branch point from which both AMP and GMP derive. A DISTURBANCE AT IMP PROPAGATES INTO BOTH ARMS, which is why an ITPA defect is a purine-metabolism disease and not merely a guanine one.
THE HONEST SUMMARY	THE GUANINE ARM CARRIES THIS ARGUMENT. THE ADENINE ARM IS A SHARED UPSTREAM POOL, not a second mechanism, and claiming otherwise would be the kind of overreach this corpus corrects elsewhere.

THE EXPERIMENTS

9. Six Null Hypotheses

Each stated so a result can reject it · the first two are the narrow case and need no animal

T-1 · Whether the editing product behaves as the printed letter

THE NARROW CASE · BIOCHEMISTRY ONLY · RUN THIS FIRST

T-1	THE NARROW CASE · BIOCHEMISTRY ONLY · RUN THIS FIRST
THE NULL HYPOTHESIS	H_0: A SYNTHETIC RNA CARRYING INOSINE AT A DEFINED POSITION IS BOUND BY A GIVEN RNA-BINDING PROTEIN WITH THE SAME AFFINITY AS THE OTHERWISE IDENTICAL SEQUENCE CARRYING GUANOSINE.
WHAT IS MEASURED	Dissociation constants for the inosine-containing and guanosine-containing oligonucleotides, across a panel of proteins that bind the target motif.
THE MATERIAL	Two synthetic oligonucleotides differing at one position. NOTHING ELSE. This is the cheapest decisive experiment in the paper.
WHAT REJECTS IT	Any systematic affinity difference. THAT WOULD ESTABLISH THAT THE EDITING PRODUCT IS NOT INTERCHANGEABLE WITH THE LETTER IT IS REPORTED AS, in the direct case, with no cell involved.
WHAT FAILURE TO REJECT MEANS	The proteins tested cannot resolve the amine either, and for those targets the printed letter is an adequate description. A REAL AND USEFUL BOUNDARY on the companion paper's claim.
COST	Two oligonucleotides and a binding assay.

T-2 · Whether the three-hundred-fold filter is general or particular to tubulin

NO WET LABORATORY · A LITERATURE AND STRUCTURE SURVEY

T-2	NO WET LABORATORY · A LITERATURE AND STRUCTURE SURVEY
THE NULL HYPOTHESIS	H_0: AMONG GUANINE-NUCLEOTIDE-BINDING PROTEINS WITH PUBLISHED NUCLEOTIDE SPECIFICITY DATA, DISCRIMINATION AGAINST THE INOSINE FORM IS NOT SYSTEMATICALLY ATTRIBUTED TO CONTACT WITH THE 2-EXOCYCLIC AMINE.
WHAT IS MEASURED	Proportion of characterized G-nucleotide sites whose specificity is attributed to that contact, and the distribution of measured discrimination ratios.
THE MATERIAL	Published specificity measurements and deposited structures. The tubulin case gives one calibrated point at three hundred fold; THE QUESTION IS WHETHER IT IS TYPICAL OR EXCEPTIONAL.
WHAT REJECTS IT	A consistent pattern. THAT WOULD TURN ONE MEASUREMENT INTO A RULE and would tell every editing program what the printed letter is costing across a whole protein class.
WHAT FAILURE TO REJECT MEANS	Tubulin is unusual. The claim narrows to tubulin and to the brain, WHICH IS STILL WHERE THIS PAPER IS AIMED.
COST	Weeks of reading. No reagents, no permission.

T-3 · Whether ITP reaches microtubules when the proofreader is gone

CELL BIOLOGY · THE CENTRAL TEST OF §6

T-3	CELL BIOLOGY · THE CENTRAL TEST OF §6
THE NULL HYPOTHESIS	H_0: IN ITPA-DEFICIENT CELLS, THE PROPORTION OF MICROTUBULE-INCORPORATED NUCLEOTIDE THAT IS INOSINE DIPHOSPHATE IS INDISTINGUISHABLE FROM ITPA-PROFICIENT CONTROLS.
WHAT IS MEASURED	Nucleotide species recovered from polymerized microtubules, quantified by mass spectrometry, in ITPA-deficient against proficient cells.
THE MATERIAL	ITPA-deficient cell lines already exist and are published. THE MEASUREMENT IS A PULL-DOWN AND A MASS SPECTRUM. The prior is favorable: all four nucleotides were hydrolyzed during assembly and the diphosphates were incorporated into the microtubule, in vitro, at saturation.
WHAT REJECTS IT	Detectable IDP in the polymer, scaling with ITP pool size. THAT WOULD PUT THE INOSINE FORM INSIDE THE CYTOSKELETON OF A DISEASE CELL and would open the tubulinopathy comparison as a mechanism rather than a rhyme.
WHAT FAILURE TO REJECT MEANS	The filter holds at physiological pool concentrations. THE §6 HYPOTHESIS IS WRONG AND SHOULD BE WITHDRAWN, and the depolarization mechanism stands alone.
COST	Existing cell lines, standard mass spectrometry.

T-4 · Whether dynamic instability changes with the pool

IN VITRO RECONSTITUTION · THE DIRECT FUNCTIONAL READ

T-4	IN VITRO RECONSTITUTION · THE DIRECT FUNCTIONAL READ
THE NULL HYPOTHESIS	H_0: MICROTUBULE CATASTROPHE AND RESCUE FREQUENCIES ARE UNCHANGED ACROSS THE RANGE OF ITP-TO-GTP RATIOS SPANNING NORMAL AND ITPA-DEFICIENT CELLS.
WHAT IS MEASURED	Catastrophe frequency, rescue frequency and growth rate by total internal reflection microscopy, across a titration of ITP against GTP at fixed total nucleotide.
THE MATERIAL	Purified tubulin and two nucleotides. THE PUBLISHED RESULT THAT BULK ASSEMBLY IS INSENSITIVE AT SATURATION MAKES THIS THE SHARPER QUESTION: bulk polymer mass can be identical while the DYNAMICS — which is what a neuron uses — differ.
WHAT REJECTS IT	A shift in catastrophe or rescue frequency within the physiological range. DYNAMIC INSTABILITY IS THE PROPERTY NEURONS DEPEND ON, and a change there is a mechanism.
WHAT FAILURE TO REJECT MEANS	Dynamics are as insensitive as bulk assembly. THE STRONGEST NEGATIVE AVAILABLE, and it would close §6 cleanly.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

T-4	IN VITRO RECONSTITUTION · THE DIRECT FUNCTIONAL READ
COST	Purified protein and a microscope. NO CELLS, NO ANIMALS.

T-5 · Whether the two brain phenotypes overlap at the tissue level

NEUROPATHOLOGY · A COMPARISON NOBODY HAS DRAWN

T-5	NEUROPATHOLOGY · A COMPARISON NOBODY HAS DRAWN
THE NULL HYPOTHESIS	H_0: THE CORTICAL MALFORMATION PATTERN IN ITPA DEFICIENCY DOES NOT RESEMBLE THE TUBULINOPATHY PATTERN MORE THAN IT RESEMBLES OTHER DEVELOPMENTAL AND EPILEPTIC ENCEPHALOPATHIES.
WHAT IS MEASURED	Blinded radiological scoring of ITPA-deficiency brain imaging against tubulinopathy imaging and against a matched set of other encephalopathies, on the features that define each group.
THE MATERIAL	Published imaging from a characterized ITPA cohort of 40 subjects with a described recurrent pattern, and published tubulinopathy series. NO NEW PATIENTS AND NO NEW SCANS.
WHAT REJECTS IT	Greater similarity to tubulinopathy than to the comparison group. A CONVERGENCE OF TWO LESIONS ON ONE PATHWAY, established from images already acquired.
WHAT FAILURE TO REJECT MEANS	The resemblance is generic to severe encephalopathy. AN IMPORTANT NEGATIVE, because it is the objection a neuroradiologist would raise first and this design answers it in advance.
COST	Reading time and a blinding protocol.

T-6 · Whether editing and the pool are independent, as §4 asserts

THE TEST OF THIS PAPER'S OWN DISTINCTION

T-6	THE TEST OF THIS PAPER'S OWN DISTINCTION
THE NULL HYPOTHESIS	H_0: TRANSCRIPTOME-WIDE A-TO-I EDITING LEVELS ARE UNCHANGED IN ITPA-DEFICIENT CELLS RELATIVE TO CONTROLS.
WHAT IS MEASURED	Per-site inosine occupancy by direct RNA nanopore sequencing, ITPA-deficient against proficient, distinguishing ADAR-dependent sites from inosine incorporated during synthesis.
THE MATERIAL	ITPA-deficient cells and the published nanopore models that separate inosine from adenosine and guanosine. THE 2026 WORK ALREADY SHOWS THAT MOST INOSINE IN RNA IN THESE CELLS IS INCORPORATED DURING SYNTHESIS RATHER THAN EDITED IN, WHICH IS THE PREDICTION THIS EXPERIMENT TESTS DIRECTLY.

T-6	THE TEST OF THIS PAPER'S OWN DISTINCTION
WHAT REJECTS IT	A change at ADAR-dependent sites specifically. THE TWO AXES WOULD THEN NOT BE INDEPENDENT and §4 of this paper needs rewriting — which is the correct outcome if it is true.
WHAT FAILURE TO REJECT MEANS	The axes are separable, as §4 claims, AND THE PAPER'S OWN ORGANIZING DISTINCTION IS CONFIRMED BY MEASUREMENT rather than by assertion.
COST	One flow cell per condition.

10. What This Paper Does Not Claim

— IT DOES NOT CLAIM THAT RNA EDITING DAMAGES MICROTUBULES. The coding axis and the metabolic axis are separated in §4 precisely so that this conflation is not available, and T-6 tests the separation.

— IT DOES NOT CLAIM THAT ITPA DEFICIENCY IS A TUBULINOPATHY. The published mechanism is membrane depolarization and hyperexcitability, it is well evidenced, and nothing here displaces it. THE MICROTUBULE QUESTION IS PRESENTED AS UNASKED, NOT AS ANSWERED.

— IT DOES NOT CLAIM TUBULIN EXCLUDES INOSINE. The same measurement that gives three hundred fold at binding ALSO SHOWS ALL FOUR NUCLEOTIDES HYDROLYZED AND INCORPORATED at saturation. Printing only the first half of that result would be the error this corpus exists to catch.

— IT DOES NOT CLAIM QUANTUM EFFECTS IN ANY OF THIS. The discrimination described here is ordinary hydrogen bonding at an ordinary binding site.

— AND IT DOES NOT REQUIRE THE READER TO ACCEPT ANY POSITION ON THE BERGER TRIPLEX ARCHITECTURE. Every number above is from a published measurement.

ONE NITROGEN, AT THE TWO POSITION OF A PURINE RING. TUBULIN WEIGHS IT AT THREE HUNDRED FOLD. THE CELL BUILT AN ENZYME TO ENFORCE IT AND A CHILD WITHOUT THAT ENZYME DOES NOT REACH SCHOOL. THE SEQUENCER PRINTS BOTH MOLECULES WITH THE SAME LETTER AND REPORTS NO ANOMALY.

THIS COMPLETES THE BEGINNING.

What the Editor Actually Writes

Gene editing, the four-letter alphabet, and the targets that are not in the sequence PP-2026-EDIT-01 v1 · 21 September 2026 · © 2026 John Allen Berger · Licensed under CC BY-NC-ND 4.0.

Deep dive one of four. Claims are tiered: [E] established science, [F] framework claim, [O] open question.

1. The Claim

A gene editor is aimed by letters. It is described in letters, its outcome is reported in letters, and the file that records what it did contains letters and nothing else. **But the chemistry it performs is not a letter operation, and the molecule it leaves behind is frequently one the alphabet has no character for.**
This paper makes three claims and one refusal.

[F] First, that the two commonest base editors in use do not write the bases their names promise. The adenine editor writes **inosine**. The cytosine editor writes **uracil**. Neither is a DNA letter. The letters in the product name — A-to-G, C-to-T — describe how a polymerase later *reads* the molecule, not what the editor *made*.

[F] Second, that the sulfur which does not appear in the alphabet is nonetheless present at four separate points in every editing experiment: in the backbone chemistry that makes a guide survive in a cell, in the nucleotide pool the edit draws from, in the two chromatin marks that decide whether the editor can reach its target at all, and in the enzyme that supplies the deoxynucleotides any new DNA is written from.

[F] Third, that a large class of therapeutic targets cannot be reached by editing a sequence, because they are not written in one. **A leg cannot be made from a DNA sequence.** Neither can a disulfide bond, a conformation, a redox state, or a modified base.

And the refusal: nothing here claims gene editing does not work. It works, it is in the clinic, and it is one of the most consequential technologies of the century. The claim is about what the notation loses between the chemistry and the record.

2. The Program, and Its Boundary

This is the first of four deep dives.

#	paper	subject
1	**this one**	gene editing, the alphabet, nucleotide metabolism, and the missing targets

#	paper	subject
2	to follow	drug discovery, built on sulfur
3	to follow	the control of gene expression
4	to follow	the sulfur RNA world — how minerals and atoms became prokaryote, archaeal and eukaryote cells and their organelles

The boundary is set and it is not crossed. These papers stop at the cell and its organelles. Tissues, organs and organ systems are outside the program. The reason is not modesty about scope but a claim about where the argument can be checked: below the cell, every assertion in these papers can be settled by a measurement on a molecule. Above it, it cannot.

3. What the Adenine Editor Actually Writes

[E] The adenine base editor was built from **TadA**, an *Escherichia coli* transfer RNA adenosine deaminase. The natural enzyme edits RNA and only RNA; the DNA-editing version was produced by directed evolution, and the working construct pairs an evolved TadA with a wild-type copy.
[E] The chemistry it performs is a deamination. It removes the amino group from adenine, and what is left is **inosine**. The published description is unambiguous: the deamination of adenine generates an inosine residue, which is interpreted by the DNA polymerases as a guanosine, and thus an A-to-G edit is achieved.

Read the order of events in that sentence. The editor makes an inosine. A polymerase later *interprets* the inosine as a guanosine. The G in "A-to-G" is an interpretation by a downstream enzyme, not a description of the product.

[F] So the adenine base editor is an inosine-writing machine that reports its output in a character set with no inosine in it. The corpus already records inosine as the molecule with no letter, and records what the deaminases do as **remove a nitrogen, install an oxygen**. The editor is that reaction, performed on purpose, on a chosen base, at a chosen address.

[F] And it is worth stating what was actually engineered. TadA edits transfer RNA at the wobble position — the same chemistry, at position thirty-four, that the cell has used since before there were vertebrates. The laboratory did not invent adenine deamination. **It took a tRNA-editing enzyme, moved it onto DNA, and aimed it.** The tool and the target enzyme are one protein family separated by directed evolution.

4. What the Cytosine Editor Actually Writes, and the Inhibitor That Proves It

[E] The cytosine base editor deaminates cytosine to **uracil**, which the cell's polymerases read as thymine, producing the C-to-T substitution.
Uracil in DNA is not a DNA letter. It is damage, and the cell treats it as damage.
[E] Base excision repair recognizes the uracil and removes it, which reduced editing efficiency so severely that second-generation editors had to carry a **uracil**

glycosylase inhibitor fused to the construct to stop the cell from undoing the edit.

[F] That inhibitor is the strongest single piece of evidence in this paper, and it was put there by engineers for practical reasons with no argument in mind. **The cell does not agree that a C-to-T edit has occurred.** The cell sees a uracil sitting in DNA where no uracil belongs, and sends a glycosylase to cut it out. To make the edit stick, the editor must carry a protein whose only job is to stop the cell from repairing what the editor calls a letter and the cell calls damage.

The notation says a letter changed. The chemistry says a base was deaminated and a repair pathway was suppressed. **Those are not the same event, and only one of them is in the file.**

5. The Backbone That Has No Letter

[E] Replace one non-bridging oxygen in the **phosphate** backbone with a **sulfur** atom and the result is a **phosphorothioate**. It is the most widely used chemical modification in oligonucleotide therapeutics, and the reason is entirely practical: it resists nucleases, it changes protein binding, and it extends half-life in a body from minutes to something clinically useful. Antisense oligonucleotide drugs are built on it, and synthetic guide RNAs are routinely protected with it.

[F] Now ask what a sequence file records about that. Two molecules — one phosphodiester, one **phosphorothioate** — have **identical sequences**. Same letters, same order, same length. They have different nuclease resistance, different protein binding, different tissue distribution, different pharmacokinetics and different toxicity. **The alphabet cannot tell them apart, because the difference is an oxygen swapped for a sulfur in a position the alphabet does not describe.**

[E] And the substitution creates a stereocenter. A **phosphorothioate** linkage is chiral at phosphorus, giving Rp and Sp configurations, which differ in nuclease stability and in their interactions with target RNA. Stereopure oligonucleotides are a real and active therapeutic program.

[F] So the same four letters, written in the same order, can describe molecules that differ both in which atom sits on the phosphate and in the handedness of the bond that carries it. The file has no column for either. This is the corpus’s flat-map argument appearing inside the most commercially advanced corner of the field: the notation records connectivity and drops the geometry, and the geometry is what the drug is.

6. The Pool the Alphabet Says Does Not Exist

An edit that writes new DNA — prime editing, homology-directed repair, any polymerase-mediated fill-in — draws its material from the nucleotide pool. The alphabet implies that pool has four members. It does not.

[E] The cell maintains a dedicated staff of enzymes whose only function is to remove nucleotides from the pool that should not be incorporated:

the enzyme	what it removes	why it exists
ITPA	ITP and dITP — the **inosine** triphosphates	inosine arrives in the pool and must not be polymerized
dUTPase	dUTP	uracil must not enter DNA
MTH1 / NUDT1	8-oxo-dGTP	oxidized guanine must not enter DNA
SAMHD1	regulates dNTP levels generally	pool size gates replication and reverse transcription

[F] A janitorial staff is evidence about the building. **The cell employs four cleaners for nucleotides that the four-letter alphabet says do not exist.** ITPA exists because inosine triphosphate is a real and regular member of the pool. dUTPase exists because uracil triphosphate is. If the pool held four species there would be nothing for these enzymes to do.
[E] And the consequence is clinical rather than theoretical. ITPA deficiency produces severe toxicity from azathioprine and from ribavirin — which is to say that when the cleaner fails, the drug poisons the patient. The corpus already carries ITPA as the enzyme that closes the metabolic circuit at inosine.

[F] This is where gene editing meets nucleotide metabolism directly. An editor that deaminates adenine to inosine in DNA is performing, at a chosen address, the same reaction that ITPA spends its working life cleaning up elsewhere. The technology and the housekeeping are the same chemistry pointed in opposite directions.

[E] One more link completes it. Every deoxynucleotide in that pool was made by **ribonucleotide reductase**, which cannot turn over until **thioredoxin** or **glutaredoxin** has reduced it. **[F]** So every base that any editor writes into DNA was paid for by a **sulfur** atom, two enzymes upstream, in a step no sequence file records.

7. Aimed by Letters, Gated by Sulfur

Off-target prediction is done on sequence. Candidate sites are ranked by mismatch count and position, because that is what the notation supports. But whether an editor can reach a site is not decided by sequence alone — it is decided by whether the chromatin is open.
[E] Chromatin accessibility is governed substantially by two covalent marks. Histone acetylation is written from **acetyl-CoA**, which is a **thioester**. DNA and histone methylation are written from **S-adenosylmethionine**, which is a **sulfonium**.

[F] Both currencies are **sulfur**. The editor is aimed by letters and gated by **sulfur**, and neither gate appears in the guide design. A site can be a perfect sequence match and unreachable; another can carry mismatches and be edited efficiently, because the first is closed and the second is open. The variable that decides is carried on a **carbon**–**sulfur** bond in one case and a **sulfur**-methyl bond in the other.

[O] How much of the residual unexplained variance in editing efficiency is accounted for by the metabolic state of these two currencies — the acetyl-CoA pool and the SAM-to-SAH ratio at the moment of editing — is open, and to this author's knowledge has not been directly tested as a design variable.

8. The Targets That Are Not in the Sequence

Here is the claim that gives the paper its shape, and it is the plainest thing in it.
A leg cannot be made from a DNA sequence.

There is no sequence in any genome that reads *leg*. A limb arises from a gene regulatory network running in time, in a field of cells, under mechanical and chemical gradients, with the same genes used repeatedly for different purposes at different moments. The sequence is a parts list and a set of conditional instructions. It is not a drawing. Nothing in it can be edited to say *longer*, *sooner*, or *on the other side*, because those words correspond to no string.

That is not a mystical claim. It is a statement about what kind of information a sequence is, and it has a practical consequence: **a technology that edits sequence can only reach targets that sequence specifies.** Everything else must be reached indirectly, by editing something upstream and hoping.

[F] The targets outside the reach of the alphabet fall into recognizable classes, and **sulfur** is disproportionately represented among them.

class of target	example	why the sequence cannot hold it
covalent protein modification	a **disulfide** bond; **persulfidation**; **glutathionylation**; **S-nitrosylation**	the modification is made after translation, on a residue the sequence merely supplies
conformation	a prion; an amyloid	the pathogenic entity is a shape, and two molecules of identical sequence differ in it
modified bases	**2-thiouridine** at position thirty-four; **inosine** at the wobble; pseudouridine	written by an enzyme onto an already-made transcript; editable only one level removed
redox state	the **glutathione** couple; the **cysteine** proteome's oxidation state	a continuously varying quantity, not a discrete symbol
metabolite levels	acetyl-CoA; SAM; the dNTP pool	a flux, with no address
backbone chemistry	**phosphorothioate**	a substitution at an atom the alphabet does not name
morphology and timing	a leg; a body axis; when a cell divides	emergent from a network in time, encoded nowhere as a string

[F] Read the first row against the whole corpus. The **disulfide** is the only covalent cross-link between side chains in the canonical twenty, it is the thing that holds a folded protein in its working shape, and **it is not in the genome.** The genome supplies two **cysteines**. Whether they are joined, when, in which compartment, and whether the bond is later reduced, are decided by chemistry the sequence does not write. Editing can put a **cysteine** somewhere. It cannot make a bond.

9. What This Means for the Program

None of this argues against editing. It argues about where to expect the field's limits to appear, and the prediction is specific.

[F] Editing will continue to succeed where the target is genuinely a string: a stop codon to remove, a splice site to restore, a repeat to shorten, a gene to silence. It will continue to disappoint where the target is a modification, a conformation, a redox state or a rate — not because the delivery is imperfect or the guide is poorly designed, but because **there is no string to edit**.

[F] And the four places **sulfur** entered this paper were not sought out. They were arrived at by asking, at each stage of an ordinary editing experiment, what the chemistry actually was. **Sulfur** is in the backbone that makes the guide survive, in the enzyme that makes the nucleotides, in the two marks that decide whether the site is reachable, and in the modifications that constitute a large share of the targets the method cannot reach. **None of the four is visible in a sequence file.**

10. What Would Show This Is Wrong

- Show that the adenine base editor's immediate product is guanine rather than **inosine**, and section three fails outright.
- Show that second-generation cytosine base editors do not require a uracil glycosylase inhibitor, or that the requirement has some cause other than the cell excising the editor's product, and section four fails.
- Produce a sequence file format in routine use whose alphabet distinguishes a **phosphorothioate** linkage from a phosphodiester one, or distinguishes Rp from Sp, and section five fails.
- Show that the nucleotide pool of a human cell contains only the four canonical deoxynucleoside triphosphates, and the existence of ITPA, dUTPase and MTH1 becomes unexplained.
- Show that chromatin accessibility at an editing site is independent of histone acetylation and of methylation state, and section seven fails.
- Name a DNA sequence that specifies a limb in the way a blueprint specifies a part, and section eight fails.

11. What This Paper Refuses

It does not claim gene editing does not work, is not valuable, or should be approached with less enthusiasm than it receives. It works, and the clinical results are real.

It does not claim the field is unaware that base editors deaminate. Every primary paper says so plainly; the point is that the *record* does not, and reasoning is done from the record.

It does not claim the four-letter alphabet should be replaced. It claims the alphabet is a notation with known contents, that those contents exclude the chemistry described above, and that a reader who reasons from the notation alone will not

see what has been excluded.

It does not claim that targets outside the sequence are unreachable by any means — only that they are unreachable **by editing a sequence**, and that reaching them requires acting on the enzymes, pools and conditions that produce them.

And it does not claim **sulfur** is the only thing the alphabet loses. It loses every modification. **Sulfur** is simply the one that turns up at four separate points in a single experiment.

Why the Cytosine Editor Cannot Fix Tay-Sachs, and What That Reveals

PP-2026-HEXA-01 v1 · Deep Dive 1, Supplement A · Dr. John Allen Berger, PhD ·

1. The Question, and the Short Answer

The question asks whether the cytosine-to-uracil-to-thymine base editor malfunctions in the HEXA gene. The answer separates two things that are usually collapsed together, and separating them is the whole point.

The cytosine base editor does not malfunction in HEXA. It is pointed the wrong way. Not one of the four common Tay-Sachs alleles is a lesion that C-to-T chemistry can reverse. The editor performs exactly the reaction it was built to perform, at exactly the rate it performs it everywhere else, and the result is still no enzyme, because the reaction it performs is not the reaction the gene needs.

That distinction matters more than the chemistry. A tool that fails loudly gets fixed. A tool that works perfectly on the wrong target gets funded.

2. The Four Common Alleles and What Each One Actually Requires

Tay-Sachs disease is caused by loss of the alpha subunit of beta-hexosaminidase A, encoded by HEXA on chromosome 15. Four alleles account for most of the clinical burden, and they fail in four different ways.

allele	population and phenotype	the physical lesion	what correction requires	can a cytosine editor do it
c.1274_1277dup, p.Tyr427Ilefs*5	Ashkenazi Jewish; about 80 percent of pathogenic HEXA alleles in that population; acute infantile	a four-base TATC duplication inserted into exon 11, throwing the reading frame and stopping five codons later	removal of four bases	No. Base editors of every class are blind to insertions and deletions. There is no base to deaminate.
c.1421+1G>C	Ashkenazi Jewish; acute infantile	a transversion at the intron 12 splice donor, destroying the GT	restoring C to G, a transversion	No. The standard cytosine editor makes transitions only.
c.805G>A, p.Gly269Ser	the late-onset allele	a transition, G to A	restoring A to G	No. That is the adenine editor's reaction. The cytosine editor runs in the opposite direction.
7.6 kb deletion	French Canadian; acute infantile	the promoter and exon 1 are physically gone	gene replacement	No. There is no sequence left to edit.

 © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

Read the fourth column downward. The cytosine editor is not a poor choice for Tay-Sachs. It has no target in Tay-Sachs at all.

3. What Actually Worked, and It Was the Other Editor

The one Tay-Sachs allele that has been corrected in an animal by base editing is c.805G>A, the late-onset glycine-to-serine substitution at codon 269, and it was corrected by an adenine base editor, not a cytosine one.
In the published work, an ABE7.10 variant restored the sequence in patient fibroblasts at roughly 80 percent. Delivered to mice as a split-intein adenine editor across two AAV-PHP.eB vectors by retro-orbital injection, it reached a mean of 9.3 percent correction in brain, 11.8 percent in spinal cord, and 1.1 percent in liver, and that was enough to move the disease.

Two bystander edits came along with it. One was the adenine immediately upstream, c.804, which converted the proline codon at position 268 from CCA to CCG. That is a synonymous change and it cost nothing. The second was intronic, at c.805-3.

Hold on to the first bystander, because it is the place where the cytosine editor's behavior stops being hypothetical.

4. Where a Cytosine Editor Aimed at HEXA Would Do Real Damage

The adenine editor got away with its bystander. A cytosine editor aimed at the same window would not, and the reason is written into the local sequence.
From the bystander data, the sense strand around the late-onset site reads:

position	c.802	c.803	c.804	c.805
normal base	C	C	A	G
base in the late-onset allele	C	C	A	A
codon	Pro268	Pro268	Pro268	Gly269, mutated to Ser269

Any editing window wide enough to reach c.805 contains c.802 and c.803. Those two cytosines are the proline codon. A cytosine editor has no mechanism for choosing among the cytosines in its window. Deaminate either one and CCA becomes TCA, which is serine; deaminate the other and it becomes CTA, leucine; deaminate both and it is TTA, leucine again. The silent bystander of the adenine editor becomes a missense bystander for the cytosine editor, in a protein already known to fail by misfolding.
Position 268 is not a neutral address. It sits eight residues from Cys277, the first cysteine of the 277-to-328 disulfide bond, and the loop that bond closes contains Glu323, the catalytic proton donor of the enzyme.

So the honest description is this. The cytosine editor cannot reach the mutation, and in reaching for it, it can break the residue next door, inside the loop that holds the active site together.

5. The One Place the C-to-U Chemistry Does Fit, by Being Allowed to Fail

There is a single Tay-Sachs allele where cytosine deamination is the right starting chemistry, and it is the intron 12 donor, c.1421+1G>C. Restoring that C to G is a transversion, and transversion editors exist. The C-to-G editor is the ordinary cytosine editor with its safety catch deliberately removed.
This is worth stating plainly, because it inverts the usual account.

A cytosine base editor deaminates cytosine to uracil. Uracil in DNA is not a base. It is a lesion, and the cell is built to destroy it: uracil-DNA glycosylase finds it, cuts it out, and leaves an abasic site. To make the edit stick as thymine, the editor carries a bolted-on inhibitor, UGI, a small protein borrowed from a bacteriophage, whose only job is to stop the cell from repairing what the editor just did.

The C-to-G editor throws UGI away. It wants the glycosylase to cut. The abasic site is then resolved toward guanine. What is called the cytosine editor's failure mode in one design is its mechanism in the other.

That is the general lesson, and it is not specific to HEXA. The editor does not write thymine. It writes a lesion and then suppresses the repair of that lesion, and whether the outcome is T, G, A, or an indel is decided by which repair enzymes are present in that cell, at that moment, at that locus. Editing efficiency is not a property of the editor. It is a property of the editor and the cell's repair state together.

6. The Sulfur That No One Puts on the List

This paper sits in a sulfur volume, and the reason is not decorative.
The editors themselves are sulfur enzymes. Both base editor families are zinc-dependent deaminases, and in both, the catalytic zinc is held by one histidine and two cysteine thiolates. In rat APOBEC-1, the cytosine deaminase used in the first cytosine editors, the zinc is coordinated at His61, Cys93 and Cys96, with Glu63 as the proton donor. In E. coli TadA, the adenosine deaminase that became the adenine editor and the one that actually corrected the Tay-Sachs allele, the zinc is coordinated at His57, Cys87 and Cys90, with Glu59 as the proton donor.

Two cysteine sulfurs, in each case, hold the metal that polarizes the water that becomes the hydroxide that attacks the base. Remove the thiolates and there is no zinc, no hydroxide, and no deamination. The entire apparatus of genome editing rests on a pair of sulfur atoms, and sulfur appears nowhere in the name of the technology, nowhere in the four-letter alphabet it edits, and nowhere in the way it is taught.

The target protein is also built of sulfur. The alpha subunit of beta-hexosaminidase A carries three disulfide bonds, at 58-104, 277-328 and 505-522. The catalytic proton donor, Glu323, sits inside the 277-328 loop, five residues from

Cys328. The enzyme's active site is held in register by a disulfide bond.

And several Tay-Sachs alleles are cysteine chemistry outright. Among the annotated pathogenic variants of the alpha chain, Arg178Cys, Trp420Cys, Trp474Cys, Arg499Cys and Arg504Cys each introduce a cysteine that does not belong there, and Cys458Tyr removes one that does. Arg504Cys is the sharpest case: it places a free thiol immediately beside Cys505, which is one half of the 505-522 pair. A free thiol next to a native disulfide is the standard recipe for disulfide scrambling, and the misfolded chain is then sent to endoplasmic-reticulum-associated degradation rather than to the lysosome. The gene is transcribed. The message is translated. The protein is destroyed before it ever reaches the place it works.

7. Why This Is the Deep Dive's Central Point

The four-letter alphabet, ATGC in DNA and AUGC in RNA, can describe all four common HEXA lesions and can describe the corrected sequence exactly. It cannot describe any of the following:

- that the zinc in the editing enzyme is held by two cysteine thiolates
- that uracil, one of the four letters, is a lesion when it appears in DNA rather than RNA, and is actively hunted and removed
- that the corrected protein must form three specific disulfide bonds, in a specific order, in a specific compartment, at a specific redox potential
- that a correct sequence bearing an extra cysteine produces a destroyed protein
- that the same chemistry, C to U, yields T when repair is blocked and G when repair is invited

Write the sequence perfectly and you may still get no enzyme, because what has to be right is a pattern of sulfur bonds, and sulfur bonds are not in the alphabet. This is the same boundary as the one that says a leg cannot be made from a DNA sequence, met at the scale of a single lysosomal enzyme, where it can be measured rather than argued.

8. What Would Refute This

the claim	what would refute it
The cytosine editor has no target among the common HEXA alleles	A demonstration that any of the four is corrected by C-to-T transition chemistry, or evidence of a fifth common allele that is a G:C-to-A:T reversal
The bystander cytosines at c.802 and c.803 make a cytosine editor unsafe at this locus	Deep sequencing of a cytosine editor at this window showing the proline codon untouched at meaningful efficiency
The editors depend on cysteine-coordinated zinc	A functional base editor built on a deaminase with no cysteine in its metal site, or activity retained after both cysteines are substituted
Disulfide pattern, not sequence, is the limiting step for many missense HEXA alleles	Restoration of enzyme activity by these alleles when disulfide formation is prevented, or evidence that the misfolding alleles fail for reasons unrelated to thiol chemistry

the claim
Editing outcome is set by cellular repair state as much as by editor design

what would refute it
Identical product purity from the same editor across cells with very different uracil-glycosylase levels

Two Deaminases, One Disease

Alu, A-to-I Editing, and a Combined Mechanism for Tay-Sachs

PP-2026-HEXA-02 v1 · Deep Dive 1, Supplement B · Dr. John Allen Berger, PhD ·

1. The Arithmetic Is Right, and So Is the Instinct

The figure of 300 million is correct, and it is worth stating in the unit that makes it correct. There are roughly 1.1 million Alu copies in the human genome, each about 280 to 300 bases long. That is close to 300 million bases of Alu, which is about 10 to 11 percent of the 3.1 billion base genome. Alu is the most abundant repeat family in the human genome, and a new Alu inserts somewhere in the population about once every twenty births.

Something present at 10 percent of the genome is not decoration, and the instinct that it must be involved is correct. The purpose of this paper is to say precisely where it is involved in Tay-Sachs, because Alu enters this disease at three different levels, by three different mechanisms, and only one of them is editing. Keeping the three apart is what turns a suspicion into a mechanism.

2. Level One, DNA: Alu Destroys HEXA by Recombination, Not by Editing

This is the level where Alu is a proven cause of Tay-Sachs disease.

Alu elements are close enough in sequence to one another that two copies in different introns of the same gene can mispair during recombination. Everything between them is then deleted. This is non-allelic homologous recombination, and across the human and chimpanzee lineages it accounts for on the order of 500 fixed deletion events each since the split six million years ago. It causes far more disease than Alu insertion does.

In HEXA it has been caught in the act. A reported infantile Tay-Sachs patient carries a homozygous 4.6 kilobase deletion removing exons 6 through 10. The breakpoints lie in an AluSz6 element in intron 5 and an AluJo element in intron 10, two Alu copies sharing 76 percent identity. The deletion runs from 576 bases upstream of exon 6 to 475 bases downstream of exon 10, and removes 192 amino acids of the alpha chain, including catalytic sequence. The phenotype is ordinary infantile Tay-Sachs.

The same mechanism dominates the sister disease. In HEXB, which encodes the beta subunit, an Alu-type deletion removing the 5’ end of the gene is the single most common Sandhoff allele. And the French Canadian Tay-Sachs allele is a 7.6 kilobase deletion taking the HEXA promoter and exon 1.

So at the DNA level the answer to the question is direct. Alu is involved in Tay-Sachs, it is involved by recombination, and where it acts there is no gene left to edit. ADAR plays no part in this. Neither does ADAT.

3. Level Two, RNA: This Is Where ADAR and Alu Actually Meet

ADAR, adenosine deaminase acting on RNA, converts adenosine to inosine in double-stranded RNA. Inosine is read as guanosine by the ribosome and by the spliceosome, so an A-to-I edit is a functional A-to-G change made after transcription and never written into the gene.
The connection to Alu is not incidental, it is almost the whole story. More than 99 percent of known human A-to-I editing events fall inside Alu elements. The reason is structural. When two Alu copies land in the same pre-mRNA in opposite orientations, they base-pair with each other and form a long, stable double-stranded RNA hairpin, which is precisely what ADAR recognizes. Something on the order of 1.6 million sites have been catalogued directly and the true number is estimated above 100 million. Virtually every adenosine inside a double-stranded Alu is edited in some transcript somewhere, usually at low frequency.

This has one documented point of contact with the GM2 pathway, and it is not in HEXA.

ADAR1 edits the 3’ untranslated region of GM2A, at Alu-containing sequence, at two sites, and that editing raises GM2A expression at both RNA and protein level. The work was done in glioblastoma stem cells, where disrupting ADAR1, GM2A, HEXA or HEXB all produced the same failure of ganglioside delivery to the lysosome.

GM2A is the GM2 activator protein. It is the substrate-specific cofactor that lifts GM2 ganglioside out of the membrane and presents it to beta-hexosaminidase A. Without it the enzyme cannot reach its substrate. Loss of GM2A causes the AB variant of GM2 gangliosidosis, which is clinically almost indistinguishable from infantile Tay-Sachs, with the same age of onset, the same cherry-red macula, the same seizures and regression, the same death at two to three years, and one difference that matters here: **hexosaminidase A activity is normal.** Roughly thirteen infantile cases have ever been reported.

That is the honest placement of ADAR in this disease. Alu-dependent A-to-I editing does not cause Tay-Sachs by damaging HEXA. It sets the expression level of the one other protein without which the HEXA enzyme cannot perform its reaction, and the disease that follows from losing that protein is, to the clinic, Tay-Sachs.

Alu and ADAR reach the Tay-Sachs phenotype by standing one step to the side of the Tay-Sachs gene.

4. Level Three, tRNA: ADAT Has No Alu, and Belongs Here for a Different Reason

ADAT is a different enzyme family with a different substrate, and it should not be merged with ADAR. ADAT1 deaminates A37 in tRNA-Ala. The ADAT2/ADAT3 heterodimer deaminates A34, the wobble base of the anticodon, in seven to eight tRNAs, among them tRNA-Ala, tRNA-Arg, tRNA-Ile, tRNA-Leu, tRNA-Pro, tRNA-Ser, tRNA-Thr and tRNA-Val. ADAT3 is a catalytically dead paralog that serves as the recognition subunit; ADAT2 carries the active site. Inosine at position 34 lets one tRNA read three codons instead of one.
There is no Alu in a tRNA. ADAT does not edit messages and does not edit HEXA.

There is nonetheless a genuine kinship worth recording, because it is the sort of thing the four-letter account of genetics never mentions. Alu is descended from 7SL RNA and is transcribed by RNA polymerase III from an internal promoter, the same architecture used by tRNA genes. Alu is, by ancestry and by transcriptional machinery, a tRNA-like element that colonized the introns of protein-coding genes. The repeat that deletes HEXA and the transcript that ADAT modifies come from the same side of the transcription apparatus.

And ADAT enters this disease for a second reason, which is not pathological at all.

5. The Editor That Corrected Tay-Sachs Is a Domesticated ADAT

The one Tay-Sachs allele corrected in a living animal by base editing is c.805G>A, the late-onset Gly269Ser substitution, and the tool that corrected it was an adenine base editor.
The deaminase inside that editor is TadA, the E. coli tRNA adenosine deaminase. TadA is the bacterial counterpart of ADAT2. Its natural job is the same job ADAT2 does in us: make inosine at the wobble position of a tRNA. Directed evolution taught it to accept single-stranded DNA presented by a Cas9 nickase, and the resulting enzyme reached roughly 80 percent correction in patient fibroblasts and, delivered as a split-intein pair of AAV-PHP.eB vectors, 9.3 percent in mouse brain and 11.8 percent in spinal cord.

So ADAT is not a cause of Tay-Sachs. ADAT is the instrument that treats it. A tRNA wobble enzyme, older than the disease and older than the gene’s introns, was repurposed into the only agent that has so far reversed a Tay-Sachs allele in a brain.

6. The Two Editors Combined

This is where the picture the question asks for comes together. Put the cytosine editor and the adenine editor side by side and they stop looking like two tools and start looking like one principle applied twice.

	cytosine base editor	**adenine base editor**
enzyme, and its day job	APOBEC-1, a messenger RNA C-to-U editor of apolipoprotein B	TadA, a transfer RNA A-to-I wobble editor, the bacterial ADAT2

	cytosine base editor	adenine base editor
reaction performed	cytosine to uracil	adenine to inosine
what is therefore written into DNA	uracil, a base that belongs in RNA	inosine, a base that belongs in RNA
how the machinery reads it	uracil is read as thymine	inosine is read as guanine
how the cell attacks it	uracil-DNA glycosylase excises it	alkyladenine glycosylase excises hypoxanthine
the safety catch	UGI, a bacteriophage protein bolted on to block the glycosylase	none required; the repair is slower
releasing the catch on purpose	drop UGI and the C-to-G editor appears	fuse the glycosylase and the A-to-Y editor appears
catalytic zinc	held by one histidine and two cysteines: His61, Cys93, Cys96 in rat APOBEC-1, with Glu63 as proton donor	held by one histidine and two cysteines: His57 and the cysteine pair of the E-P-C-V-M-C motif in TadA, with Glu59 as proton donor
what it can do in HEXA	correct none of the common alleles; risks converting Pro268 to leucine or serine as a bystander	corrected c.805G>A in mouse brain and spinal cord

Read across the middle rows. Neither editor writes a DNA base. Both write an RNA base into DNA and then negotiate with the repair system about what it becomes. Uracil becomes thymine only because a phage protein is holding the glycosylase off. Inosine becomes guanine only because the glycosylase is slower than replication. Remove the restraint in either case and the same chemistry produces a transversion instead of a transition. Editing efficiency and editing purity are not properties of the editor. They are properties of the editor and the cell's repair state together, and that is true in the same way for both.

7. What the Combination Reveals About Tay-Sachs Itself

Tay-Sachs is not one mechanism. It is at least four failures wearing one name, and the two editors sort them cleanly, because each allele is defined by which editor can touch it.

failure mode	representative allele	what has gone wrong	cytosine editor	adenine editor
frame failure	c.1274_1277dup, p.Tyr427Ilefs*5, about 80 percent of Ashkenazi pathogenic alleles	four bases inserted, frame shifted, stop five codons later	no, indels are invisible to it	no, indels are invisible to it
splice failure	c.1421+1G>C, intron 12 donor	the GT of the donor destroyed, transversion	only by dropping UGI, as a C-to-G editor	no, wrong base and wrong direction
fold failure	c.805G>A Gly269Ser, and the cysteine variants Arg178Cys, Trp420Cys, Trp474Cys, Arg499Cys, Arg504Cys, Cys458Tyr	sequence readable, protein made, then misfolded and destroyed before reaching the lysosome	no, and it endangers Pro268 in the attempt	yes, demonstrated in vivo
presence failure	4.6 kb AluSz6 by AluJo deletion; 7.6 kb French Canadian deletion; HEXB Alu deletion in Sandhoff	the sequence is physically gone, by Alu recombination	nothing to edit	nothing to edit

failure mode	representative allele	what has gone wrong	cytosine editor	adenine editor
cofactor failure, one step to the side	GM2A loss, the AB variant	enzyme normal, activator missing, substrate never presented	not applicable	not applicable; but ADAR edits this transcript's Alu 3' UTR

The combined picture is this. The commonest allele is an indel that no base editor of either polarity can reach. The Alu-mediated alleles have deleted the target. The editable fraction is the missense fraction, the fold failures, and those are exactly the alleles where getting the sequence right is necessary and not sufficient, because what fails in them is disulfide formation, not coding.

The two editors together therefore say something the four-letter alphabet cannot say on its own. The alleles that base editing can fix are the alleles whose problem is not really the letters.

8. The Fifth Letter, and the Sulfur Under All of It

Collect what the two editors and the two deaminase families have in common.

Inosine is the fifth letter, and it is everywhere in this story. ADAR makes it in messages, in Alu hairpins, where it is read as G. ADAT makes it at tRNA wobble, where it reads three codons. TadA, an ADAT, makes it in DNA inside the adenine editor, where it is read as G and then hunted as a lesion. Uracil is the corresponding case on the pyrimidine side: a legitimate RNA letter, a lesion in DNA, and the intermediate of the cytosine editor. The genetic alphabet is four letters only if you agree in advance not to look at the intermediates. The cell runs on five in each polymer and spends considerable energy policing the difference.

And every enzyme named in this paper is a sulfur enzyme. APOBEC-1, TadA, ADAT2 and ADAR all belong to the zinc-dependent deaminase superfamily, whose signature is a zinc atom held by one histidine and two cysteine thiolates, with a glutamate shuttling the proton. In rat APOBEC-1 the site is His61, Cys93 and Cys96, with Glu63. In E. coli TadA it is His57 and the cysteine pair in E-P-C-V-M-C, with Glu59. The zinc polarizes a water molecule into the hydroxide that attacks the base. Take away the two sulfurs and there is no zinc, no hydroxide, and no editing of any kind, natural or engineered.

The same holds at the target. The alpha chain of beta-hexosaminidase A carries three disulfide bonds, at 58-104, 277-328 and 505-522, and the catalytic proton donor Glu323 sits inside the 277-328 loop. Six of the annotated pathogenic variants of this chain either create a cysteine where none belongs or destroy one that does.

And at the wobble position itself, where ADAT puts inosine, the cell's alternative solution to the same decoding problem is 2-thiouridine, built by a sulfur relay that begins with a cysteine desulfurase stripping sulfur from free cysteine. Position 34 is solved either by an oxygen-path modification or by a sulfur-path modification. The two routes sit at the same address in the anticodon.

So the complete answer to the question is that Alu is deeply involved in Tay-Sachs, at the DNA level by recombination and at the RNA level through ADAR editing of the activator protein's transcript; that ADAT is involved not as a cause but as the ancestor of the cure; and that both base editors, the pathogenic deaminases and the target enzyme are all held together by cysteine sulfur that the four-letter account never mentions.

9. What Would Refute This

the claim	what would refute it
Alu enters HEXA pathology by recombination, not by editing	Identification of an ADAR editing site within HEXA transcript that measurably alters splicing, stability or coding in human neurons
ADAR's contact with the GM2 pathway is through GM2A, not HEXA	Demonstration that ADAR1 loss changes HEXA transcript or hexosaminidase A activity independently of GM2A
ADAT plays no pathogenic role in Tay-Sachs	Evidence that wobble inosine levels alter HEXA translation specifically, for instance through codon bias in the alpha chain
Both editors write an RNA base into DNA and depend on repair suppression	A base editor whose product is a canonical DNA base at the moment of catalysis, requiring no glycosylase management
The editable HEXA alleles are the ones whose defect is folding rather than coding	Restoration of enzyme activity in the misfolding alleles by sequence correction alone in a cell unable to form the three disulfides
The deaminases all depend on cysteine-coordinated zinc	A functional natural or engineered deaminase with no cysteine in its metal site

Is Tay-Sachs a Metabolic Disease or a Genetic One?

PP-2026-HEXA-03 v1 · Deep Dive 1, Supplement C · Dr. John Allen Berger, PhD ·

1. The Short Answer

Tay-Sachs is **germline in cause, metabolic in mechanism, and somatic only in its expression and its treatment.**
It is not a somatic genetic disease in the technical sense. A somatic disease arises from a mutation acquired in a body cell after conception, as cancer does. Tay-Sachs is inherited, autosomal recessive, present in every cell from the fertilized egg onward. There is no somatic event.

But the question is better than a definitional answer deserves, because on every axis except inheritance the disease behaves as a metabolic disorder and not as a genetic one. The genotype tells you who is at risk. It does not tell you who is sick, how sick, when, or where in the body. Those four things are decided by quantities: how much enzyme survives folding, how fast substrate arrives, and whether the ratio between them crosses a threshold. The evidence for that is strong and it is worth setting out in full.

2. Six Findings That Place the Disease in the Metabolism

2.1 The carrier settles it immediately

A Tay-Sachs carrier has one broken HEXA allele and roughly half-normal hexosaminidase A. Half the coding information at that locus is destroyed, and the carrier is entirely well, for life, with no storage, no neuropathology and no shortened lifespan.
If the disease were a disease of sequence, half the sequence would be half a disease. It is not a disease at all. Whatever Tay-Sachs is, it is not the presence of a mutation.

2.2 The threshold is quantitative, and it is near ten percent

Conzelmann and Sandhoff measured the relationship directly, in hexosaminidase A and again in arylsulfatase A. Substrate degradation rises steeply with residual enzyme activity and reaches the normal control rate at roughly **10 to 15 percent of normal activity**. Above that line, cells clear their substrate at the normal rate and nothing accumulates. Below it, influx exceeds capacity and storage begins, at a rate set by the size of the shortfall.
This is the governing equation of the disease and it is a rate equation, not a sequence. It explains why the carrier at 50 percent is well, why small differences in residual activity produce large differences in age of onset, and why a few percentage points of enzyme separate death in infancy from walking into middle

age. Genes do not have percentage points. Enzymes do.

2.3 The pseudodeficiency alleles put genotype and metabolism in direct conflict, and metabolism wins

Two HEXA alleles, p.Arg247Trp and p.Arg249Trp, produce an enzyme that cannot cleave the synthetic substrate used in the clinical assay but cleaves the natural substrate, GM2 ganglioside, perfectly well. The genotype is abnormal. The enzyme assay is abnormal. The person is healthy and stays healthy.

This is a clean experiment that biology ran for us. When the sequence says disease and the metabolism says no disease, the patient follows the metabolism. These alleles exist chiefly as a source of false positives in carrier screening, which is precisely the point: a screening program built on sequence can be wrong about the thing that matters.

2.4 Three different genes produce one disease

Break HEXA and the result is Tay-Sachs. Break HEXB, the beta subunit, and the result is Sandhoff disease. Break GM2A, the activator protein that presents the substrate to the enzyme, and the result is the AB variant, in which **hexosaminidase A activity is entirely normal** and the infant dies on the same schedule, with the same cherry-red macula, the same seizures and the same regression.

Three genes, three enzymes' worth of different molecular biology, one clinical disease. The entity we call Tay-Sachs is not defined by a gene. It is defined by a reaction that fails to happen. That is a metabolic definition, and it is the only definition that covers all three.

2.5 The same genotype kills some cells and spares others

Every cell in a Tay-Sachs child carries the same two alleles. Fibroblasts store GM2 and live. Neurons store GM2 and die, distended by membranous cytoplasmic bodies. Gangliosides are the principal glycolipids of neuronal plasma membrane, so the neuron is where GM2 throughput is greatest, and the neuron is where the shortfall between influx and capacity is largest.

Selective vulnerability in a uniformly mutated body cannot be explained by the mutation. It is explained by flux. The tissue that fails is the tissue with the highest substrate load, exactly as the rate equation predicts.

2.6 The two therapies that ignore the gene entirely, and what their failures prove

Two therapeutic strategies attack the metabolism without touching the sequence, and both have been tried in patients.

Pharmacological chaperone. Pyrimethamine stabilizes the folding of mutant hexosaminidase A. In an open-label extended study of late-onset Tay-Sachs, given cyclically at about 2.7 mg daily on average, or 6.25 mg three times a week, it raised leukocyte hexosaminidase A by a mean of 2.24-fold over baseline. That sounds substantial until it is placed against the threshold: it brought activity to

roughly 2.2 percent of normal, well short of the 10 percent needed. An initial rise was followed by a second phase of decline and inhibition, which forced cyclic dosing.

Substrate reduction. If capacity cannot be raised, lower the influx and the same residual enzyme becomes sufficient. This is the logic of glucosylceramide synthase inhibition. Sanofi took venglustat into the phase 3 AMETHIST trial in GM2 gangliosidoses and **discontinued it on 25 April 2024 for absence of positive trends on clinical endpoints.**

Neither worked. That is worth stating plainly, and it does not weaken the metabolic reading of the disease. It confirms it, because the metabolic model predicts both failures. Pyrimethamine raised capacity by an amount that does not reach the threshold. Substrate reduction lowers the rate of new accumulation but removes nothing already stored and returns no neuron already lost. A rate intervention arrives too late once the integral has been taken. Both drugs failed in the way a flux model says they should fail, which is the behavior of a correct model, not a wrong one.

3. Where It Is Genuinely Genetic

The case is not one-sided and the genetic side should be stated at full strength.
Tay-Sachs is completely heritable and completely penetrant at a given genotype. No exposure, diet, infection or lifestyle produces it. Carrier screening in the Ashkenazi Jewish population, built on a handful of sequence variants, has been one of the most effective public health genetics programs ever run. And genotype predicts phenotype class reliably: two null alleles give the acute infantile form, one null and one missense gives the subacute juvenile form, two missense alleles give the late-onset form.

Read that last rule carefully, though, because of what it actually says. Genotype predicts phenotype **through residual activity**. Null alleles make no enzyme, so two of them leave nothing. Missense alleles make enzyme that partly survives folding, so two of them leave a few percent. The genotype is not acting on the phenotype directly. It is setting a number, and the number does the work.

4. Where “Somatic” Actually Belongs

Somatic genetics does not cause Tay-Sachs. It is how Tay-Sachs is now being treated.
The adenine base editing work corrected the late-onset allele in 9.3 percent of mouse brain and 11.8 percent of spinal cord. That is a deliberately manufactured **somatic mosaic**: a body in which some cells carry the corrected sequence and most do not. It moved the disease anyway, and the threshold explains why a minority correction can be enough. Lysosomal enzymes are secreted and taken up again by neighboring cells through the mannose-6-phosphate receptor, so a

corrected cell can supply enzyme to uncorrected cells around it. This cross-correction is the principle underlying enzyme replacement and gene therapy in lysosomal disease generally.

So the full classification is three-part, and each part answers a different question.

the question	the useful answer	what it gives you
Who will get it?	genetic	carrier screening, prenatal diagnosis, recurrence risk
Why are they sick, how sick, and where?	metabolic	residual activity, flux, the ten percent threshold, tissue selectivity
What can be done?	somatic	a manufactured mosaic of corrected cells, plus cross-correction

5. The Answer to the Question as Asked

More metabolic than genetic, yes, on the evidence, and decisively so for everything except who is at risk. The mutation is the cause. The metabolism is the disease.
A cleaner way to put it: **Tay-Sachs is a genetic condition and a metabolic disease.** The condition is present at conception and never changes. The disease begins months after birth, when a quantity crosses a line, and progresses at a rate set by how far below the line it sits. Those are two different objects and the language of medicine usually runs them together.

It is not a somatic genetic disease. But somatic genetics is now the most promising way to treat it, and the reason that works is the metabolic threshold, not the genetic correction as such. You do not have to fix every cell. You have to get enough capacity above the line.

6. Why This Belongs in the Volume

This is the four-letter alphabet meeting its limit again, in the cleanest form yet.
The sequence is binary. A base is A, T, G or C. A gene is intact or it is not. The disease is continuous: nanomoles per milligram per hour, substrate influx, a threshold near 10 percent, an age of onset that slides from six months to forty years across a few percentage points of enzyme. **Sequence has no units, and the disease lives entirely in the units.**

And the quantity that governs everything, residual activity, is not a property of the sequence at all. It is the fraction of translated chains that fold correctly and reach the lysosome instead of being destroyed at the endoplasmic reticulum. Folding here means three disulfide bonds, at 58-104, 277-328 and 505-522, formed in the correct pairing in the oxidizing environment of the endoplasmic reticulum, with the catalytic proton donor Glu323 sitting inside the middle loop. That yield is set by thiol-disulfide chemistry and the redox buffer around it.

The number that decides whether a child lives to three or to sixty is therefore a **sulfur number**, and it appears nowhere in the gene, nowhere in the four letters,

and nowhere on any label.

7. What Would Refute This

the claim	what would refute it
Severity tracks residual enzyme activity rather than genotype identity	Two patients with the same measured residual activity and reproducibly different ages of onset, with the difference attributable to genotype rather than to flux or folding yield
The disease is defined by the blocked reaction, not the broken gene	A clinical or pathological feature that reliably separates HEXA, HEXB and GM2A disease at matched residual capacity
Tissue selectivity is a flux phenomenon	Demonstration that neurons die from a cause unrelated to ganglioside load, for example a neuron-specific function of the hexosaminidase alpha chain independent of catalysis
The failures of chaperone and substrate reduction therapy confirm the threshold model	A trial in which activity was raised well above 10 percent of normal, early, and the disease still progressed at the untreated rate
Residual activity is set largely by folding yield and therefore by thiol chemistry	Evidence that missense alleles reach the lysosome at normal efficiency and fail by catalysis alone
Tay-Sachs is not somatic in origin	Identification of post-zygotic HEXA mutation as a recurring cause of the disease

PERSPECTIVE · HYPOTHESIS PAPER

Sulfur and Xanthine Supply the Purine Terminus for ALS

A Shared-Cofactor Hypothesis Linking Thiol Chemistry and Xanthine Oxidoreductase to Amyotrophic Lateral Sclerosis

PP-2026-PERSP-02 v1 · September 2026

A perspective drawn from the evidence volume

Published by NovagonDNA, Naperville, Illinois.

First edition, 2026. Distributed by the author.

What this paper is, and who it is for

Three bodies of evidence about amyotrophic lateral sclerosis have grown up beside one another without meeting. One says the disease is a thiol failure. One says it is a purine failure. One says that correcting the purine number does nothing. This paper argues that they are one observation seen from three sides, and that the joint between them is an atom rather than a statistic.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

The paper is written for the reader who wants the chemistry carried down to the bond. It expects scientific literacy and no specialist standing. A neurologist can read the metabolism; a metabolic physician can read the trial; neither is expected to be at home in both, which is the condition that produced the gap this paper is about.

Eight words this paper cannot do without, in plain English

Every one of them is the name of a thing rather than a label for a category, and a reader who wants to check a claim against the literature will need them.

the word	the meaning
persulfide	A sulfur atom carried on another sulfur atom, on the surface of an enzyme. It is how a cell moves sulfur from one place to another without letting it loose.
molybdenum cofactor	A pterin-based helper, built starting from GTP, that several enzymes cannot work without. Also called Moco or molybdopterin.
sulfuration	The act of putting one sulfur atom onto the molybdenum of that cofactor after the protein is already folded. An enzyme called MOCOS does nothing else.
desulfo form	The same enzyme with that one atom missing. It is catalytically dead.
dithiolene	Two sulfur atoms on the pterin ring that grip the molybdenum like a claw.
salvage	Recovering a base that has already been made once and putting it back into service instead of building a new one.
ledger	Used here in its plain accounting sense. A number that reports a balance is not the same thing as the transaction that moved it.
index	A measurement that tracks a quantity without being that quantity. The central claim of this paper is that circulating urate is one.

A note on the color index

Every shaded word in this paper carries the color index of the evidence volume it is drawn from. One color, one element, one base, throughout. The colors are one-to-one labels assigned by mapping, not by measurement; spectral order carries no meaning. Hydrogen = red is the single assignment with a physical basis, the Balmer-alpha line at 656 nanometers.

THE COLOR INDEX

color	element	base	where it appears in this paper
ORANGE	oxygen, O 8	hypoxanthine	inosine, IMP, oxidase, oxidoreductase, superoxide, peroxidation
YELLOW	sulfur, S 16	thymine	cysteine, glutathione, persulfide, disulfide, sulfido, sulfite
INDIGO	selenium, Se 34	xanthine	xanthosine, XMP, xanthinuria, selenocysteine
RED	hydrogen, H 1	adenine	adenosine, AMP, ATP, dehydrogenase
GREEN	nitrogen, N 7	guanine	GMP, GTP, amino, nitrate, ammonia
PURPLE	phosphorus, P 15	uracil	phosphate, pterin, uridine
BLUE	carbon, C 6	cytosine	carbonyl

Urate, uric acid, uricase, allantoin and hyperuricemia carry no color, under the ruling recorded at section 15. Element symbols appear alongside the colors so that no figure depends on color alone.

A note on the method

Every Part of this paper ends by stating the conditions under which it would be wrong. Where a finding was not reproduced, where a trial missed its endpoint, and where the evidence runs against the argument, the record is printed rather than omitted. Section 18 collects the refutations in one place; sections 17 and 19 separate what is refused from what is claimed.

A note on the spelling

This paper uses sulfur throughout, following the volume it is drawn from. IUPAC standardized on that form in 1990 and the Royal Society of Chemistry followed in 1992.

PART ONE · THE ENZYME AT THE END OF THE PURINE PATH

1. The Enzyme Is Held Together by Sulfur ↩

What xanthine oxidoreductase is made of

The enzyme that performs both oxidations of purine disposal is a homodimer of about 300 kilodaltons. Each half of it carries three prosthetic groups.

per subunit	
one	molybdenum cofactor — the pterin-based Moco, also called molybdopterin
two	[2Fe-2S] iron-sulfur clusters, non-identical
one	FAD

Where the sulfur is

The molybdenum atom is not held by the protein directly. It is chelated by a dithiolene — two sulfur atoms carried on the pterin. And there is a third sulfur beyond those two: a terminal Mo=S sulfido ligand in the equatorial position.

sulfur atoms at one active site 2 dithiolene, clamping the molybdenum 1 terminal sulfido, on the molybdenum 4 inorganic, in the two [2Fe-2S] clusters — 7 before counting the cysteines that hold the clusters in place

And the third one is the one that decides

The terminal sulfido is labile. Treat the enzyme with cyanide and that atom leaves as thiocyanate. What remains is called the desulfo form.

The desulfo form is catalytically dead. The equatorial sulfido ligand is required for the enzyme to hydroxylate hypoxanthine and xanthine at all.

There is an enzyme whose entire job is to put it back

Molybdenum cofactor sulfurase — MOCOS in humans, ABA3 in *Arabidopsis* — converts the molybdenum cofactor from the desulfo form into the sulfo form.

A gene, a transcript, a folded protein and an active site, maintained by selection across plants and animals alike, existing to reinstall one sulfur atom onto one metal atom.

---

2. One Atom, Two Phenotypes ↩

The rule that splits the molybdoenzymes

"Xanthine dehydrogenase and aldehyde oxidase, but not sulfite oxidase and nitrate reductase, require the post-translational sulfuration of their Mo-site for becoming active."

enzyme	requires the terminal Mo=S
xanthine dehydrogenase / oxidase	yes
aldehyde oxidase	yes
sulfite oxidase	no
nitrate reductase	no

The purine enzymes need the sulfur. The sulfur enzyme does not. That single asymmetry accounts for everything below.

---

3. A Disulfide Bond Decides Which Product the Enzyme Makes ↩

And the switch is reversible

Xanthine oxidoreductase exists in two forms. As a dehydrogenase it passes electrons from the reduced flavin to NAD. As an oxidase it passes them to molecular oxygen and releases superoxide. The conversion between the two is effected by the formation of a disulfide bond between a pair of cysteine residues, and it is reversible by reduction. Proteolysis of the segment carrying those cysteines makes the conversion permanent.

A sulfur-sulfur bond is the switch that turns a tidy dehydrogenase into a source of superoxide. The enzyme that makes the antioxidant becomes, on the flip of one disulfide, a maker of the oxidant the antioxidant is supposed to answer.

A cell whose reducing capacity is failing therefore does not simply lose urate. It converts the urate-producing machine into a radical source. The two halves of the ALS literature meet at that cysteine pair, and they meet there physically rather than by analogy.

PART TWO · ONE DONOR, AND WHAT DEPENDS ON IT

---

4. Sulfur Runs the Traffic Between the Purine Ring and the Cofactors ↩

One donor, every cofactor, and a disease that removes it

A cell needs sulfur in many places at once, and it does not fetch it separately each time. One enzyme takes sulfur off the amino acid cysteine, carries it on its own surface as a reactive chain of

two sulfurs, and hands it out.

destination	why it matters
Iron-sulfur clusters	the cages inside the enzyme that makes DNA, and inside xanthine oxidoreductase itself
Thiolated bases in transfer RNA	the modifications that decide which codons get read
Molybdenum cofactor	required by the enzyme that empties the purine ring, and by the enzyme that disposes of sulfite
Thiamine, biotin, lipoic acid	central vitamins of energy metabolism

One donor. Four destinations. Cut the donor and all four stop at once.

Xanthine oxidoreductase is unusual in being a customer of two of the four simultaneously. Its clusters come from the first destination and its terminal sulfido from the third. An enzyme that occupies the terminus of purine catabolism sits downstream of sulfur supply twice over.

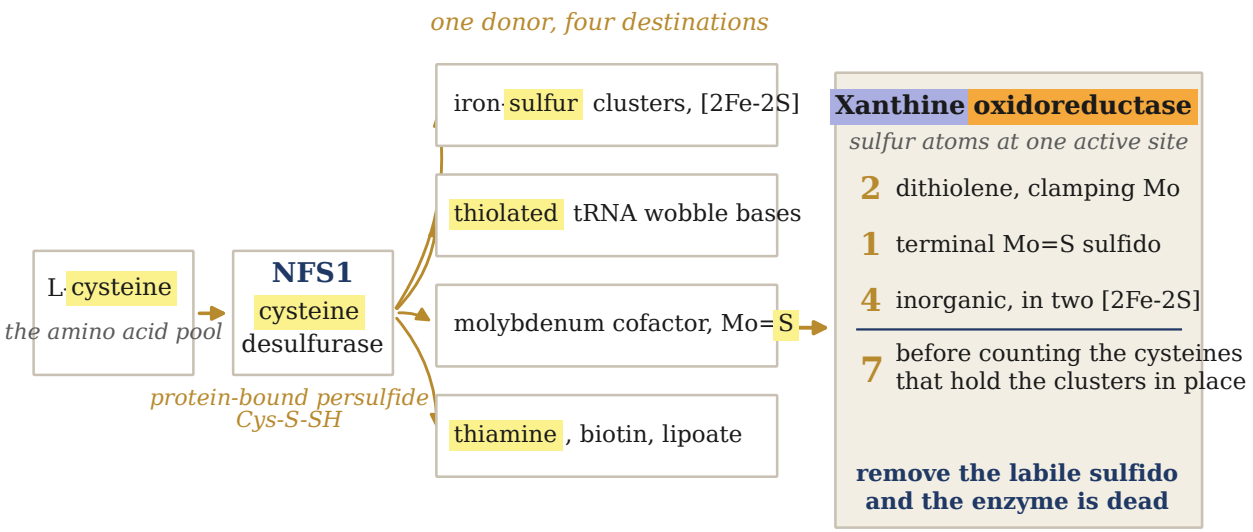

Figure 1. One donor, four destinations, and the sulfur inventory of xanthine oxidoreductase. Counting only the sulfur at one active site gives seven, and one of the seven is the labile terminal sulfido that MOCOS exists to reinstall.

5. The Cofactor That Empties Purines Is Built From a Purine ↩

Where the loop closes

Molybdenum cofactor is assembled starting from GTP — a purine nucleotide. An enzyme carrying two iron-sulfur clusters grips the guanine and opens its ring. The product is carried through a pterin intermediate, given its dithiolene, loaded with molybdenum, and — for xanthine

oxidoreductase and aldehyde oxidase — finished by MOCOS.

The enzyme that empties purines cannot work without a cofactor made out of a purine, provisioned with sulfur from the same donor that builds the enzyme that makes DNA. That is a closed loop, and it is not a metaphor.

---

6. The Courier Is Also the Shield ↩

The reactive sulfur layer this framework had filed as transport

Until recently the persulfide in this relay was treated as a delivery intermediate. The current literature treats it as a functional species in its own right.

property of RSSH	what was found	what it does
Two-electron reactivity	enhanced relative to ordinary thiols	maintains cellular redox homeostasis
One-electron reactivity	potent radical-trapping antioxidant activity	inhibits phospholipid peroxidation
Consequence	suppression of the lipid peroxidation chain reaction	inhibits ferroptotic cell death

The molecule that carries sulfur to the purine enzyme is also the molecule that protects the membrane on the way there.

The consequence for this paper is direct. A supply failure is expected to present simultaneously as reduced urate, as increased lipid peroxidation, and as impaired iron-sulfur and tRNA-thiolation chemistry. That is close to a description of the ALS motor neuron, and it is one lesion rather than three.

---

7. The Disease That Proves It ↩

Four human genotypes, and the dissociation they perform

If the purine arm and the sulfur arm genuinely share a part, then lesions in the shared part should knock out both arms, while lesions in either arm alone should leave the other untouched. Human genetics has already run that experiment.

disorder	enzymes lost	index metabolites	which arm fails
Xanthinuria type I	XDH alone	(hypo)xanthine up, urate down	purine only
Xanthinuria type II	XDH and AO	(hypo)xanthine up, urate down	purine only
Isolated sulfite oxidase deficiency	SO alone	sulfite up, S-sulfocysteine up	sulfur only
Molybdenum cofactor deficiency	XDH, AO and SO	both sets, plus cystine down and urate down	both, via the shared cofactor

Knock out the purine enzymes and sulfur is untouched. Knock out the sulfur enzyme and purines are untouched. Knock out the part they share and both fail. That is how you know it is a shared part and not a coincidence.

And it is the sulfite that does the damage, not the missing urate

Infants with molybdenum cofactor deficiency present within days with seizures and severe brain injury, and most die within three years. The clinical class is called sulfite intoxication disorders, because it is the accumulated sulfite that destroys the brain.

What this section establishes, and what it does not

Established, from clinical biochemistry: that the four-way comparison above is real and long known. Not claimed: that this framework predicted any of these diseases, or that metabolic physicians were unaware of the connection. They have measured sulfite and urate in the same patient for decades and know perfectly well why both are abnormal. What this paper adds is only that the same shared-supply logic has never been carried into ALS.

PART THREE · THE TWO LEDGERS OF A SINGLE DISEASE

---

8. The Sulfur Ledger in ALS ↩

What the redox literature has already measured

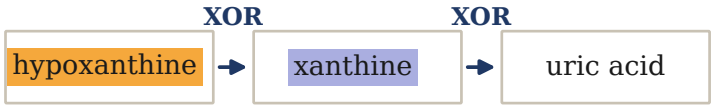
finding	what was measured
Glutathione	reduced in motor cortex, measured *in vivo* by J-edited magnetic resonance spectroscopy rather than inferred from post-mortem tissue; plasma non-protein sulfhydryls decline progressively
SOD1 thiol chemistry	wild-type and mutant SOD1 depend on a stable intrasubunit disulfide; oxidative modification and glutathionylation at Cys111 destabilise the dimer and promote non-native disulfide formation, misfolding and aggregation
The cysteine proteome	sulfenylation, S-nitrosylation and persulfidation are now argued to constitute a redox code whose disruption underlies neurodegeneration, with ALS as the exemplar
Hydrogen sulfide	significantly raised in cerebrospinal fluid in sporadic ALS but not in serum, 37 patients against 14 matched controls, $p < 0.00001$; raised in SOD1 G93A spinal cord at 90, 110 and 130 days
Hydrogen sulfide, toxicity	the donor NaHS kills motor neurons dose-dependently from 100 micromolar, with complete loss at 800 micromolar, while sparing astrocytes, and raises intracellular calcium in a manner reversed by intracellular ATP
Sulfur amino acid metabolism	sulfite and sulfinate species have been proposed as an excitotoxic route through inhibition of glutamate handling; this line is contested, and section 18 prints the contradiction

Every entry above is a sulfur measurement, and none of them is about purines.

9. The Purine Ledger in ALS ↩

What the epidemiology and the animal work have already measured

finding	what was measured
Urate and survival	in 251 US patients, risk of death fell by 39 percent for every 1 mg/dL increase in serum urate over five years, in men and not in women; reproduced in a 329-patient Chinese cohort; in 942 EMPOWER patients, urate at or above the median of 5.1 mg/dL predicted better one-year outcomes
Case against control	a meta-analysis of 8 case-control and 3 cohort studies found 1168 ALS patients to have significantly lower urate than 1391 healthy controls, with higher urate associated with decreased all-cause mortality among 3190 patients
Cognition	in 841 Italian patients, higher urate was associated with better cognitive and behavioural scores
XOR inhibition in mice	three non-purine-analogue inhibitors — febuxostat, Y-700 and FYX-051 — given orally from 80 days of age delayed onset, prolonged survival and stage duration, improved motor testing and preserved motor neurons with fewer inclusion bodies. Allopurinol, which carries a purine-analogue pyrazolopyrimidine ring, did not
Pharmacoepidemiology	in 42,885 patients with Alzheimer's, Parkinson's and/or ALS against 207,764 controls older than 66, allopurinol exposure was associated with a significant but modest reduction in risk of all three



the human terminus: uricase is deleted, and urate is unshaded

One disulfide sets the branch

XDH electrons to NAD
disulfide forms, reversibly
XO electrons to O2, superoxide

The sulfur ledger in ALS

- glutathione deficit in motor cortex, in vivo
- thiols fall in plasma as the disease runs
- SOD1 Cys111 oxidation, non-native bonds
- hydrogen sulfide raised in CSF and cord
- sulfite and sulfinate, proposed excitotoxic
- one desulfurase supplies all of the above

The purine ledger in ALS

- urate lower in patients than in controls
- higher baseline urate, longer survival
- non-purine XOR inhibitors delay onset
- allopurinol use: modestly lower risk
- raising urate with inosine: no benefit
- MOCOS and uricase both broken at a CpG

Figure 2. Two ledgers, one supply. The double-headed arrow is the subject of this paper. Urate is drawn unshaded, under the ruling at section 15.

10. The Trial That Moved the Index and Not the Disease ↩

The prediction that was tested before it was made

Inosine given orally or by feeding tube raised serum urate and was safe and tolerable over 12 weeks. The randomised trial that followed, SURE-ALS2, treated 23 participants for 24 weeks at doses targeting serum urate of 7 to 8 mg/dL — well inside the range that the cohort studies associate with longer survival.

what was measured	result
serum urate	raised to target, 7 to 8 mg/dL, and held for 24 weeks
ALSFRS-R progression	no detectable benefit
nephrolithiasis	14 percent of those treated

The number that predicts survival was moved to the value that predicts survival, held there for six months, and the disease did not notice.

That result is an anomaly for an account in which urate is the agent. It is the expected result for the

account set out in Part Four.

11. The Candidate Genes Nobody Followed Up ↩

A historical footnote that turns out to be chemical

When SOD1 mutations were linked to familial ALS, investigators searching for other enzymes of oxygen-radical metabolism examined the two human molybdenum hydroxylases as candidate genes for autosomal recessive familial ALS: aldehyde oxidase at 2q33, and xanthine dehydrogenase at 2p22. Aldehyde oxidase was judged the stronger candidate, partly for its expression in spinal cord glia, while XDH expression in spinal cord was reported as minimal.

The two enzymes examined are precisely the two that require MOCOS sulfuration. The genetic hypothesis was not confirmed. The chemical adjacency it noticed was never followed up.

PART FOUR · THE CLAIM, AND THE TESTS ATTACHED TO IT

12. Urate Is a Ledger Entry, Not a Lever ↩

The hypothesis, stated so that it can be attacked

	the claim
H1	In ALS, the low serum urate that predicts shorter survival is principally an index of persulfide supply to molybdenum cofactor sulfuration and iron-sulfur cluster assembly, and only secondarily a loss of circulating antioxidant capacity.
H2	The proximate injury is not a deficit of the terminal product but a shift in the branch: as reducing capacity falls, the reversible cysteine-pair disulfide converts XDH to XO, so that the enzyme that was making the antioxidant begins making superoxide.
H3	An intervention that raises urate without restoring persulfide supply should move the index and not the disease. An intervention that suppresses the oxidase branch, or that restores sulfuration, should move the disease.

Why this reorganizes the urate paradox

The paradox as usually stated is that blocking the enzyme that makes urate helps animals while high urate helps patients. Under H1 to H3 the paradox dissolves, because the two observations concern different variables. High urate in patients reports that the sulfur relay is intact enough to keep Moco sulfurated and clusters assembled; it is a biomarker of an upstream competence. XOR inhi-

bition in mice removes the superoxide-producing branch and simultaneously spares hypoxanthine for re-entry into salvage, raising the supply of high-energy purine compounds — which is the mechanism the original authors proposed. Neither observation is about urate as a chemical.

Inosine supplies substrate. It raised the index exactly as designed and changed nothing, because the supply line was never touched.

---

13. Why the Purine-Analogue Inhibitor Failed Where the Others Worked ↩

A structural prediction, not a post-hoc one

Allopurinol carries a purine-analogue ring and is itself handled as a substrate, entering the salvage pathway. The three non-purine inhibitors are not. Under H2 the therapeutic object is to shut the superoxide branch while leaving the salvage pool intact, and only the non-purine compounds do both. That follows from the ring chemistry, and it was the stated rationale of the original mouse study rather than a reading imposed afterwards.

---

14. The Gene That Broke Twice, and the Test Attached to It ↩

Carried forward as hypothesis-generating, and no further

Human uricase is disabled by a CGA to TGA transition at a CpG dinucleotide in exon two — CGA being the only codon in the genetic code that becomes a stop codon by mutating a CpG. MOCOS, the sulfurase that installs the terminal sulfur on xanthine oxidoreductase, is reported to carry the identical class of lesion. Two disablements by one mutational mechanism at opposite ends of one pathway is either a pattern or a coincidence, and the source volume prints it as neither.

The test, unchanged

Count CpG dinucleotides per coding kilobase across the pathway gene set — *UOX, MOCOS, XDH, MTHFR, CBS, SUOX, ITPA, IMPDH1* and *IMPDH2* — against controls matched for coding length and GC content, with a permutation null over gene labels. Then ask separately whether reported disease-causing substitutions in those genes fall at CpG sites more often than each gene's own density predicts.

---

15. The Color Ruling This Paper Records ↩

Why urate is unshaded, and why oxygen is not

Urate, uric acid, uricase, allantoin and hyperuricemia carry no color in this notation. The ruling stands on two grounds: urate sits outside the boundary of purine metabolism proper, and the molecule is the product of a pathway that in humans terminates abnormally.

No suppression, though. Oxygen keeps its color wherever it is warranted. The shader colors atoms and reactions, not nouns, and a ruling that a noun is unshaded does not travel to the chemistry that noun participates in.

There is a second reason to leave urate unshaded here, particular to this paper. The argument is that urate is a readout rather than an agent. A notation that gave it a color of its own would be asserting the opposite on every page.

---

16. The Experiments This Paper Generates ↩

Four, each with the condition that would sink it

	the experiment	falsification, written before the answer
1	Measure the sulfuration state, not the product. In ALS post-mortem spinal cord and in SOD1 G93A mice, determine the ratio of sulfo to desulfo Moco on XOR and aldehyde oxidase, quantify MOCOS protein and activity, and measure the XDH:XO ratio alongside.	If sulfo : desulfo and MOCOS activity are indistinguishable from controls while urate is low, H1 fails, and the low urate should be attributed to substrate flux or renal handling.
2	Test supply against product in the same animals. Compare inosine, a non-purine XOR inhibitor, and an agent that raises persulfide availability, with serum urate, cortical and spinal glutathione, protein persulfidation, lipid peroxidation and survival measured in every arm.	If the persulfide arm raises its own markers without affecting onset or survival, H1 to H3 lose their therapeutic content even if the chemistry stands.
3	Stratify the human urate signal by a sulfur variable. In an existing cohort with stored samples, ask whether the survival association of baseline urate survives adjustment for a persulfide-supply index: protein persulfidation, total sulfane sulfur, S-sulfocysteine, and the cysteine : cystine ratio.	Under H1 the urate association should attenuate substantially when the sulfur index is entered. If urate remains an independent predictor with that index in the model, urate is doing work of its own and H1 is wrong as stated.
4	Run the CpG test of section 14.	If the pathway genes show no CpG enrichment against matched controls, and their reported lesions fall at CpG sites no more often than density predicts, the uricase and MOCOS observations are two coincidences and should be withdrawn from the argument.

17. What This Paper Refuses ↩

The claims that were available and are not made

the claim	the status
That sulfur supply causes ALS	refused. Nothing here establishes direction, and a supply deficit downstream of motor neuron injury would produce the same ledger.
That XOR is a disease gene	refused. The 1995 candidate-gene work was not confirmed and is cited as chemistry, not genetics.
That urate has no antioxidant activity	refused. Plasma urate runs about 300 micromolar, higher than ascorbate, and is about as effective in the assays that made the case. H1 concerns what the number reports, not what the molecule can do in a tube.
That this framework predicted molybdenum cofactor deficiency	refused. That disease wascharacterized d long before, by people who understood the shared part perfectly well.
That the findings assembled here are new	refused. Every entry in Part Three is separately published. The assembly is the contribution, and an assembly is a weaker thing than a discovery.

18. What Would Show This Is Wrong ↩

Printed at full strength, including the evidence that runs against it

One. The sulfur amino acid data are inconsistent

Elevated plasma cysteine and altered sulfate handling were reported in motor neurone disease. A separate study found fasting plasma cysteine and inorganic sulfate, and brain cysteine content, to be normal in ALS. The sulfite-excitotoxicity proposal rests on the first line and not the second. Nothing in H1 to H3 requires elevated cysteine — the hypothesis concerns the disposition of sulfur into cofactors rather than its bulk concentration — but the disagreement is real and is not smoothed over here.

Two. XDH expression in spinal cord is low

The 1995 candidate-gene study reported minimal XDH expression in spinal cord, with aldehyde oxidase the more abundant molybdenum hydroxylase there. If the relevant sulfurated enzyme in motor tissue is aldehyde oxidase rather than XDH, then the systemic urate reading is a peripheral proxy for a central sulfuration state, and the inference chain is one link longer. Experiment 1 measures both for that reason.

Three. Hydrogen sulfide is elevated, not depleted

A naive supply-failure model predicts less reactive sulfur, and CSF hydrogen sulfide in ALS is higher. The resolution offered here is that bulk hydrogen sulfide and targeted persulfide transfer are different quantities: the disposal enzymes SQR, ETHE1 and rhodanese and the donor enzymes CBS, CSE and 3-MST are distinct from the NFS1 relay, and loss of a disposal enzyme lowers reduced glutathione while raising sulfide. That resolution is plausible and currently untested, and it is the weakest joint in the argument.

Four. The sex specificity is unexplained

The urate and survival association is repeatedly reported in men and not in women. No part of H1 to H3 predicts that, and any complete account will have to.

Four ways to be wrong, named before the evidence was assembled. A model that cannot be refuted is decoration.

---

19. What This Paper Claims ↩

Narrow, and for that reason testable

the claim	basis
That xanthine oxidoreductase is a sulfur-assembled enzyme, and that one labile sulfur atom gates purine disposal	structural and enzymological, established, not this paper's finding
That the thiol literature and the purine literature in ALS are reporting on one supply line	the shared-cofactor architecture of Part Two, plus the four-way dissociation of section 7
That circulating urate in ALS is better read as an index of that supply than as an independent agent	H1, and the negative inosine trial that H1 predicts
That this reading makes the SURE-ALS2 result expected rather than anomalous	section 10, and the argument of section 12

The paper claims necessity at one point and sufficiency at none. That is the honest shape of a first-principles case, and it is strong enough to be tested.

PROVENANCE, DECLARATIONS AND SOURCES

Provenance

The biochemical framework of Parts One and Two — the seven-sulfur inventory of the XOR active

site, the one-donor and four-destination relay, the closed loop between Moco and the purine ring, and the four-way disorder comparison — is drawn from The Scientific Arc of Man's Evolution from the Big Bang to the Human Genome, PP-2026-MASTER-01 v329, September 2026, Licensed under CC BY-NC-ND 4.0., an evidence volume of approximately 1,778

pages by the present author; the relevant material ap- pears at its sections 8 to 9, 51 to 56, 767 to 780 and 1667 to 1676. The color index, the section architecture and the page furniture of this paper are that volume's. The ALS-specific evidence of Part Three and the trial results of Part Four are drawn from the primary and review literature listed below. Where the volume's claims are its own rather than the field's, they are marked as such in the text and carried with their stated falsification conditions.

Declarations

Funding. None.

Competing interests. The author declares none.

Clinical note. Nothing here is medical advice. Inosine raises serum urate and, in the randomised trial cited, produced nephrolithiasis in 14 percent of treated participants without clinical benefit. XOR inhibitors are not approved for ALS.

PERSPECTIVE · HYPOTHESIS PAPER

Sulfur and Neurodegeneration

Thiol-Dependent Entry as a Shared Vulnerability

A Shared-Chemistry Hypothesis Linking Cysteine Gating to Amyotrophic Lateral Sclerosis, Alzheimer Disease, Tay–Sachs Disease and Friedreich Ataxia

PP-2026-PERSP-03 v3 · September 2026

A perspective drawn from the primary literature, in the furniture of the evidence volume

Published by NovagonDNA, Naperville, Illinois.

First edition, 2026. Distributed by the author.

What this paper is, and who it is for

Six separate literatures describe six separate failures. Protein import into mitochondria fails in amyotrophic lateral sclerosis. Sulfatide disappears from myelin in Alzheimer disease. Protein anchoring to membranes is disordered in Huntington disease. Cofactor assembly fails in Friedreich ataxia. A lysosomal enzyme never leaves the endoplasmic reticulum in Tay–Sachs disease. Antioxidant capacity collapses in Parkinson disease. Each is studied by people who do not, in the ordinary course of their work, read the others.

This paper argues that the six are one observation seen from six sides, and that the joint between them is an atom rather than a theme. The argument is that sulfur sits at the thresholds — not as bulk substance but as the chemistry by which a cell decides what is admitted, assembled and anchored — and that the thiol-gated subset of those thresholds is where a disproportionate number of these diseases break.

It is written for the reader who wants the chemistry carried down to the bond. It expects scientific literacy and no specialist standing. A neurologist can read the genetics; a biochemist can read the pathology; neither is expected to be at home in both, which is the condition that produced the gap this paper is about.

End matter		Provenance · Declarations · Sources

Nine words this paper cannot do without, in plain English

Every one of them is the name of a thing rather than a label for a category, and a reader who wants to check a claim against the literature will need them.

the word	the meaning
thiol	The sulfur-hydrogen group on a cysteine side chain. The reactive part. Nearly everything in this paper happens at one.
disulfide	Two sulfur atoms bonded to each other, formed by oxidation of two thiols. A covalent staple that can be undone.
relay	A chain of proteins that passes oxidizing power from one to the next. The disulfide relay uses it to lock imported proteins in place.
translocase	A machine that moves a protein across a membrane it cannot otherwise cross. TOM and TIM are the mitochondrial ones.
β-barrel	A protein folded into a closed cylinder that sits in a membrane as a pore. TOM40 is one.
S-acylation	Attachment of a fatty acid to a cysteine through a thioester bond. Reversible, which is the point. Commonly called palmitoylation.
sulfatide	A myelin lipid carrying a sulfate group. Built by moving sulfate from PAPS onto a sugar-lipid.
ERAD	Endoplasmic reticulum-associated degradation. The quality-control route that destroys a protein which fails to fold, before it can leave.
gate	Used here in its plain sense. A step that must be passed, that can be closed, and whose closure is not the same event as damage.

A note on the color index

Every shaded word in this paper carries the color index of the evidence volume. One color, one element, one base, throughout. The colors are one-to-one labels assigned by mapping, not by measurement; spectral order carries no meaning. Hydrogen = red is the single assignment with a physical basis, the Balmer-alpha line at 656 nanometers.

THE COLOR INDEX

color	element	base	where it appears in this paper
YELLOW	sulfur, S 16	thymine	cysteine, disulfide, persulfide, sulfatide, glutathione, sulfate, sulfur, thymidylate, thioester
ORANGE	oxygen, O 8	hypoxanthine	oxidation, oxidase, peroxide, oxidative
INDIGO	selenium, Se 34	xanthine	selenocysteine, GPX4
RED	hydrogen, H 1	adenine	hydrogen sulfide, H_2S
GREEN	nitrogen, N 7	guanine	amino, homocysteine, glutamate
PURPLE	phosphorus, P 15	uracil	PAPS, phosphate, ATP
BLUE	carbon, C 6	cytosine	acyl, palmitoyl

Iron, myelin, urate, the gangliosides and the disease names carry no color, under the ruling recorded in the volume. Element symbols appear alongside the colors so that no figure depends on color alone.

A note on the method

Every Part of this paper ends by stating the conditions under which it would be wrong. Where a finding was not reproduced, where a trial missed its endpoint, and where the evidence runs against the argument, the record is printed rather than omitted. Section 13 collects the refutations in one place; sections 12 and 14 separate what is refused from what is claimed.

A note on the spelling

This paper uses sulfur throughout, following the volume it is drawn from. IUPAC standardized on that form in 1990 and the Royal Society of Chemistry followed in 1992.

PART ONE · THE SHAPE OF THE ARGUMENT

1. Degeneration as a Failure of Entry ⟵

Why accumulation describes the endpoint and not the lesion

Most accounts of neurodegeneration are accounts of accumulation. Something misfolds, aggregates, and the cell is poisoned by what it cannot clear. The framing is productive, and it is what the neuropathology shows. It is also an account of the endpoint.

An alternative framing asks what stopped working first. Neurons are unusually dependent on gated transfer. Proteins made in the cytosol must be admitted into mitochondria. Lipids must be sulfated to build myelin. Soluble proteins must be anchored into membranes before they can be trafficked at all. Cofactors must be inserted into apoproteins before those proteins function.

Each of these is a threshold step. Each has a gate. Each gate can fail without anything accumulating first, and the accumulation that follows is then a consequence rather than a cause.

The observation this paper is about

A strikingly high proportion of these gates run on sulfur chemistry. Not on sulfur as a bulk constituent — the brain contains far more carbon, nitrogen and phosphorus — but on the specific reactivity of the cysteine thiol: its ability to form and break disulfide bonds, to carry acyl groups as thioesters, to donate sulfur to metal clusters, and to be oxidized and reduced reversibly at physiological potentials.

That reactivity makes cysteine an excellent gatekeeper. It also makes it an excellent single point of failure. A gate that opens by reduction closes when the cell oxidizes. A gate that requires a sulfur donor stalls when the donor pool contracts.

The proposal is not that sulfur causes neurodegeneration. It is that the thiol-gated subset of cellular entry steps is enriched for disease genes, and that this enrichment is the signal

worth following.

The argument proceeds by examining six gates in descending order of evidentiary strength, then stating what the framework does not cover, then listing the experiments that would falsify it.

2. The Sulfur Inventory of the Brain ⟷

What the sixty percent figure does and does not license

The brain is roughly sixty percent lipid by dry weight. That figure invites an inference which the biochemistry does not support: that sulfur, being important, must be a major constituent of that lipid.

The bulk membrane lipids contain no sulfur at all. Glycerophospholipids are built from carbon, hydrogen, oxygen, nitrogen and phosphorus. Cholesterol, which the brain holds in unusual abundance — on the order of a quarter of the body's total — is carbon, hydrogen and oxygen. By mass, sulfur is a trace element in neural membrane.

The correction matters because it forces the argument into its stronger form.

Sulfur is not the brick. It is the tooling, the key and the hinge.

role	chemistry	where it acts in brain
lipid assembly	coenzyme A thioester, C–S	every fatty acid synthesized or oxidized passes through a thioester bond
lipid methylation	SAM sulfonium	methyl donation to phospholipid headgroups and to myelin basic protein
structural lipid	sulfatide	major myelin glycosphingolipid; sulfate installed from PAPS
protein anchoring	S-acyl thioester on cysteine	palmitoylation of synaptic and trafficking proteins
catalytic cofactor	iron-sulfur cluster	respiratory complexes I–III, aconitase, DNA repair enzymes
redox buffering	glutathione thiol	principal cytosolic antioxidant; highest demand in dopaminergic neurons
signaling	persulfidation	reversible modification of cysteines by sulfane sulfur
nucleotide synthesis	thymidylate synthase active-site cysteine	every thymine methyl group in the genome is installed by way of a covalent thiol adduct

The clearest case of tooling rather than material

Thymidylate synthase makes every molecule of thymine in the genome. Its active-site cysteine attacks C6 of dUMP to form a covalent adduct, which activates C5 so that a one-carbon unit can be transferred from methylene-tetrahydrofolate and then reduced to a methyl group. Release regenerates the free thiol.

The methyl carbon is a folate carbon, not a sulfur one. The thiol is the catalyst and is consumed by nothing. The sulfur and folate pools are nonetheless coupled one step away, at methionine synthase, where 5-methyl-tetrahydrofolate remethylates homocysteine to methionine and feeds the transsulfuration branch of section 3.

Every row is a point of leverage. None is a point of bulk. The distinction is the difference between a claim that sulfur is abundant, which is false, and a claim that sulfur is load-bearing, which is what this paper defends.

3. Cysteine as the Hub Metabolite ↩

One pool, seven branches, and why the failures should correlate

Every gate described in this paper draws on one pool. Cysteine is the entry point for essentially all functional sulfur in the brain, and the branches leaving it are the branches that fail.

Cysteine reaches neurons by two routes. It is imported as cystine through the system x_c^- antiporter, SLC7A11, which exchanges it for glutamate — a coupling that makes cysteine supply hostage to glutamatergic tone. It is also made by transsulfuration, in which homocysteine condenses with serine by way of cystathionine β-synthase and is cleaved by cystathionine γ-lyase. Both enzymes also generate hydrogen sulfide, which makes transsulfuration a supply line and a signaling pathway at once.

methionine → *SAM* → *homocysteine* → *CBS / CSE*

cystine via SLC7A11 → ***CYSTEINE*** ← *transsulfuration*

and from there —

glutathione · *H_2S and persulfides* · *iron-sulfur clusters by way of NFS1*

coenzyme A · *taurine* · *PAPS* → *sulfatide*

Each terminal branch has an established disease association. Glutathione depletion is among the earliest detectable changes in the Parkinsonian substantia nigra. Persulfidation declines with brain aging and in neurodegeneration, and cystathionine γ-lyase has been tied to cognitive function through neurotrophin signaling and neurogenesis. Iron-sulfur assembly fails in Friedreich ataxia. PAPS-dependent sulfation builds the sulfatide whose loss is sufficient for Alzheimer-like pathology.

Why the structure of this matters

These are not independent risk factors. They are downstream branches of one upstream pool, which means a single constraint — cysteine availability, or the redox poise that determines how much of it is usable — propagates simultaneously into mitochondrial import, myelin maintenance, antioxidant capacity and protein trafficking.

This is the mechanistic core of the hypothesis, and its most testable consequence: it predicts correlated rather than independent failure across systems that are currently studied separately.

PART TWO · THE SIX GATES

4. The Mitochondrial Disulfide Relay ⟷

Where import and oxidation are the same event

This is the strongest case, and the one from which the rest of the argument generalizes.

Proteins destined for the mitochondrial intermembrane space carry no cleavable presequence and cannot be pulled in by membrane potential. They are instead trapped there by covalent modification. MIA40, the human CHCHD4, oxidizes cysteines in the incoming substrate, forming a disulfide bond that locks the protein into its folded conformation and prevents it from diffusing back out. The substrate arrives reduced and unfolded. It is admitted by being oxidized. MIA40 is then re-oxidized by Erv1, a flavin-dependent sulfhydryl oxidase that passes the electrons to cytochrome *c* and ultimately to O_2.

The gate is not merely sulfur-containing. Disulfide formation *is* the translocation mechanism. Import and oxidation are one event.

The substrates that matter

The canonical MIA40 clients are twin-CX_9C and twin-CX_3C proteins. Three of them bear directly on neurodegeneration.

substrate	function	disease link
Tim9–Tim10	chaperone β-barrel precursors across the intermembrane space	required for TOM40 and VDAC biogenesis
CHCHD10	intermembrane space protein, cristae organization	mutations cause ALS–FTD
SOD1	superoxide dismutase, matured by its copper chaperone	mutations cause familial ALS

A *CHCHD10* mutation has been shown to cause a Mia40-dependent mitochondrial import deficit in ALS, which ties the disease gene to the gate rather than merely to the organelle. SOD1 is itself an intermembrane space import substrate whose maturation requires an intramolecular disulfide at Cys57–Cys146, installed by way of its copper chaperone; ALS-associated mutants misfold through aberrant *intermolecular* disulfide crosslinking, and glutathionylation at Cys111 promotes dissociation of the dimer. Misfolded small TIMs are cleared by the i-AAA protease, so relay failure is degradative as well as kinetic.

What is claimed here, and what is not

Two independent ALS genes converge on a single thiol-operated entry step. This paper treats that convergence as mechanistically informative rather than coincidental — specifically, as evidence that intermembrane space import competence is a disease-relevant variable in its own right, measurable independently of aggregation and of bulk mitochondrial function.

That is an interpretation. The established findings are the relay chemistry and the two gene associations. The interpretation is what section 13 offers to have refuted.

5. The Outer Membrane Pore ↩

Thiol-assembled, and not thiol-operated

TOM40 is the general entry pore of the mitochondrial outer membrane. Roughly ninety-nine percent of the thousand to fifteen hundred mitochondrial proteins are nuclear-encoded and cross through it. It is the most heavily trafficked doorway in the cell.

It is also not thiol-gated, and this section exists partly to say so.

Passage through TOM40 depends on presequence recognition at the TOM20, TOM22 and TOM70 receptors. The subsequent inner-membrane step runs on membrane potential at TIM23 and on ATP-driven mtHsp70. No disulfide chemistry participates. A framework that claimed otherwise would be overreaching, and the overreach would be easy to catch.

Where the connection actually lies

TOM40 is a β-barrel. Its precursor must be escorted across the aqueous intermembrane space by the small TIM chaperones and handed to the SAM50 complex for insertion into the outer membrane. Those small TIMs are MIA40 substrates, folded by site-specific oxidation of their cysteines.

TOM40 precursor $\rightarrow$ *through the TOM complex* $\rightarrow$ *Tim9–Tim10, folded by MIA40* $\rightarrow$ *SAM50 insertase* $\rightarrow$ *TOM40 seated in the membrane*

No relay, no folded chaperones, no pore.

Sulfur does not operate this door. Sulfur builds it. The dependency is one step removed, and nothing more than that is claimed.

The TOMM40 genetics, stated with the caveats that belong to them

TOMM40 sits at 19q13.32, immediately adjacent to *APOE* and in tight linkage disequilibrium with it. An intronic poly-T variant, rs10524523, was proposed to modify age of onset in late-onset Alzheimer disease. Three qualifications are required, and omitting any of them would misrepresent the field.

1. Independence from *APOE* is contested. Much of the *TOMM40* signal attenuates under proper conditioning on *APOE* ε4, and the debate has been characterized in the literature as a story about linkage disequilibrium. Cis-regulatory work suggesting the poly-T affects *TOMM40* and *APOE* expression keeps the question open rather than settling it.
2. The definitive clinical test did not succeed. The TOMMORROW trial, built on a *TOMM40* and *APOE* genotype risk algorithm with low-dose pioglitazone, was stopped for futility.
3. This is an Alzheimer locus and not an ALS locus. *APOE* ε4 is not an established risk factor for sporadic ALS.

***TOMM40* supports the general proposition that entry machinery matters in neurodegeneration. It does not support the specific proposition that the failure is thiol-mediated, and it is not recruited for that purpose here.**

6. The Myelin Membrane ↩

The one place where sulfur is structural, and the cleanest causal evidence in the paper

Sulfatide, 3-O-sulfogalactosylceramide, is a major myelin glycosphingolipid. It is made by transferring sulfate from PAPS, the universal activated sulfate donor, onto galactosylceramide

by way of cerebroside sulfotransferase. Its degradation requires arylsulfatase A; loss of that enzyme causes metachromatic leukodystrophy, a demyelinating disease of sulfatide accumulation.

Why this is causal and not correlative

The critical result is a subtraction experiment. Adult-onset central nervous system myelin sulfatide deficiency is sufficient, on its own, to cause Alzheimer-like neuroinflammation and cognitive impairment in mice — not as a consequence of amyloid or tau, but as a primary lesion. Subsequent work established that the resulting astrogliosis and myelin lipid dyshomeostasis proceed independently of TREM2-mediated microglial activation, which rules out one obvious confound. Sulfatide in cerebrospinal fluid has accordingly been examined as a neurodegeneration biomarker.

What is claimed here

Sulfatide synthesis is a sulfur-flux-limited step. It requires PAPS, which requires activated sulfate, which requires cysteine oxidation upstream. The framework therefore predicts that sulfatide depletion should not be an isolated lipid abnormality but should co-vary with other sulfur-dependent readouts in the same tissue — glutathione state, persulfidation level, iron-sulfur enzyme activity.

That co-variation has not been tested directly. It is prediction three of section 13.

7. The Membrane Anchor ⟵

A thioester deciding where a protein is allowed to be

Many neuronal proteins are functionally soluble but must be reversibly attached to membranes to be trafficked, clustered at synapses, or carried along axons. That attachment is made through sulfur.

S-acylation, commonly S-palmitoylation, attaches a fatty acyl chain to a cysteine residue through a thioester bond, catalyzed by the ZDHHC family of acyltransferases. The bond is labile, which is the point. Unlike a lipid anchor installed once, S-acylation is a reversible switch, and it governs where a protein is and how long it stays there.

The disease evidence

Altered palmitoylation is an established mechanism across neurodegenerative disorders, with documented consequences for axonal transport — the process whose failure is most characteristic of motor neuron disease. Inhibition of zDHHC7-driven S-palmitoylation prevents cognitive deficits in an experimental Alzheimer model, which establishes that the modification is manipulable and disease-relevant rather than merely correlated. Most directly relevant here, ZDHHC17 has been linked to ALS, VCP-associated multisystem proteinopathy and Huntington disease in recent work: one acyltransferase touching three degenerative conditions.

What is claimed here

S-acylation is the gate at which a protein is admitted to a membrane compartment. Its substrate is a cysteine. Its chemistry is a thioester. Its reversibility depends on the redox and acyl-CoA state of the cell.

This makes it, formally, the same kind of gate as the MIA40 relay: a cysteine thiol deciding whether a protein reaches where it is supposed to be. The two differ in compartment and in chemistry, and not in logic.

8. Iron-Sulfur Cluster Assembly ⟵

The proof of principle, because here the direction of causation is not in question

Iron-sulfur clusters are cofactors of respiratory complexes I to III, of aconitase, and of several DNA repair enzymes. They are built on a scaffold in the mitochondrial matrix, and the sulfur is supplied by NFS1, a cysteine desulfurase that abstracts sulfur directly from free cysteine and hands it, as a persulfide on its own active-site cysteine, to the assembly machinery. The reaction is literally the transfer of one sulfur atom from one thiol to another.

Friedreich ataxia results from loss of frataxin, which participates in that assembly process. The clinical consequence is progressive neurodegeneration — spinocerebellar and sensory, with cardiomyopathy. There is no ambiguity about direction: the sulfur-handling defect is the primary genetic lesion, and degeneration follows.

Why this gate anchors the argument

Every other gate in this paper is a candidate. This one is a demonstration. It establishes three things.

1. A defect confined to sulfur trafficking is sufficient to produce human neurodegeneration.
2. The affected step is cofactor insertion — a gated transfer, not a bulk supply problem.
3. Neurons are among the tissues least able to tolerate such a defect.

The third point carries the most weight and has the least explanation behind it. Cells vary in their tolerance for reduced iron-sulfur flux, and postmitotic neurons with high oxidative load sit at the intolerant end. That pattern — a ubiquitous housekeeping process failing tissue-specifically in neurons — recurs throughout this paper and is returned to in section 13.

9. The Secretory Folding Gate ⟵

The same relay chemistry, in the other compartment

Sections 4 and 5 concerned proteins entering mitochondria. This one concerns proteins

leaving the endoplasmic reticulum, and it matters because the chemistry is the same while the compartment is not.

Lysosomal hydrolases are disulfide-bonded proteins folded in the endoplasmic reticulum. The ER runs its own oxidative relay: protein disulfide isomerase installs the bonds, and ERO1, a FAD-dependent sulfhydryl oxidase, re-oxidizes PDI and passes the electrons to O_2.

Two compartments, two disulfide relays, the same chemistry and the same terminal electron acceptor. Neither system was described with the other in view.

Tay–Sachs disease as a failure of exit

Tay–Sachs disease is an inherited lysosomal storage disease that destroys nerve cells in the brain and spinal cord. It follows from loss of β-hexosaminidase A, a heterodimer whose α chain is encoded by *HEXA* on chromosome 15. Without it, GM2 gangliosides are not hydrolyzed, neurons become distended with stored lipid, and a relentless deterioration begins. In the infantile form death usually occurs before the age of four.

The active site is not thiol-operated

Only the α subunit can hydrolyze GM2. It does so because of Arg-424, which binds the N-acetyl-neuraminic residue, and a loop of Gly-280, Ser-281, Glu-282 and Pro-283 that receives the GM2 activator protein; the loop is absent from the β subunit. Catalysis itself runs through an aspartate–glutamate pair with substrate assistance from the 2-acetamido group.

Not one of those residues is a cysteine. The chemistry of the active site is not thiol chemistry, and this paper does not claim that it is.

But the fold is, and that is where the disease acts

Many Tay–Sachs alleles do not abolish catalysis. They produce an α chain that fails to fold, never passes ER quality control, and is destroyed: *HEXA* mutations target the α chain of hexosaminidase A to ER-associated degradation. The enzyme is competent. The admission fails.

The therapeutic result closes the argument. Pyrimethamine raises β-hexosaminidase A activity in patients with late-onset Tay–Sachs by acting as a pharmacological chaperone, stabilizing the fold so the protein survives quality control.

A dead active site cannot be rescued by a chaperone. That the rescue works establishes the lesion as a folding-and-exit problem rather than a catalytic one.

The ceramide fork

Tay–Sachs also sits beside a disease already in this paper. Both branches begin at ceramide, which is built by condensing serine with palmitoyl-CoA — a thioester, so the same sulfur-dependent assembly step described in section 2.

$$\textit{serine} + \textit{palmitoyl-CoA} \rightarrow \textit{ceramide}$$
$$\textit{galactosylceramide} \rightarrow \textit{sulfatide} \;\mid\; \textit{glucosylceramide} \rightarrow \textit{GM3} \rightarrow \textit{GM2}$$
$$\textit{arylsulfatase A fails} \rightarrow \textit{metachromatic leukodystrophy} \;\mid\; \textit{HEXA fails} \rightarrow \textit{Tay–Sachs}$$

One backbone, one thioester origin, two catabolic failures, two neurodegenerative diseases. Section 6 took the sulfated branch. This section takes the other one.

What is claimed here

The gate is the ER disulfide relay, and Tay–Sachs is an instance of its failure — for the missense alleles that misfold, which is not all of them. Section 13 records that limit as the sixth way this framework could be wrong.

The structural point is the one repeated from section 5: **thiol-assembled, not thiol-operated.** TOM40 and hexosaminidase A are unrelated proteins in unrelated compartments, and the same verdict fits both. A pattern that survives being tested twice in systems that share nothing else is worth more than either instance alone.

PART THREE · THE SYNTHESIS

10. Redox Poise as the Shared Currency ⟲

The single parameter all six gates read

The six gates are chemically distinct. What links them is that each is sensitive to the same variable: how oxidized the cell's thiol pool is.

A disulfide relay requires substrates delivered reduced and an oxidant to close the bond, so it fails at both extremes. A thioester anchor requires a free thiol and is destroyed by over-oxidation of that cysteine. A desulfurase requires free cysteine as substrate. A sulfotransferase requires sulfate generated by oxidizing cysteine in the first place. An ER relay fails when the compartment's oxidant supply or its reductive capacity moves in either direction.

Thiol redox poise is not one more risk factor alongside these gates. It is the parameter all of them read.

One. Glutathione

Depletion of reduced glutathione in the substantia nigra is among the earliest detectable biochemical changes in Parkinson disease, and motor cortex glutathione deficit has been measured in vivo in ALS. It is a depletion of the cell's principal thiol buffer, in the tissue that degenerates.

Two. Persulfidation

Protein persulfidation, the reversible modification of cysteines by sulfane sulfur derived from H_2S, declines with brain aging and in neurodegeneration. The persulfidome is tissue-specific and cystathionine γ-lyase-dependent, and that enzyme has been tied to cognitive function through neurotrophin signaling and neurogenesis. This is the same transsulfuration branch that supplies cysteine.

Three. Ferroptosis

Glutathione peroxidase 4 uses a selenocysteine active site to reduce lipid peroxides. Midbrain dopamine oxidation drives ubiquitination of GPX4 and ferroptosis of dopaminergic neurons, and ferroptosis-related factors in the substantia nigra associate with Parkinson disease. Cysteine supply, by way of system x_c^-, is the rate-limiting input to this defense. Independently, hydropersulfides have been shown to inhibit lipid peroxidation and protect cells from ferroptosis by scavenging radicals.

The synthesis

Each of these is usually described as a distinct pathology: oxidative stress, gasotransmitter decline, iron-dependent cell death. Under the present framework they are three readouts of one constraint, differing in which downstream branch of the cysteine pool they happen to measure.

That reframing has a practical consequence. If it is right, these measures should be correlated within individuals and within tissue, and interventions that raise cysteine availability should move all of them together. If they are genuinely independent, the framework is wrong.

11. The Boundary of the Framework ↩

What this does not explain, stated before anyone has to find it

A framework that explains everything explains nothing. This section states the scope as a property of the argument rather than as something a reader has to discover.

Nucleocytoplasmic transport

C9orf72 repeat expansion, the single largest genetic contributor to ALS and frontotemporal dementia, disrupts transport through the nuclear pore. That is a gated entry failure and it fits the broad frame of section 1. It is not thiol-operated. Karyopherin-mediated transport runs on the Ran GTPase gradient. The framework gains nothing by annexing it, and says so.

Membrane-potential-driven import

The TIM23 pathway carrying presequence proteins into the matrix runs on membrane potential and on ATP-driven mtHsp70. It is the larger of the two mitochondrial import routes by substrate count, and no disulfide chemistry participates.

TDP-43 proteinopathy

TDP-43 mislocalization and aggregation appear in the great majority of ALS cases and define the neuropathology. TDP-43 carries cysteines, and oxidation-dependent aggregation has been proposed, but the primary lesion is not established as thiol-mediated and is not claimed as such here.

Null alleles

A mutation that produces no protein at all is outside this framework by construction. The commonest Tay–Sachs allele is of that kind, and section 13 states the consequence. A gate can only be the lesion where there is something to admit.

Polyglutamine expansion, α-synuclein, tau

These have their own mechanisms. Where sulfur enters, for instance through S-acylation of trafficking proteins, it modifies the process rather than initiating it.

The honest scope is this. Thiol gating is one failure mode among several, distinguished by the fact that it recurs across diseases that otherwise share no mechanism. That recurrence is the whole claim. It is weaker than saying sulfur causes neurodegeneration, and it is considerably more defensible.

PART FOUR · STANDING

12. What This Paper Refuses ↩

The claims that were available and are not made

the claim	the status
That sulfur deficiency causes neurodegeneration	refused. Nothing here establishes direction for five of the six gates, and a supply deficit downstream of neuronal injury would produce the same ledger.
That the six diseases share an etiology	refused. They share a class of vulnerable step. That is a much smaller claim and it is the one made.
That *TOMM40* is evidence for thiol gating	refused in section 5, in the paper's own text, on the grounds that TOM40 is not thiol-operated.
That thiol gating explains ALS	refused. *C9orf72* is the largest genetic contributor and its lesion is at the nuclear pore, which this framework does not reach.
That thiol gating explains Tay–Sachs	refused. It reaches the misfolding missense alleles. It does not reach the frameshift and null alleles, which are the majority.
That the TATC insertion acts through the chemistry of its bases	refused. The four-base insertion in exon 11 of *HEXA* shifts the reading frame; a premature stop codon and destruction of the transcript follow from the frame, not from the methyl groups on the inserted thymines. Any four-base insertion at that position does the same.
That the thymine methyl group is a sulfur carbon	refused. It is transferred from methylene-tetrahydrofolate. The cysteine of thymidylate synthase is the catalyst, not the donor, and that distinction is the whole point of section 2.
That the findings assembled here are new	refused. Every entry is separately published. The assembly is the contribution, and an assembly is a weaker thing than a discovery.
That the enrichment has been demonstrated	refused. It is proposed and specified in section 13, prediction five. It has not been run.

13. What Would Show This Is Wrong ⟵

Printed at full strength, including the evidence that runs against it

One. Cause and consequence are not separated

This is the principal weakness. Degenerating neurons have failing mitochondria, depleted glutathione and disordered lipid, and all three would appear in a cross-sectional study regardless of what initiated the process. Only prediction two below — measuring gate competence before overt degeneration — separates them, and that measurement has not been made for most of the gates described here. The weakness is structural, not incidental.

Two. The pattern may be selection bias

Sulfur chemistry is ubiquitous in biology. Any sufficiently broad search for sulfur-dependent steps among disease genes will find some. The framework is defended against this only by the enrichment test of prediction five, and until that test is run, what is reported here is a hypothesis generated by inspection rather than a result.

Three. It may reduce to oxidative stress

A reader may reasonably object that thiol gating failure is a restatement of oxidative stress, a concept whose explanatory value in neurodegeneration has been debated for three decades. The distinction claimed is specific: oxidative stress accounts predict damage proportional to exposure, while a gating account predicts threshold failure at defined steps with identifiable substrates. These differ in dose-response shape and in which proteins are affected, and the two are separable by experiment. If they prove not to be separable, the framework adds nothing to what is already said.

Four. Tissue specificity is unexplained

Thiol gating operates in every cell. Why motor neurons, or dopaminergic neurons of the substantia nigra, and not hepatocytes? Postmitotic status, axon length, oxidative load and low baseline glutathione reserve are available as contributors but have not been demonstrated to combine into the observed selectivity. This is a gap and it is named as one.

Five. The cysteine data in ALS are not uniform

Elevated plasma cysteine and altered sulfate handling were reported in motor neurone disease. A separate study found fasting plasma cysteine and inorganic sulfate, and brain cysteine content, to be normal in ALS. Nothing in this framework requires elevated cysteine — the hypothesis concerns the disposition of sulfur into gates rather than its bulk concentration — but the disagreement is real and is not smoothed over.

Six. The commonest Tay–Sachs allele is not a folding defect

Section 9 rests on the missense alleles that misfold and are cleared by ERAD, and on the fact that a pharmacological chaperone rescues them. It does not rest on the four-base TATC insertion in exon 11, which accounts for over eighty percent of patients and produces no α chain at all. For those patients the secretory folding gate is not the lesion, because nothing arrives at it. The gate account covers a minority of the Tay–Sachs allele spectrum and is stated at that width.

The predictions, and what refutes each

	prediction	what would refute it
1	Thiol-dependent readouts — glutathione state, persulfidation, PAPS flux, iron-sulfur enzyme activity — co-vary within affected tissue	these measures vary independently of one another in the same samples
2	MIA40-substrate import competence is reduced in patient-derived cells carrying *CHCHD10* or *SOD1* mutations *before* overt degeneration	import competence is normal until after degeneration is established
3	Sulfatide depletion co-varies with cysteine-pool measures rather than appearing as an isolated lipid abnormality	sulfatide falls while glutathione and persulfidation are unchanged
4	Raising cysteine availability moves several downstream branches together	an intervention raises glutathione with no effect on persulfidation or sulfation
5	Disease genes are enriched in thiol-gated steps relative to a matched set of non-thiol-gated entry steps	a systematic count, properly matched, finds no enrichment
6	Neuronal vulnerability tracks thiol-flux demand rather than metabolic rate alone	vulnerability rank follows oxidative load with no residual contribution from thiol demand
7	ER redox poise predicts which *HEXA* missense alleles are rescuable by a pharmacological chaperone	rescuability is uncorrelated with PDI and ERO1 oxidation state and tracks only residue position

The decisive test

Prediction five settles the matter, because it tests the central assertion directly and quantitatively. The others are consistent with a general oxidative stress account; only an enrichment analysis distinguishes thiol gating from oxidative damage generally.

The analysis is tractable. Assemble the set of gated cellular entry, assembly and anchoring steps; classify each as thiol-dependent or not by its chemistry; overlay curated neurodegeneration gene sets; test for enrichment against a background matched for expression level, essentiality and tissue distribution. The matching is the difficult part and the result is only as good as it.

Six ways to be wrong and seven predictions that can fail, named before the evidence was assembled. A model that cannot be refuted is decoration.

14. What This Paper Claims ↩

Narrow, and for that reason testable

the claim	basis
That intermembrane space protein import is a thiol-operated gate, and that two ALS genes are substrates of it	established relay chemistry plus the *CHCHD10* import-deficit finding, section 4
That TOM40 is assembled by way of that gate although not operated by it	small TIM and SAM50 biogenesis, section 5
That sulfatide loss is a primary lesion sufficient for Alzheimer-like disease	the adult-onset subtraction experiment, section 6
That a sulfur-trafficking defect alone can cause human neurodegeneration	Friedreich ataxia, section 8, where direction of causation is not in question
That the ER runs the same relay chemistry, and that *HEXA* missense alleles fail at it	ERAD targeting of the α chain and the pyrimethamine rescue, section 9
That these gates share one upstream pool and should therefore fail together	the transsulfuration architecture of section 3; predicted, not shown

The paper claims necessity at five points and sufficiency at one. That is the honest shape of a first-principles case, and it is narrow enough to be tested.

PROVENANCE, DECLARATIONS AND SOURCES

Provenance

The color index, the section architecture, the falsification convention and the page furniture of this paper are those of *The Scientific Arc of Man's Evolution from the Big Bang to the Human Genome*, *PP-2026-MASTER-01*, *September 2026*, *Licensed under CC BY-NC-ND 4.0.*, *an evidence volume by the present* author.

The biochemical content of this paper is not drawn from that volume. It is assembled from the primary and review literature listed below, and the assembly — the proposition that the thiol-gated subset of cellular entry steps is a single vulnerable class — is the contribution offered. Where a claim is this paper's own rather than the field's, it is marked as such in the text and carried with its stated falsification conditions.

Declarations

Funding. None.

Competing interests. The author declares none.

Clinical note. Nothing here is medical advice. No intervention described in this paper is approved for the prevention or treatment of any neurodegenerative disease. N-acetylcysteine and related cysteine precursors are discussed as experimental probes of the hypothesis and not as treatments.

Status. Hypothesis paper, third version. Section 9, its refusals and the sixth falsification were added in v2; the title was changed in v3 and no argument was altered with it. The central enrichment test, prediction five of section 13, has not been performed.

Sulfur Is Us

Sulfur is everywhere and in everything

PP-2026-SULFUR-US-01 v2 · 21 September 2026 · © 2026 John Allen Berger · Licensed under CC BY-NC-ND 4.0.

Twelve registers, seven operations, eighteen functional groups, and the three accounts that lose the atom. Claims are tiered throughout: [E] established science, [F] framework claim, [H] hypothesis, [O] open question.

1. The Claim, in One Paragraph

Sulfur is not one more element on a list. It is present, and performing work, at every scale of organization that exists — from the four fundamental forces that decide whether a bond can form at all, through the states of matter, the molecular clouds that predate the sun, the three kingdoms, the raw stock of the planet, the molecules of life, the load-bearing tissue of a body, the organs that sense, the tissue that thinks, the food on a plate, and the drugs in a cabinet. There is no rung of that ladder where sulfur is absent and no rung where it is idle. This paper sets out the twelve places where an account is kept of what matter is doing, shows that sulfur has an entry in every one, and then shows that the three accounts human beings actually keep — the sequence file, the nutrition label, and the clinical differential — have no line for the atom at all.
[F] The claim is falsifiable in the strongest way a claim can be. Name a scale at which sulfur performs no work, and the ladder breaks.

2. What First Principles Means Here

This paper is written from the bottom up rather than the top down. Where the literature says a nutrient, it asks what the nutrient is made of; where it says a mineral, it asks what form the atom is actually in when a cell uses it; and where a label prints a number, it asks what the number is a number of. The descent stops where the questions run out.
That method produced the finding this paper is built on, and it produced it by accident. The question that started it was an ordinary one — what does the body do with sulfur — and the answer turned out to be that nobody keeps a record of it. Not the geneticist, who has four letters and no fifth. Not the nutritionist, who has thirty-three Daily Values and none for sulfur. Not the physician, who has a differential diagnosis built on enzymes and no assay for the element those enzymes are made of. Three professions, three registers, one omission, and the same cause underneath all three.

3. The Twelve Registers

The twelve groups are not twelve categories of a single noun. That distinction matters, because the list reads as though it might be. They are twelve **scales of organization at which the same atom does different work** — and the unifying subject is not sulfur but *place*. Sulfur is simply

the one thing present at all twelve.
Each register is given below with an operational definition: a test that decides membership, so that a reader can place a term without asking the author what he meant.

Register one, the Claim. The test is whether the statement asserts scope rather than naming a thing. This register holds the thesis itself and nothing else. It is listed because a claim that sulfur is everywhere is a different kind of statement from a claim that sulfur is in keratin, and confusing the two is how an argument becomes a slogan.

Register two, the Forces. The test is whether the term names one of the four fundamental interactions, such that removing it prevents the bond from forming at all. Electromagnetism governs every covalent bond sulfur makes. The strong force fixed sulfur-32 in the oxygen-burning shells of massive stars, which is to say it decided that sulfur would exist in quantity rather than as a trace. The weak force and gravity complete the set.

Register three, the States of Matter. The test is whether the term names a bulk phase the element occupies at a stated temperature and pressure. Sulfur occupies all four. As a solid it forms S8 crown rings. As a liquid it does something almost nothing else does: heated past about 159 degrees Celsius its viscosity rises rather than falls, because the rings open and polymerize. As a gas it travels as Hydrogenhydrogen sulfide and sulfur dioxide. As plasma it sits in stars.

Register four, the Universe and the Ground. The test is whether the term names a place rather than a composition. Carbonyl sulfide, Carboncarbon monosulfide, Hydrogenhydrogen sulfide, silicon sulfide and Nitrogennitrogen sulfide are found in cold molecular clouds, made before the sun condensed. Comet 67P carries sulfur species. The Murchison meteorite delivered alkyl sulfonic acids. Volcanic fumaroles and the Lost City hydrothermal field are where the element meets the planet.

Register five, the Kingdoms. The test is whether the term names one of the three divisions of the Linnaean scheme or the rank beneath them. *Allochromatium vinosum* and the purple sulfur bacteria make a living from it. *Allium* stores it as alliin and releases it as allicin. *Brassica* stores it as glucosinolates and releases it as isothiocyanates. And native sulfur is itself a recognized mineral species, which places the element in the mineral kingdom in the strict sense as well as the loose one.

Register six, Raw Stock. The test is whether the material is extracted from the ground rather than synthesized by a cell. Gypsum and the sulfate evaporites, pyrite, the Frasch process, and sulfuric acid — which is the most-produced industrial chemical on Earth, and has been used as an index of a nation’s industrial capacity for a century.

Register seven, the Molecules of Life. The test is whether the thing is built on a carbon skeleton assembled by a living cell. Methionine and cysteine, glutathione, coenzyme A, S-adenosylmethionine, biotin, thiamine, lipoic acid, taurine, the iron–sulfur clusters, the molybdenum cofactor, and heparan sulfate. This register is the load-bearing one, for reasons section ten sets out.

Register eight, the Body, Structural. The test is whether the tissue bears load or holds shape. Keratin holds hair, nail and skin together by disulfide bonds, and the density of those bonds is why hair behaves as hair. Chondroitin and dermatan sulfate sit in cartilage, fascia, tendon and ligament.

Register nine, the Body, Sensing. The test is whether the structure transduces a signal that originated outside the body. The rhodopsin disulfide is in the eye. The olfactory receptors detect thiols at concentrations no other class of odorant approaches. And the sulfur volatiles carry a large part of what is called taste.

Register ten, the Body, Thinking. The test is whether the structure carries or modifies a signal that originated inside the body. White matter is literally sulfated — the myelin sheath contains sulfatide, a sulfated lipid, and the word *white* in white matter is a description of that sheath. HydrogenHydrogen sulfide acts as a gasotransmitter. Glutathione defends the neuron. And 2-thiouridine holds the ribosome’s reading frame.

Register eleven, What We Eat. The test is whether the substance crosses the gut wall. Allium and brassica, egg and meat as the supply of cysteine and methionine, sulfites as preservatives, and the bile salts without which fat is not absorbed at all.

Register twelve, What We Make and Do. The test is whether the thing is produced by human intention rather than by chemistry alone. The sulfa drugs, penicillin’s thiazolidine sulfur, captopril’s thiol, vulcanized rubber, gunpowder, and wool.

4. The Seven Operations

Twelve registers is a large number of places, and a reader is entitled to ask whether the list is a ladder or a pile. It is a ladder, and the reason is that across all twelve registers sulfur does only seven distinct things.

It **carries electrons reversibly**, across nine formal oxidation states from sulfide at minus two to sulfate at plus six, all of them reachable at the temperature of a body. It **makes the only reversible covalent cross-link** between side chains in the canonical twenty amino acids — the disulfide, which can be made and broken without destroying the protein that carries it. It **holds metals**, because a soft ligand binds soft metals hard, which is why iron–sulfur clusters are among the oldest cofactors there are. It **stores and transfers acyl groups** through the thioester, which gives up its energy readily where the corresponding oxygen ester holds on. It **carries methyl groups** as the sulfonium of S-adenosylmethionine. It

tunes recognition, most sharply as 2-thiouridine at position thirty-four of a transfer RNA anticodon. And it **absorbs oxidative damage**, as glutathione, as thioredoxin, and as the peroxiredoxins.

[F] Seven operations, twelve registers. Every appearance of sulfur anywhere in this paper is one of those seven, which is what makes the list a structure rather than an inventory.

5. The Eighteen Functional Groups

The standard chemical-class table lists eighteen functional groups built on sulfur. Placing them across the twelve registers produced a structural result that was not anticipated.

Functional groups do not begin until register four. Registers two and three have none, and cannot have any, because a functional group is a bonding arrangement and those registers concern the atom before it has bonded to anything. **[F]** The ladder therefore has two halves, and they are joined at the molecular cloud — where carbonyl sulfide and Carboncarbon monosulfide and Hydrogenhydrogen sulfide are the first sulfur functional groups that ever existed, made before there was a planet for them to be made on.

#	group	formula	operational test	where it works
1	Thiol	R–SH	one sulfur, one carbon, one hydrogen, no oxygen on the sulfur	cysteine, glutathione, coenzyme A; the most potent odorants known; N-acetylcysteine and captopril; ethanethiol odorized into natural gas
2	Sulfide, thioether	R–S–R′	sulfur bonded to two carbons, no oxygen, no second sulfur	methionine’s backbone; dimethyl sulfide, the largest natural sulfur flux from ocean to air; polyphenylene sulfide
3	Disulfide	R–S–S–R′	a sulfur bonded to another sulfur and to carbon	insulin’s three; antibody architecture; keratin; the permanent wave; vulcanized rubber
4	Sulfoxide	R–S(=O)–R′	one double-bonded oxygen, two carbons; stereogenic at sulfur	alliin in garlic; the onion’s lachrymatory factor; omeprazole; DMSO
5	Sulfone	R–SO2–R′	two double-bonded oxygens, two carbons	dapsone; MSM; polysulfone dialysis membranes
6	Sulfinic acid	R–SO2H	one =O, one –OH, one carbon	cysteine sulfinic acid; hypotaurine; the hyperoxidized

#	group	formula	operational test	where it works
				peroxiredoxin
7	Sulfonic acid	R–SO3H	two =O, one –OH, one carbon	taurine; Murchison’s alkyl sulfonic acids; detergents; Nafion
8	Sulfonate ester	R–SO3–R′	a sulfonic acid whose –OH is replaced by –OR′	ethyl methanesulfonate, the standard laboratory mutagen; busulfan; the mesylate and triflate leaving groups
9	Thiocyanate	R–S–C≡N	sulfur bonded to a nitrile carbon	rhodanese detoxifying cyanide; lactoperoxidase making hypothiocyanite
10	Isothiocyanate	R–N=C=S	nitrogen bonded to a carbon double-bonded to sulfur	mustard, wasabi and horseradish acting on TRPA1; sulforaphane
11	Thioketone	R–C(=S)–R′	a carbon double-bonded to sulfur, two carbon substituents	azathioprine and 6-mercaptopurine; methimazole and propylthiouracil
12	Thial	R–C(=S)–H	a carbon double-bonded to sulfur, carrying a hydrogen	the onion’s tear gas, syn-propanethial S-oxide
13	Thiocarboxylic acid	R–C(=O)–SH	a carbonyl carbon bearing a sulfhydryl	ThiS-thiocarboxylate into thiamine; MoaD-thiocarboxylate into molybdopterin
14	Carbothioic O-acid	R–C(=S)–OH	a thiocarbonyl carbon bearing a hydroxyl	no established biological role
15	Thioester	R–C(=O)–S–R′	a carbonyl bonded to a sulfur bonded to carbon	acetyl-CoA and the whole acyl economy; ubiquitin transfer; histone acetylation
16	Thionoester	R–C(=S)–O–R′	a thiocarbonyl bonded to an OR′	no established biological role
17	Dithiocarboxylic acid	R–CS2H	one carbon bearing both =S and –SH	the dithiocarbamate fungicides; vulcanization accelerators; disulfiram
18	Dithioate ester	R–C(=S)–S–R′	a thiocarbonyl bonded to a thioether sulfur	RAFT polymerization chain-transfer agents

Three findings came out of building that table, and each is checkable.

The proton pump inhibitor is three sulfur functional groups in one drug. [E] Omeprazole is a sulfoxide. It is a prodrug, activated by stomach acid into a sulfenamide, which then forms a disulfide with a cysteine of the gastric proton

pump and shuts the enzyme down. Three groups, and the target is a fourth. Esomeprazole is the single enantiomer at the sulfur atom, which means that chirality at a sulfur atom is not a textbook curiosity but a commercial fact with a patent history.

A plant's sulfur group switches a human sulfur sensor. [E] Sulforaphane is an isothiocyanate released when a brassica is damaged. It acts by modifying the reactive cysteines of KEAP1, which releases NRF2, which turns on the synthesis of glutathione. **[F]** That is register five reaching into register seven through register eleven, and every step of the path — the signal, the sensor, and the response — is made of sulfur.

One group's principal use is to damage register seven. [E] The sulfonate ester is the standard laboratory mutagen: ethyl methanesulfonate alkylates guanine and produces G:C to A:T transitions, and geneticists reach for it when they want mutations on purpose. The same group, as busulfan, conditions bone marrow before transplant. It is the only one of the eighteen whose main job is destruction, and it deserves its own treatment in any Part on mutation.

Two distinctions have to be kept. **Malathion and dimethoate are routinely called dithioates, but they are phosphorodithioates** — the dithioate sits on phosphorus, not carbon, and they are not group eighteen. And **the table is not all of sulfur chemistry**: sulfenic acids, thiosulfinates, persulfides, sulfoniums and polysulfides all do real biological work and are absent from it. Allicin is a thiosulfinate. S-adenosylmethionine is a sulfonium. The persulfide is how a cysteine desulfurase hands its sulfur to an acceptor.

Two of the eighteen — the carbothioic O-acid and the thionoester — have no established biological role at all. That is printed here rather than padded, because a table that found a use for all eighteen would be worth less than one that admits two are laboratory species.

6. Where Sulfur Is, and the Organ That Does Not Exist

Registers two through four are everywhere there is matter. Register five is everywhere there is life. Registers six, eleven and twelve are wherever there are people. Registers seven through ten are inside a body, and the way the body holds the element there is the first thing that should have raised a question.

[E] Sulfur is among the most abundant elements in the human body by mass. And the body has no organ that stores it. There is no sulfur equivalent of the liver's ferritin, no equivalent of the bone's calcium reserve, no depot that can be drawn down in a shortage and topped up in a surplus. The element is held in working molecules or it is not held at all.

[F] That absence explains the clinical picture. A shortage of iron announces itself as a falling level, because there is a level to fall. A shortage of sulfur announces itself as work not getting done, because there is no level — only function. Every

disease in section ten follows from that fact.

7. When Sulfur Is Used, and How the Timing Is Realized

The question of when an element is used is usually answered by pointing at a regulatory pathway. For sulfur the answer is stranger, and it is the strongest single result in this paper. **[E]** Peroxiredoxin oxidation–reduction cycles are a universal marker of circadian rhythm in all three domains of life. They have been demonstrated in bacteria, in archaea, and in eukaryotes including human red blood cells. They run on a twenty-four hour period. They persist without transcription of any kind, which was shown decisively in the red blood cell, a cell that has no nucleus and performs no gene expression at all. And the authors who established the conservation date the mechanism’s emergence to the Great Oxidation Event, roughly two and a half billion years ago.

The peroxiredoxin does its work with a peroxidatic cysteine. The quantity that oscillates on a twenty-four hour cycle is the oxidation state of a sulfur atom.

[F] So the oldest and most conserved timekeeper known to biology is a sulfur redox cycle, and it is dated to the same event that this corpus already dates by sulfur isotopes. That is two independent datings of one moment — one made from the rock, one made from the clock — and neither was derived from the other.

Four more timings run on sulfur, and each is established. Entry into S-phase is gated by ribonucleotide reductase, which cannot work until thioredoxin and glutaredoxin have reduced it; no deoxyribonucleotides, no replication. Progress through the cell cycle tracks the redox potential of the glutathione couple. Whether a methyl mark is written onto chromatin is decided by the ratio of S-adenosylmethionine to S-adenosylhomocysteine, which is a sulfonium accounting. And whether the ribosome holds its reading frame depends on 2-thiouridine at position thirty-four.

[F] Five timing mechanisms, five sulfur atoms. The body does not have a clock that consults sulfur. Sulfur is what the clock is made of.

8. How the Body Knows to Replace What Is Missing

This was the question that produced the sharpest finding, and the answer begins with a negative. **[E] There is no sulfur sensor.** Nothing in human physiology counts sulfur atoms. There is no counterpart to the iron regulatory proteins, which bind iron-responsive elements and titrate the metal directly. There is no counterpart to the oxygen sensing performed by the hypoxia-inducible factor system. A human body cannot report how much sulfur it holds, because nothing in it is measuring.

What exists instead is a set of sensors that detect sulfur’s *work* rather than its quantity — and every one of them is itself built out of sulfur.

KEAP1 senses by having its own reactive cysteine thiols modified; when they are, it

releases NRF2, and the cell responds by synthesizing glutathione and importing cystine. GCN2 senses uncharged transfer RNA, methionyl-tRNA among it, and signals through ATF4 to turn on transsulfuration and cystine transport. SAMTOR binds S-adenosylmethionine — a sulfonium — directly, and gates mTORC1 and with it the decision to grow. Cystathionine beta-synthase is allosterically activated by the same sulfonium, which routes homocysteine down the transsulfuration path when methyl groups are plentiful.

[F] Every sensor for sulfur is built out of sulfur. KEAP1 senses with a thiol. GCN2 senses a sulfur amino acid failing to load. SAMTOR binds a sulfonium. The body never measures the atom; it measures what the atom is doing, and infers a shortage from the work not getting done.

[E] When that inference comes too late, the failure has a name. Cystine import through SLC7A11 fails, the selenoprotein GPX4 can no longer function, lipid peroxides accumulate, and the cell dies by ferroptosis.

[F] This is the notation argument arrived at from inside the body instead of from inside a file format. Biology itself keeps no register for the sulfur atom — only registers for its functions. The four-letter alphabet is not an unusual failure of notation. It is what every account of sulfur does, including the one a cell keeps about itself.

[O] Whether a direct sulfur sensor exists and has simply not been found is open. It is worth somebody's instrument time, because at present the claim rests on an argument from silence.

9. Why Sulfur, Stated Without Design

The question is usually put as why sulfur was chosen. Nothing in this corpus is explained by design, so the question has to be taken apart into two that can be answered: why sulfur was available, and why nothing has replaced it.

[E] Why it was available. Sulfur is forged by oxygen burning in massive stars and in Type Ia supernovae. It reached the molecular clouds as carbonyl sulfide, Carboncarbon monosulfide and Hydrogenhydrogen sulfide. It was abundant on the early Earth, delivered by volcanism and by hydrothermal circulation, into an ocean that was anoxic and sulfidic for a very long stretch of its history. The element was present, in quantity, before there was anything alive to use it.

[E] Why nothing replaced it. Six properties, and no other available atom combines them.

It occupies nine formal oxidation states, from minus two to plus six, all of them reachable at biological temperature; oxygen has effectively two. Its thiol is reactive at the pH of a body — cysteine's pKa sits near 8.3 and can be tuned by the surrounding protein down toward three to five, so that a single residue can act as nucleophile, radical, metal ligand or redox switch, and the protein decides which.

It forms a reversible covalent bond: the disulfide is the only covalent cross-link between side chains in the canonical twenty, and the only one that can be undone. It is soft, and a soft ligand binds soft metals hard, which is why the iron–sulfur clusters are among the oldest cofactors in existence. Its thioester holds energy and releases it where a carbon–oxygen ester will not. And the carbon–sulfur bond is longer and weaker than the carbon–oxygen bond it stands next to in the periodic table, which means it breaks where the other holds — and that is what makes transfer chemistry possible at all.

[F] The honest answer. Sulfur did not orchestrate life. It was the most chemically versatile atom available at the moment the foundations were laid, it was built into them, and it cannot be replaced now because replacing it would mean rebuilding everything standing on top of it. The conductor was not appointed. It was the first instrument in the room, and the orchestra was written around what it could already play.

[O] Whether that centrality is chemical necessity or frozen accident is not settled here. The distinction is testable in principle — build a working redox and acyl-transfer chemistry on a different atom and count the cost — and it has not been tested.

10. Which Register Is Most Dangerous, and What It Kills With

Register seven, the Molecules of Life. Registers two through six are not alive and cannot be harmed. Registers eight through twelve are built out of register seven — the structural body, the senses, the thinking tissue, the food and the pharmacy are all assembled from its molecules. It is the only rung whose failure climbs.

The danger is not absence

The question assumes that the danger lies in sulfur being missing. It does not. **[E]** In molybdenum cofactor deficiency and in isolated sulfite oxidase deficiency the atom is abundant and arrested part-way along its journey, at sulfite. Sulfite and S-sulfocysteine accumulate. S-sulfocysteine activates NMDA receptors. Sulfite depletes intracellular ATP and impairs mitochondrial respiration. Infants present in the first days of life with severe encephalopathy and refractory seizures, and about seventy-five percent die in infancy.
[F] The unfinished atom becomes an excitotoxin. Sulfur halted one step short of its destination does not merely fail to do its work — it poisons the tissue that was waiting for it. That is a different category of danger from deficiency, and it is the worst thing the element does.

And the enzyme that finishes sulfur is held by sulfur

[E] Sulfite oxidase carries the molybdenum cofactor, in which the metal is held by a pyranopterin dithiolene — two sulfur atoms. Loss of sulfite oxidase activity alone is necessary and sufficient to produce the entire phenotype. And the sulfur atom that goes into building that

cofactor is delivered there as a thiocarboxylate, by MoaD.
[F] So sulfur holds the metal that completes sulfur's own oxidation, and sulfur delivers the sulfur that builds the holder. When that grip fails the atom cannot finish and turns on the brain. The same cofactor family gates xanthine, where a terminal sulfido ligand decides whether the purine valve opens at all. Two gates, one metal, the same element holding it in both.

The diseases

tier	disease	gene	what breaks
lethal in infancy	Molybdenum cofactor deficiency A, B, C	MOCS1, MOCS2, GPHN	sulfite oxidase, xanthine dehydrogenase, aldehyde oxidase and mARC lost together
lethal in infancy	Isolated sulfite oxidase deficiency	SUOX	clinically identical; uric acid stays normal, which is how the two are told apart
childhood	Multiple sulfatase deficiency	SUMF1	every sulfatase in the body fails at once
childhood	Metachromatic leukodystrophy	ARSA	sulfatide cannot be degraded and myelin is destroyed
childhood	Friedreich ataxia	FXN	iron–sulfur cluster assembly
childhood	Acute infantile liver failure	TRMU	2-thiouridine at tRNA position 34
childhood	Cardiomyopathy with lactic acidosis	MTO1	the same tRNA thiolation
childhood	Glutathione synthetase deficiency	GSS	5-oxoprolinuria, hemolysis, neurological damage
lifelong	Classical homocystinuria	CBS	dislocated lens, marfanoid habitus, osteoporosis, thromboembolism
lifelong	Hunter, Sanfilippo, Morquio	IDS, SGSH, GALNS	sulfated glycosaminoglycans accumulate
lifelong	Diastrophic dysplasia	SLC26A2	the sulfate transporter itself
lifelong	X-linked ichthyosis	STS	steroid sulfatase, and the skin
lifelong	Taurine transporter deficiency	SLC6A6	retinal degeneration and cardiomyopathy

[E] Type A molybdenum cofactor deficiency now has a treatment. Fosdenopterin reduced the risk of death by eighty-two percent against untreated controls, and it has to be started fast.
[E] Commoner than every disorder in the table put together: paracetamol overdose kills by depleting glutathione until the reactive metabolite attacks the hepatocyte. The antidote is N-acetylcysteine. It is one of the clearest cases in medicine of an element being handed back directly.

Every failure surfaces somewhere above

A failure in register seven does not present as a register seven disease. It presents wherever the molecule was doing its work. Sulfatide that cannot be degraded presents as white matter disease, in register ten. Failed tRNA thiolation presents as liver failure and cardiomyopathy, in register eight. Accumulated sulfated glycosaminoglycans present in cartilage, fascia, tendon and bone. Failed steroid sulfatase presents as skin. Homocysteine that cannot cross to cysteine presents as a dislocated lens and a thrombosis. Failed taurine transport presents as a degenerating retina. And sulfite that cannot reach sulfate presents as the whole brain, within days.
[F] Not one of them presents as sulfur deficiency, because no clinic can diagnose that. There is no assay, no reference range, and no line on any panel. The diagnosis is always made downstream, from the wreckage.

11. The Three Registers That Lose the Atom

[E] Thirty-three nutrients carry an established Daily Value. Fourteen are mandatory on the Nutrition Facts panel. Sulfur is on neither list. It has no Daily Value, no Estimated Average Requirement, no Recommended Dietary Allowance, no Adequate Intake, and no Tolerable Upper Intake Level.
The National Academies state the reason in their own words: neither an Estimated Average Requirement, and thus no Recommended Dietary Allowance, nor an Adequate Intake for sulfate is established, because sulfate requirements are met when intakes include recommended levels of the sulfur amino acids.

[F] That reason deserves reading twice. The official ground for sulfur having no number of its own is that the body obtains it already built into methionine and cysteine — as a molecule, not as an element. The reasoning is sound. It is also, stated by the body that sets the standards, the premise this corpus argues from: the atom is compounded before it is used, so the register records the compound and loses the atom.

[E] Selenium has a Daily Value. Sulfur does not. The two sit one row apart in group sixteen, and the lighter, more abundant, more chemically active partner is the one with no number.

[F] Three registers, one omission. The sequence file records A, T, G, C and U, and loses every modification, sulfur among them. The nutrition label records what was swallowed, and loses the atom because it was swallowed inside a molecule. The clinical differential records the enzyme that failed, and loses the element that enzyme was built from. The cause is the same in all three cases: **the atom is always inside a molecule when anyone looks.**

12. What Would Show This Is Wrong

- Name a register at which sulfur performs none of the seven operations, and the ladder in section four fails.
- Demonstrate a human sensor that titrates sulfur or sulfide directly, rather

than sensing a thiol, an uncharged tRNA or a sulfonium, and section eight fails outright.

- Produce a Daily Value, an Estimated Average Requirement, a Recommended Dietary Allowance, an Adequate Intake or a Tolerable Upper Intake Level for sulfur as sulfur, in any national reference standard, and the central claim of section eleven fails.
- Produce a clinical assay with a reference range for sulfur status in a human being, and the closing claim of section ten fails.
- Show a storage organ or dedicated reserve pool for sulfur in the human body, and section six fails.
- Show that sulfur scarcity produces faster or higher mortality than sulfur arrested at sulfite, and the central claim of section ten is inverted.
- Show peroxiredoxin oxidation rhythms absent from a domain of life where they have been reported present, and section seven narrows.
- Show that an eighth distinct operation is needed to account for any appearance of sulfur in section five, and the count of seven is wrong.
- Name a nineteenth sulfur functional group in general use that section five omits, and the table is incomplete.

13. What This Paper Refuses

It does not claim sulfur is unique in being everywhere. Carbon, hydrogen, oxygen and nitrogen are everywhere too. It claims that sulfur is the one of those that the registers do not record.
It does not claim the nutrition labels are wrong. They are correct about what they measure, and the reasoning for leaving sulfur out is explicit and defensible. It does not claim that a sulfur Recommended Dietary Allowance ought to be set; that is a question for the bodies that set them and this paper does not answer it.

It does not claim that sulfur deficiency is a common or a commonly missed diagnosis in the general population. There is no evidence for that and none is offered here.

It does not claim that the peroxiredoxin rhythm causes circadian timing rather than reporting it. That dispute is real, it is live, and it is not settled here.

It does not claim that sulfur was selected for its role. It claims only that sulfur was there first, and that nothing has been able to take the job from it since.

And it does not claim the eighteen functional groups exhaust sulfur chemistry. Two of the eighteen earn no biological entry at all, and five further classes that do real work are missing from the source table entirely.

Tay-Sachs Disease

One Name, Four Failures, and the Limits of a Four-Letter Alphabet

PP-2026-TSD-01 v1 · Deep Dive 1, Consolidated · Dr. John Allen Berger, PhD · NovagonDNA

Color Key

Terms and individual nucleotide letters are colored to the Berger index throughout this paper.

color	element	what carries it here
yellow	sulfur	sulfur, thiol, disulfide, cysteine, thiolate, every sulfur compound
orange	oxygen	inosine, hypoxanthine, and the base letter I
red	hydrogen	adenine, adenosine, and the base letter A
green	nitrogen	guanine, guanosine, and the base letter G
blue	carbon	cytosine, cytidine, and the base letter C
purple	phosphorus	uracil, uridine, phosphate, and the base letters U and T
indigo	selenium	xanthine, orotate, and their nucleosides

Thymine has no element of its own in the index. It is treated here as 5-methyluracil and carries uracil's purple, so that the two pyrimidines that occupy the same position in DNA and RNA read as one family. Reassign it if you want thymine separated.

Part I. The Object

1. What This Paper Establishes

Tay-Sachs disease is usually described in one sentence: a mutation in HEXA abolishes beta-hexosaminidase A, GM2 ganglioside accumulates in neurons, and the child dies before school age. Every clause of that sentence is true, and together they conceal the disease rather than describe it.

This paper sets out three findings that only appear when the molecular, the recombinational and the metabolic accounts are placed in a single frame.

The first finding is that the origin of an allele, the editability of an allele, and the severity it produces are three independent axes. They do not predict one another. The allele responsible for roughly eighty percent of the disease in the population where it is commonest cannot be reached by any base editor of any

polarity. The alleles that Alu elements create have removed the target altogether. The single allele that has been corrected in a living brain is the one whose defect is not really a coding defect. And there are alleles that look pathogenic by sequence, test abnormal by enzyme assay, and produce a person who is entirely well. Sorting the alleles along all three axes at once is the organizing act of this paper.

The second finding is that the two base editors, the cytosine editor and the adenine editor, are one principle applied twice, and that the principle is not what it is usually said to be. Neither editor writes a DNA base. Both write a base that belongs in RNA and then manage the cell's attempt to remove it. What the edit finally becomes is decided by repair, not by chemistry.

The third finding is that the quantity which governs the entire clinical spectrum, residual enzyme activity, is not a property of the sequence. It is a folding yield, set by disulfide chemistry in the endoplasmic reticulum. The number that separates death at three years from a diagnosis in middle age is a sulfur number, and it is not in the gene, not in the four letters, and not on any label.

Taken together these say that Tay-Sachs is a genetic condition and a metabolic disease, that those are two different objects, and that the language of medicine routinely runs them together.

2. The Gene, the Enzyme, and the Reaction

HEXA sits on chromosome 15 and encodes the alpha chain of beta-hexosaminidase. The enzyme that degrades GM2 ganglioside, beta-hexosaminidase A, is a heterodimer of that alpha chain with a beta chain encoded by HEXB. The beta-beta homodimer, hexosaminidase B, exists too, and it cannot do this job.

The reaction requires a third protein. GM2 ganglioside sits in the lysosomal membrane with its oligosaccharide head group too close to the bilayer for the enzyme to reach. The GM2 activator protein, encoded by GM2A, lifts the single ganglioside molecule out of the membrane and presents it to the enzyme. Without the activator, the enzyme is present, correctly folded, catalytically competent, and unable to find its substrate.

So the reaction has three protein requirements and a fourth, structural requirement that is rarely counted: the alpha chain must fold correctly, which means forming three specific disulfide bonds, at residues 58 to 104, 277 to 328, and 505 to 522. The catalytic proton donor, Glu323, sits inside the second of those loops. A chain that does not form these bonds is not a weak enzyme. It is destroyed at the endoplasmic reticulum and never reaches the lysosome at all.

Four requirements, three genes, and one bond pattern that no gene specifies directly.

3. The Allele Matrix

This table is the spine of the paper. Everything that follows is an expansion of one of its columns.

allele	how it arose	Alu involved	cytosine editor	adenine editor	residual activity	phenotype
c.1274_1277dup, p.Tyr427Ilefs*5	four-base TATC duplication in exon 11	no	no, indels are invisible	no, indels are invisible	null	acute infantile
c.1421+1G>C	transversion at the intron 12 splice donor	no	only as a C-to-G editor, with the safety catch removed	no	null	acute infantile
c.1073+1G>A	splice donor transition	no	no	in principle, untested	null	acute infantile

p.Arg247Trp, p.Arg249Trp	pseudodeficiency missense	no	not indicated	not indicated	normal against natural substrate	none, healthy
GM2A loss, the AB variant	a different gene entirely	ADAR edits this transcript's Alu-bearing 3' untranslated region	not applicable	not applicable	hexosaminidase A normal	acute infantile

Read the table across and the independence of the three axes becomes visible. The commonest allele is uneditable. The Alu-made alleles have no target left. The editable allele is the mild one. The pathogenic-looking alleles at the bottom make a healthy person. And the last row has a normal HEXA gene, a normal enzyme, and a dead child.

Part II. How the Alleles Arise

4. Four Classes of Lesion, Not One

The alleles above fall into four mechanistic classes, and the classes matter more than the individual variants because each class fails in a different place in the pathway from gene to functioning enzyme.

Frame failure. Four bases, TATC, inserted into exon 11 shift the reading frame and place a stop codon five codons downstream. This is c.1274_1277dup, which

accounts for approximately eighty percent of pathogenic HEXA alleles in the Ashkenazi Jewish population and is carried on about 1.3 percent of Ashkenazi chromosomes. Transcription proceeds. Translation proceeds. A truncated, useless chain results, and the message itself is a candidate for nonsense-mediated decay.

Splice failure. The intron 12 donor variant c.1421+1G>C destroys the invariant GT of the splice donor. The message is mis-spliced. The gene is intact and readable, and no correct protein emerges from it.

Fold failure. The missense alleles, including the late-onset c.805G>A and every one of the cysteine-altering variants, produce a full-length chain of the correct length with one residue changed. The chain is made. It then fails to fold, and is degraded by the endoplasmic-reticulum associated degradation machinery before it can be trafficked to the lysosome. Nothing is wrong with the reading of the gene.

Presence failure. The large deletions have removed the sequence. There is no gene to read.

The general rule stated in the clinical literature follows directly: two null alleles give the acute infantile form, one null and one missense gives the subacute juvenile form, and two missense alleles give the milder late-onset form. That rule is usually presented as a genotype-phenotype correlation. It is better understood as an arithmetic statement about how much enzyme survives, which is the subject of Part IV.

5. Alu at Ten Percent of the Genome, and What It Actually Does Here

There are on the order of 1.1 million Alu copies in the human genome, each roughly 280 to 300 bases long. That is close to 300 million bases of Alu, about ten to eleven percent of the 3.1 billion base genome, making Alu the most abundant repeat family we carry. A new Alu inserts somewhere in the population roughly once every twenty births.

Something present at a tenth of the genome is not inert, and it is not inert in this disease. But it acts here by a mechanism that is frequently confused with a different one, so the distinction has to be made precisely.

Alu damages HEXA by recombination, not by editing. Alu copies are similar enough to one another that two of them in different introns of the same gene can mispair during recombination. Everything between them is then excised. This is non-allelic homologous recombination, and across the human and chimpanzee lineages it accounts for on the order of five hundred fixed deletion events in each lineage since the split six million years ago. It causes considerably more human disease than Alu insertion does.

In HEXA it has been caught directly. A reported patient carries a homozygous 4.6 kilobase deletion removing exons 6 through 10. The breakpoints lie in an AluSz6 element in intron 5 and an AluJo element in intron 10, two copies sharing seventy-six percent identity. The deletion runs from 576 bases upstream of exon 6 to 475 bases downstream of exon 10, removing 192 amino acids of the alpha chain

including catalytic sequence. The phenotype is ordinary infantile Tay-Sachs disease.

The same mechanism dominates the sister disease. In HEXB, an Alu-type deletion removing the five prime end of the gene is the single most common Sandhoff allele. And the French Canadian Tay-Sachs allele is a 7.6 kilobase deletion carrying away the HEXA promoter and exon 1.

Where Alu acts by this route, the consequence for therapy is absolute. There is no sequence left to correct. Base editing, prime editing and any other sequence-level intervention are all equally irrelevant to a gene that has been physically removed.

6. Where Alu and ADAR Genuinely Meet This Pathway

ADAR, adenosine deaminase acting on RNA, converts adenosine to inosine in double-stranded RNA. Inosine is read as guanosine by the ribosome and the spliceosome, so an A-to-I edit is a functional A-to-G change made after transcription and never written into the gene.
The link to Alu is close to total. More than ninety-nine percent of known human A-to-I editing events lie inside Alu elements. The reason is structural: when two Alu copies land in the same pre-messenger RNA in opposite orientations they base-pair with one another and form a long, stable double-stranded hairpin, which is exactly what ADAR recognizes. Approximately 1.6 million sites have been catalogued directly and the true figure is estimated above one hundred million. Virtually every adenosine inside a double-stranded Alu is edited in some transcript somewhere, usually at low frequency.

This has one documented point of contact with the GM2 degradation pathway, and it is not in HEXA.

ADAR1 edits the three prime untranslated region of **GM2A** at Alu-derived sequence, at two sites, and that editing raises GM2A expression at both RNA and protein level. The work was done in glioblastoma stem cells, where disrupting ADAR1, GM2A, HEXA or HEXB each produced the same failure of ganglioside delivery to the lysosome.

The significance for Tay-Sachs is indirect and considerable. GM2A is the activator protein. Loss of it causes the AB variant of GM2 gangliosidosis, in which infants appear normal at birth, weaken between four and twelve months, develop the cherry-red macula, seize, regress and die at two to three years, with a clinical course nearly identical to infantile Tay-Sachs and one laboratory difference: **hexosaminidase A activity is normal.** Roughly thirteen infantile cases have ever been reported.

So Alu-dependent A-to-I editing does not cause Tay-Sachs by damaging HEXA. It sets the expression level of the one other protein without which the HEXA enzyme cannot perform its reaction, and the disease that follows from losing that protein is, to the clinic, Tay-Sachs. Alu and ADAR reach the Tay-Sachs phenotype by standing one gene to the side of the Tay-Sachs gene.

7. ADAT Is Not a Cause, It Is the Ancestor of the Cure

ADAT is a different enzyme family with a different substrate and should not be merged with ADAR. ADAT1 deaminates A37 in transfer RNA for alanine. The ADAT2 and ADAT3 heterodimer deaminates A34, the wobble base of the anticodon, in seven to eight transfer RNAs, among them those for alanine, arginine, isoleucine, leucine, proline, serine, threonine and valine. ADAT3 is a catalytically dead paralog serving as the recognition subunit; ADAT2 carries the active site. Inosine at position 34 allows one transfer RNA to read three codons rather than one. There is no Alu in a transfer RNA. ADAT does not edit messages and does not edit HEXA.

A kinship is nonetheless worth recording. Alu is descended from 7SL RNA and is transcribed by RNA polymerase III from an internal promoter, the same architecture used by transfer RNA genes. Alu is, by ancestry and by transcriptional machinery, a transfer-RNA-like element that colonized the introns of protein-coding genes. The repeat that deletes HEXA and the transcript that ADAT modifies come from the same side of the transcription apparatus.

And ADAT enters this disease a second time, on the therapeutic side, which is the subject of Part III.

Part III. What Can Be Written Back

8. The Cytosine Editor, and Why It Has No Target in HEXA

A cytosine base editor fuses a cytidine deaminase, in the original designs the rat APOBEC-1 enzyme whose day job is C-to-U editing of apolipoprotein B messenger RNA, to a Cas9 nickase that presents a short window of single-stranded DNA. The deaminase converts cytosine to uracil. Replication and repair then read the uracil as thymine, and the base pair changes from C:G to T:A.
Set that reaction against the alleles.

The four-base duplication is an insertion. There is no cytosine to deaminate and no mechanism by which deamination could remove four bases. Base editors of every class are blind to insertions and deletions.

The intron 12 variant c.1421+1G>C requires restoring a C to a G, which is a transversion. The standard cytosine editor makes transitions only.

The late-onset allele c.805G>A requires restoring an A to a G. That is the adenine editor’s reaction. The cytosine editor runs in the opposite direction, and on the antisense strand it would convert C to T, which is also the wrong direction.

The large deletions have no sequence to act on.

The cytosine editor does not malfunction in HEXA. It is pointed the wrong way. That distinction matters more than the chemistry. A tool that fails loudly gets fixed. A tool that performs flawlessly on the wrong target gets funded.

9. The Bystander Hazard at Proline 268

The cytosine editor is not merely useless at the late-onset locus. It is dangerous there, and the local sequence shows why.

When an adenine editor was used at c.805, it produced a bystander edit at the adjacent adenine c.804, converting the proline codon at position 268 from CCA to CCG. That is synonymous and cost nothing. From that observation the local sense strand can be written out:

position	c.802	c.803	c.804	c.805
normal base	C	C	A	G
base in the late-onset allele	C	C	A	A
codon	Pro268	Pro268	Pro268	Gly269, mutated to Ser269

Any editing window wide enough to reach c.805 contains c.802 and c.803. Those two cytosines are the proline codon, and a cytosine deaminase has no mechanism for choosing among the cytosines inside its window. Deaminate one and CCA becomes TCA, serine. Deaminate the other and it becomes CTA, leucine. Deaminate both and it is TTA, leucine again. The harmless bystander of the adenine editor becomes a missense bystander for the cytosine editor, in a protein already known to fail by misfolding.

Position 268 is not a neutral address. It lies eight residues from Cys277, the first cysteine of the 277 to 328 disulfide bond, and the loop that bond closes contains Glu323, the catalytic proton donor. The cytosine editor cannot reach the mutation, and in reaching for it can break the residue next door, inside the loop that holds the active site together.

10. The Adenine Editor, Which Is a Domesticated Transfer RNA Enzyme

The one Tay-Sachs allele corrected in a living animal is c.805G>A, and the tool was an adenine base editor.

The deaminase inside that editor is TadA, the Escherichia coli transfer RNA adenosine deaminase. TadA is the bacterial counterpart of ADAT2. Its natural function is the same function ADAT2 performs in us: making inosine at the wobble position of a transfer RNA. Directed evolution taught it to accept single-stranded DNA presented by a Cas9 nickase.

In patient fibroblasts an ABE7.10 variant restored the sequence at roughly eighty percent. Delivered to mice as a split-intein pair of AAV-PHP.eB vectors by retro-orbital injection, it reached a mean of 9.3 percent correction in brain, 11.8 percent in spinal cord and 1.1 percent in liver, and that was sufficient to move the disease. Two bystanders came with it: the synonymous c.804 A-to-G described above, and an intronic edit at c.805-3.

So ADAT is not a cause of Tay-Sachs. ADAT is the instrument that treats it. A transfer RNA wobble enzyme, older than the disease and older than the gene’s introns, was repurposed into the only agent that has so far reversed a Tay-Sachs allele in a brain.

11. The Two Editors Are One Principle Applied Twice

Placed side by side the two editors stop looking like two tools.

	cytosine base editor	adenine base editor
enzyme and its natural role	APOBEC-1, a messenger RNA C-to-U editor of apolipoprotein B	TadA, a transfer RNA A-to-I wobble editor, the bacterial ADAT2
reaction performed	cytosine to uracil	adenine to inosine
what is therefore written into DNA	uracil, a base that belongs in RNA	inosine, a base that belongs in RNA
how the machinery reads it	uracil read as thymine	inosine read as guanine
how the cell attacks it	uracil-DNA glycosylase excises the uracil	alkyladenine glycosylase excises hypoxanthine
the safety catch	UGI, a bacteriophage protein bolted on to block the glycosylase	none required, the repair is slower than replication
releasing the catch deliberately	drop UGI and the C-to-G transversion editor appears	fuse the glycosylase and the A-to-Y transversion editor appears
catalytic zinc	one histidine and two cysteines, His61, Cys93 and Cys96 in rat APOBEC-1, with Glu63 as proton donor	one histidine and two cysteines, His57 and the cysteine pair of the E-P-C-V-M-C motif in TadA, with Glu59 as proton donor
what it can do in HEXA	correct none of the common alleles, and endanger Pro268 in the attempt	corrected c.805G>A in mouse brain and spinal cord

Read the middle rows. **Neither editor writes a DNA base.** Both write an RNA base into DNA and then negotiate with the repair system about what it becomes. Uracil becomes thymine only because a phage protein is holding the glycosylase off. Inosine becomes guanine only because its glycosylase is slower than replication. Remove the restraint in either case and the same chemistry yields a transversion instead of a transition, which is not a failure mode but the mechanism of a second class of editor.

The consequence is general and it is not specific to this gene. Editing efficiency and editing purity are not properties of the editor. They are properties of the editor and the cell’s repair state together, and that is true in the same way for both polarities.

12. What the Editors Reveal When the Alleles Are Sorted by Them

Sorting the alleles by which editor can touch them produces a result that neither editor was designed to produce.

The allele responsible for the great majority of the disease burden in the Ashkenazi Jewish population is an indel, invisible to both. The alleles created by Alu recombination have deleted their own target. The splice allele needs a transversion, available only by removing the cytosine editor’s safety catch. That leaves the missense alleles as the entire editable fraction.

And the missense alleles are precisely the alleles whose defect is not a coding defect. The message is correct in length, the ribosome reads it correctly, the chain is synthesized in full, and the protein is then destroyed because it did not fold. Correcting one base restores a sequence that was already being read correctly.

The alleles that base editing can fix are the alleles whose problem was never really the letters. That sentence is the joint conclusion of both editors, and

neither could have produced it alone.

Part IV. Why the Sequence Is Not the Disease

13. The Carrier Settles the Question Immediately

A Tay-Sachs carrier has one destroyed HEXA allele and roughly half-normal hexosaminidase A. Half the coding information at that locus is gone, and the carrier is well for life, with no storage, no neuropathology and no reduction in lifespan.

If the disease were a disease of sequence, half the sequence destroyed would be half a disease. It is not a disease at all. Whatever Tay-Sachs is, it is not the presence of a mutation.

14. The Threshold Is a Rate Equation, and It Sits Near Ten Percent

Conzelmann and Sandhoff measured the relationship directly, in hexosaminidase A and again in arylsulfatase A. Substrate degradation rises steeply with residual enzyme activity and reaches the normal control rate at approximately **ten to fifteen percent of normal activity.** Above that line cells clear their substrate at the normal rate and nothing accumulates. Below it, influx exceeds capacity and storage begins, at a rate set by the size of the shortfall.

This is the governing relation of the disease and it is a rate equation, not a sequence. It accounts for the healthy carrier at fifty percent. It accounts for the observation that small differences in residual activity produce large differences in age of onset. And it converts the genotype-phenotype rule of Part II into arithmetic: two null alleles leave nothing, one null and one missense leaves a small fraction, two missense alleles leave a few percent, and where that number falls relative to the threshold is the clinical picture.

Genes do not have percentage points. Enzymes do.

15. The Pseudodeficiency Alleles Put Sequence and Metabolism in Direct Conflict

Two HEXA alleles, p.Arg247Trp and p.Arg249Trp, produce an enzyme that cannot cleave the synthetic substrate used in the clinical assay but cleaves the natural substrate, GM2 ganglioside, perfectly well. The genotype is abnormal. The enzyme assay is abnormal. The person is healthy and remains so.

This is a clean experiment that biology ran without being asked. When the sequence indicates disease and the metabolism indicates no disease, the patient follows the metabolism. These alleles exist in clinical practice chiefly as a source of false positives in carrier screening, which is exactly the point: a program built on sequence can be wrong about the thing that matters.

16. Three Genes, One Disease

Break HEXA and the result is Tay-Sachs disease. Break HEXB and the result is Sandhoff

disease. Break GM2A and the result is the AB variant, in which hexosaminidase A activity is entirely normal and the infant dies on the same schedule with the same findings.
Three genes, three quite different molecular stories, one clinical disease. The entity is not defined by a gene. It is defined by a reaction that fails to occur. That is a metabolic definition, and it is the only definition that covers all three.

17. The Same Genotype Kills Some Cells and Spares Others

Every cell in a Tay-Sachs child carries the same two alleles. Fibroblasts store GM2 and live. Neurons store GM2 and die, distended by membranous cytoplasmic bodies until they are lost.
Gangliosides are the principal glycolipids of the neuronal plasma membrane, so the neuron is where GM2 throughput is greatest and where the shortfall between influx and capacity is largest. Selective vulnerability in a uniformly mutated body cannot be a property of the mutation. It is a property of flux. The tissue that fails is the tissue with the highest substrate load, which is what the rate equation predicts.

18. The Two Therapies That Ignore the Gene, and Why Their Failures Confirm the Model

Two strategies attack the metabolism without touching the sequence. Both have been taken into patients, and neither has succeeded.
Pharmacological chaperone. Pyrimethamine stabilizes the folding of mutant hexosaminidase A. In an open-label extended study in late-onset Tay-Sachs, given cyclically at an average of about 2.7 milligrams daily, dosed as 6.25 milligrams three times a week and guided by lymphocyte enzyme activity over a mean of roughly eighty-three weeks, it raised leukocyte hexosaminidase A by a mean of 2.24-fold over baseline. Against the threshold this is less impressive than it sounds: it brought activity to approximately 2.2 percent of normal, short of the ten percent required. An initial rise was followed by a second phase of decline and inhibition, which is what forced the cyclic schedule.

Substrate reduction. If capacity cannot be raised, lower the influx so that the existing residual enzyme becomes sufficient. This is the logic of glucosylceramide synthase inhibition. Venglustat was taken into the phase 3 AMETHIST program in GM2 gangliosidoses and **discontinued on 25 April 2024 for absence of positive trends on clinical endpoints.**

Neither worked, and that should be stated plainly. It does not weaken the metabolic reading of the disease; it confirms it, because the metabolic model predicts both failures in advance. Pyrimethamine raised capacity by an amount that does not reach the threshold. Substrate reduction lowers the rate of new accumulation but removes nothing already stored and returns no neuron already lost, so a rate intervention arrives too late once the integral has been taken. A model that predicts the failure of its own therapies is a model that is working.

19. Where Somatic Genetics Actually Belongs

Tay-Sachs is not a somatic genetic disease. A somatic disease arises from a mutation acquired in a body cell after conception, as cancer does. This one is inherited, autosomal recessive, present in every cell from the fertilized egg. There is no somatic event in its causation.
Somatic genetics is, however, how the disease is now being treated. Correction of 9.3 percent of brain and 11.8 percent of spinal cord is a deliberately manufactured **somatic mosaic**: a body in which a minority of cells carry the corrected sequence. It moved the disease anyway, and the threshold explains why a minority correction can suffice. Lysosomal enzymes are secreted and taken up again by neighboring cells through the mannose-6-phosphate receptor, so a corrected cell can supply enzyme to uncorrected cells around it. This cross-correction is the principle underlying enzyme replacement and gene therapy in lysosomal disease generally.

The classification is therefore three-part, and each part answers a different question.

the question asked	the useful answer	what it provides
Who is at risk?	genetic	carrier screening, prenatal diagnosis, recurrence risk
Why are they ill, how ill, and where in the body?	metabolic	residual activity, substrate flux, the ten percent threshold, tissue selectivity
What can be done about it?	somatic	a manufactured mosaic of corrected cells, plus cross-correction to their neighbors

Part V. The Sulfur Layer

20. Every Deaminase in This Story Is a Cysteine-Zinc Enzyme

Collect the enzymes that have appeared: APOBEC-1 in the cytosine editor, TadA in the adenine editor, ADAT2 at the transfer RNA wobble, ADAR on Alu hairpins. All four belong to the zinc-dependent deaminase superfamily, and the signature of that superfamily is a zinc atom held by **one histidine and two cysteine thiolates**, with a glutamate shuttling the proton.
In rat APOBEC-1 the site is His61, Cys93 and Cys96, with Glu63 as the proton donor; the motif reads S-P-C-G-E-C. In Escherichia coli TadA it is His57 with the cysteine pair of the E-P-C-V-M-C motif, and Glu59 as the proton donor. Human ADAR2 carries the same architecture with Glu396 as its proton donor, and additionally buries one molecule of inositol hexakisphosphate per subunit, without which it will not edit.

The zinc polarizes a water molecule into the hydroxide that attacks carbon 4 of the base. Remove the two sulfurs and there is no zinc, no hydroxide and no deamination of any kind, natural or engineered. **The entire apparatus of A-to-I and C-to-U chemistry, in the cell and in the laboratory, rests on pairs of cysteine sulfur atoms.** Sulfur appears nowhere in the name of the technology,

nowhere in the four-letter alphabet it edits and nowhere in the way any of it is taught.

21. The Target Enzyme Is Held Together by Disulfide Bonds

The alpha chain of beta-hexosaminidase A carries three disulfide bonds: 58 to 104, 277 to 328 and 505 to 522. The catalytic proton donor, Glu323, sits inside the 277 to 328 loop, five residues from Cys328. The active site of the enzyme is held in register by a sulfur bond.

Several pathogenic alleles are cysteine chemistry outright. Among the annotated variants of this chain, p.Arg178Cys, p.Trp420Cys, p.Trp474Cys, p.Arg499Cys and p.Arg504Cys each introduce a cysteine that does not belong, and p.Cys458Tyr removes one that does. **p.Arg504Cys is the sharpest case:** it places a free thiol immediately beside Cys505, which is one half of the 505 to 522 pair. A free thiol adjacent to a native disulfide is the standard recipe for disulfide scrambling. The scrambled chain is then routed to endoplasmic-reticulum associated degradation rather than to the lysosome. The gene is transcribed, the message is translated, and the protein is destroyed before it reaches the place where it works.

22. Residual Activity Is a Folding Yield, Which Makes It a Sulfur Number

Part IV established that residual enzyme activity governs the entire clinical spectrum. Part V completes the statement by naming what residual activity actually is.

For the missense alleles, and those are the alleles that produce every phenotype milder than acute infantile, residual activity is not a measure of how fast each enzyme molecule works. It is the **fraction of translated chains that fold correctly, form the three disulfide bonds in the correct pairing, survive quality control, and reach the lysosome** instead of being destroyed at the endoplasmic reticulum. That fraction is set by thiol-disulfide chemistry and by the redox buffer of the compartment in which it occurs.

Pyrimethamine is the proof. It changes no base in the gene and no amino acid in the protein. It stabilizes the fold, and enzyme activity rises 2.24-fold. A drug that touches only the folding step moves the governing quantity of the disease. The quantity is therefore a folding quantity.

The number that decides whether a child lives to three or to sixty is a sulfur number, and it appears in no gene, in none of the four letters, and on no label.

23. The Wobble: Inosine or Sulfur, at the Same Address

One further observation belongs here because it shows the same choice being made at the other end of the system.

ADAT2 and ADAT3 place inosine at position 34, the wobble base of the anticodon, so that one transfer RNA can read three codons. For a different set of transfer RNAs the cell solves the same decoding problem at the same position by a

completely different route: it builds **2-thiouridine**, by a sulfur relay that begins with a cysteine desulfurase stripping sulfur from free cysteine and passes it along a chain of sulfur carrier proteins to the wobble base.

Position 34 is solved either by an oxygen-path modification, deamination to inosine, or by a sulfur-path modification, thiolation to 2-thiouridine. Two atoms, one address, the same purpose. The four-letter alphabet contains neither of them.

Part VI. Conclusions

24. The Three-Axis Finding, Stated Plainly

Origin, editability and severity are independent.
The allele that causes most of the disease in the population where it is commonest arose by simple duplication, is untouchable by either base editor, and is a complete null. The alleles that Alu built by recombination are equally null and have removed their own target. The one allele corrected in a living brain is a transition, editable, and the mildest of the set. Alleles that look pathogenic by sequence and abnormal by assay produce people who are entirely well. And a normal HEXA gene with a normal enzyme produces a dead infant when the activator protein is missing.

No one of these three axes predicts either of the others. A reader given only a list of mutations would predict none of it.

25. A Genetic Condition and a Metabolic Disease

These are two different objects and they should be named separately.
The condition is present at conception, is inherited, is fully penetrant at a given genotype, never changes, and is what carrier screening detects.

The disease begins months after birth, when the ratio of substrate influx to degradation capacity crosses a threshold near ten percent, and it progresses at a rate set by how far below that line the ratio sits. It is expressed in the tissue with the greatest substrate load. It is treated, so far as anything treats it, by changing quantities.

The mutation is the cause. The metabolism is the disease. Somatic genetics is the treatment, and it works not by achieving completeness but by pushing enough capacity above the line and letting cross-correction distribute the surplus.

26. What the Alphabet Cannot Carry

This is where every strand of the paper arrives.
The four-letter alphabet, ATGC in DNA and AUGC in RNA, describes all four classes of HEXA lesion exactly and describes the corrected sequence exactly. It cannot express any of the following, each of which has been load-bearing

somewhere above:

- that the zinc in every editing enzyme, natural or engineered, is held by two cysteine thiolates
- that uracil and inosine, both legitimate letters in RNA, are lesions in DNA, actively hunted and removed, and that both base editors depend on suppressing that removal
- that what an edit becomes is decided by repair state rather than by chemistry
- that the corrected protein must then form three specific disulfide bonds, in the correct pairing, in a specific compartment, at a specific redox potential
- that a sequence bearing one extra cysteine yields a destroyed protein
- that the disease is continuous while the sequence is binary, and lives entirely in units the sequence does not have: nanomoles per milligram per hour, substrate flux, a threshold near ten percent, an age of onset sliding from six months to forty years across a few percentage points
- that a genotype can read as pathogenic and produce a healthy person
- that three different genes produce one disease, and one intact gene produces it too

Sequence has no units, and this disease lives entirely in the units. That is the same boundary as the one which says a leg cannot be made from a DNA sequence, met here at the scale of a single lysosomal enzyme, where it can be measured rather than argued.

27. What Would Refute This

the claim	what would refute it
Origin, editability and severity are independent axes	A demonstration that any one of the three reliably predicts another across the full allele set
The cytosine editor has no target among the common HEXA alleles	Correction of any common allele by C-to-T transition chemistry, or a fifth common allele that is a G:C to A:T reversal
A cytosine editor is unsafe at the late-onset locus because of Pro268	Deep sequencing of a cytosine editor at that window showing the proline codon untouched at useful efficiency
Both editors write an RNA base into DNA and depend on repair suppression	A base editor whose product is a canonical DNA base at the moment of catalysis, requiring no glycosylase management
Alu enters HEXA pathology by recombination rather than by editing	Identification of an ADAR editing site within the HEXA transcript that measurably alters its splicing, stability or coding in human neurons
ADAR's contact with this pathway is through GM2A, not HEXA	Evidence that ADAR1 loss alters HEXA transcript or hexosaminidase A activity independently of GM2A
Severity tracks residual activity rather than genotype identity	Two patients with the same measured residual activity and reproducibly different ages of onset, attributable to genotype rather than to flux or folding yield
The disease is defined by the blocked reaction rather than the broken gene	A clinical or pathological feature that reliably separates HEXA, HEXB and GM2A disease at matched residual capacity
Tissue selectivity is a flux phenomenon	Neuronal death from a cause unrelated to ganglioside

the claim	what would refute it
	load, such as a neuron-specific non-catalytic function of the alpha chain
The chaperone and substrate-reduction failures confirm the threshold model	A trial raising activity well above ten percent of normal, early, in which the disease still progressed at the untreated rate
Residual activity is a folding yield set by thiol chemistry	Evidence that the missense alleles reach the lysosome at normal efficiency and fail by catalysis alone
The deaminases all depend on cysteine-coordinated zinc	A functional natural or engineered deaminase with no cysteine in its metal site
Tay-Sachs is not somatic in origin	Identification of post-zygotic HEXA mutation as a recurring cause of the disease

The Mystery of the Human Accelerated Gene HAR1

The Silent 118 Base Sequences and the Reduction of Chromosomal Pairs from 24 to 23 in the Great Apes to Human Genome Development

Four independent reasons the chromosome 2 fusion cannot account for human cognitive evolution, and one 118-base sequence on chromosome 20 that has held its purpose for twenty years

PP-2026-CHR2-01 v1 · September 2026

THE COLOR INDEX

color	element	base	where it appears in this paper
RED	hydrogen, H 1	adenine	hydrogen bond, hydroxyl
BLUE	carbon, C 6	cytosine	carbon-14, cytosine
GREEN	nitrogen, N 7	guanine	amino acid, amino group
ORANGE	oxygen, O 8	hypoxanthine	oxygen, 2-oxoglutarate, dioxygenase, inosine
PURPLE	phosphorus, P 15	uracil	phosphate, phosphodiester, uracil
YELLOW	sulfur, S 16	thymine	dimethyl sulfate, thymidylate, sulfate
INDIGO	selenium, Se 34	xanthine	not carried in this paper

Every shaded word in this paper carries the color index of the evidence volume. One color, one element, one base, throughout. The table is ordered by ascending atomic number — the biological element series, CHNOPS plus selenium, in periodic order. The colors are one-to-one labels assigned by mapping, not by measurement; spectral order carries no meaning. Hydrogen = red is the single assignment with a physical basis, the Balmer-alpha line at 656 nanometers.

Iron, the chromosome band and gene names, the disease names and the hominin taxa carry no color, under the ruling recorded in the volume. Element symbols appear alongside the colors so that no figure depends on color alone.

Claims are tiered: **[E]** established science, **[F]** framework claim, **[H]** hypothesis, **[O]** open question.

Part I. The Conspicuous Event

1. The Clue That Is Too Good

Count the chromosomes of a chimpanzee, a gorilla, an orangutan. Twenty-four pairs, every time. Count our own: twenty-three.

One pair short. It is the only gross karyotypic difference between us and the other great apes, and it is visible down a light microscope to anyone who knows how to stain a metaphase spread. No sequencing required. In the whole comparative genomics of human origins, nothing else is so easy to see.

[E] The explanation is clean. Human chromosome 2 is two ape chromosomes joined end to end — conventionally 2A and 2B, welded head to head somewhere in our ancestry. The arithmetic resolves: 24 minus one merger equals 23. The largest visible difference between our genome and a chimpanzee's has a single cause.

And because it is the most conspicuous thing about our genome, it has spent decades being pressed into service as an explanation for the most conspicuous thing about us. If the human karyotype is unique in exactly one way, and human cognition is unique in some way, the temptation to connect them is considerable. Popular accounts make the link casually. Preprints propose the fusion as a developmental trigger for bipedality, or for cortical expansion. The reasoning is rarely stated outright, because stated outright it is an argument from coincidence: this is the big difference, that is the big difference, therefore.

This paper takes the fusion entirely seriously and watches it fail as an explanation four separate times, for four unrelated reasons. It then asks where the answer does live, which is somewhere far less photogenic. And it closes on a second mystery, on a different chromosome, which is genuinely unsolved and has been for twenty years.

[F] The fusion is not a fraud. It happened, the physical evidence for it is excellent, and the story of how it happened is interesting in its own right. It simply does not do the work it has been asked to do. **The most legible fact about the human genome is one of the least consequential, and the consequential ones are illegible.** That inversion is the subject of this paper.

2. The Scar

[E] In 1991, Jonathan IJdo and colleagues went looking for the seam and found it.

Telomeres are the caps on chromosome ends, built from thousands of repeats of a six-base motif: **TTAGGG** read on one strand, **CCCTAA** on the other. They belong at the ends. Their entire function is to mark an end — to tell the cell that the chromosome stops here and has not been broken.

In the middle of the long arm of human chromosome 2, at band 2q13, there is an array of that hexamer. Not at an end. Halfway along. And it is arranged **head to head** — two blocks of telomeric repeat in inverted orientation, facing each other, exactly the configuration you would get by fusing two chromosome ends.

That was the first signature, and it is the one that appears in textbooks. Two more followed.

[E] A chromosome has one centromere, the constriction where spindle fibers attach during division. Chromosome 2 has one functional centromere, inherited from ancestral 2A. It also carries, at 2q21, the unmistakable wreckage of a second: a block of degenerate satellite sequence, the remnants of 2B's centromere after it lost most of its alpha satellite repeats in a large deletion. The ancestral chromosome donated its centromere, and then that centromere was dismantled.

[E] The third signature is subtler and matters more than the other two. Centered on the fusion site is a localized spike of **G**/**C**-biased substitution clusters — a statistical excess of changes from **A** or **T** toward **G** or **C**, concentrated in that neighborhood and nowhere comparable along the rest of the arm. This is the fossil of high recombination. Chromosome ends recombine far more than chromosome middles, and the repair of recombination-associated breaks carries a chemical bias toward **G** and **C**. The spike records a region that used to be a telomere and was behaving like one.

Three independent lines of physical evidence converge on one event at one locus. As forensics it is about as good as evolutionary genomics gets. The chromosome has a scar, the scar is where the seam should be, and the scar has the right chemistry.

This is the point at which the story is usually declared closed. It is roughly where the trouble starts.

Part II. Four Failures

3. First Failure: The Scar Is Older Than the Wound

[E] In 2025, a team led by David Porubsky took the fusion site apart at high resolution, and the interpretation of the textbook signature came loose.

The region is not a simple weld. It resolves into a block of about 455 kilobases containing three distinct segmental duplications, each at least 98 percent identical to its source and at least 20 kilobases long: SD_fusion_A at 50 kb, SD_fusion_B at 36 kb, SD_fusion_C at 22 kb. They came from different places in the genome. Their copy numbers vary across the African great apes. All three show incomplete lineage sorting, with a sharp transition in the proportion of affected windows falling exactly at the fusion point, rising to 50.69 percent on the far side.

[E] Then the finding that reframes the evidence. The interstitial telomeric sequences — the head-to-head arrays that have stood for thirty years as the direct physical trace of the fusion — were **already present on SD_fusion_B and SD_fusion_C before the fusion occurred**, carried on those duplications along with other telomere-associated repeats, and already in inverted orientation.

The scar predates the wound.

[F] The inverted telomeric array at 2q13 is not, or not simply, the cauterized ends of two telomeres pressed together. Some of it was sitting there beforehand, on duplicated sequence, pointing in opposite directions, waiting. The proposed mechanism shifts accordingly: end-to-end joining **mediated by segmental duplications and their associated telomeric sequences**, rather than classical telomere-to-telomere fusion alone.

This does not unmake the fusion. Human chromosome 2 is still two ape chromosomes. But it changes what the evidence is evidence of, and it changes the question. The old question was: what fused two chromosome ends?

The new question is better, because it is answerable: why was this particular locus the one that gave way?

[E] For that, the architecture is an unusually complete answer. Interstitial telomeric sequences are among the most unstable microsatellites in any genome. They are wildly length-polymorphic, they act as **polar blocks to the replication machinery**, stalling forks in an orientation-dependent manner, and stalled forks promote template switching, single-stranded gaps and ultimately double-strand breaks. Introduce such sequences artificially into yeast and rearrangements follow. Telomeric repeats sitting in the middle of a chromosome are not an inert memorial to an old event. Wherever they are, they are a standing liability.

Stack the liabilities that the 2025 work shows were present at this locus before anything happened:

- Three duplications at 98 percent identity or better, prime substrate for non-allelic homologous recombination.
- Those duplications in **inverted** orientation, which invites hairpin and cruciform formation, fork stalling and template switching.
- Telomeric arrays layered on top, contributing their own replication blockade.

[F] The ancestral chromosome ends were loaded. The fusion did not happen at 2q13 by accident of where a cosmic ray landed; it happened there because that architecture is where such things happen. That is a genuine answer to a genuine question — just not the question the fusion is usually recruited to answer.

Alu and the building of the fragile site

[E] Alu is the most abundant repeat family in the human genome: on the order of 1.1 million copies, each roughly 280 to 300 bases, close to ten percent of the 3.1 billion base genome. It is primate-specific, derived from the 7SL RNA gene, and a new copy inserts somewhere in the population roughly once every twenty births.

[E] Alu's principal contribution to structural change is recombination, not insertion. Two copies at different positions are similar enough to mispair during recombination, and everything between them is then excised. This is non-allelic homologous recombination, and across the human and chimpanzee lineages it accounts for on the order of five hundred fixed deletion events in each lineage since the split six million years ago. It causes considerably more human disease than Alu insertion does.

[H] The relevance at 2q13 is architectural. The 2025 analysis attributes the fusion's location to three segmental duplications at 98 percent identity or better, carrying telomeric repeats in inverted orientation. Alu-mediated non-allelic homologous recombination is a recognized mechanism by which segmental duplications are created, and by which high-identity duplications subsequently recombine once they exist. Alu is also enriched in the subtelomeric regions that the ancestral 2A and 2B ends occupied. Alu is therefore a live candidate for having **built the fragile architecture** that decided where the chromosome gave way — upstream of the telomeric arrays rather than in place of them.

[O] The test is specific and available. Run RepeatMasker across the 2q13 fusion block in hg38 and ask two questions: what is the Alu density over SD_fusion_A, SD_fusion_B and SD_fusion_C relative to the chromosome 2 average, and do Alu copies sit at the duplication breakpoints. If they flank the boundaries, the recombination account gains direct support. If the block is Alu-poor, it loses it. The two 2002 papers on fusion-site genomic structure could not be consulted for this draft, so this section states a candidate mechanism and its test, not a result.

What the Alu account does not show

[F] A caution belongs here, because Alu carries two entirely separate biologies and they are easily run together.

Alu at 2q13 is a **DNA recombination substrate**. Two copies mispair during meiosis, a duplication forms or a segment is excised. The machinery is recombination and repair enzymes; the product is a change in the chromosome.

Alu in transcripts is an **RNA editing substrate**. An inverted pair within a single pre-mRNA folds back into double-stranded RNA, ADAR deaminates adenosine to inosine, and the ribosome reads inosine as guanosine. The enrichment is real and large: 23,204 **A**-to-**G** mismatches in Alu-containing sequence against 3,271 for other transition types, with editing optimal when the two copies sit 300 to 400 nucleotides apart, the length of one full Alu.

[F] Both are true. Neither implies the other. They share a sequence family and nothing else: one acts on DNA during meiosis, the other on RNA after transcription, through different enzymes, on different timescales, with different products. **The recombination account of 2q13 therefore lends no support to any claim about inosine**, and an argument that travels from one to the other on the strength of the shared word “Alu” will not survive review.

[E] Where an Alu–inosine link is load-bearing it stands on its own evidence: the editing enrichment figures above, and specific documented instances such as ADAR editing of the Alu-bearing 3′ untranslated region of the *GM2A* transcript. Those are the citations that carry an inosine claim. The chromosome 2 fusion is not one of them.

4. Second Failure: The Clocks Disagree by Fivefold

When did it happen? There are two current answers, and they are not close.

study	method	estimate
Dreszer et al. 2007	decay of the telomeric **G**/**C**-substitution bias	~740 kya (CI 0–2.8 Mya)
Poszewiecka et al. 2022	same approach, refined	**0.9 Mya** (95% CI 0.4–1.5)
Porubsky et al. 2025	incomplete lineage sorting of the segmental duplications	**> 5 Mya**

[O] A factor of five, between two competent analyzes published three years apart. This is the sort of disagreement that usually means someone has made a mistake. It more likely means the two methods are not measuring the same thing, and the mistake is in assuming they are.

[E] The first approach is elegant. While the region was a telomere it recombined heavily, and recombination-associated repair deposited its characteristic bias toward **G** and **C**. The moment the fusion buried that region in the middle of a chromosome, the recombination stopped and the bias began to decay. So the residual excess of weak-to-strong substitutions is a clock: measure how much bias is left, know the decay rate, read off the elapsed time. The refined version counts these clustered substitutions in 300-base windows and handles overlapping clusters properly. It gives 0.9 million years.

It rests on three assumptions: that the biased-substitution force near telomeres has been constant across species, that humans and chimpanzees diverged around 6 million years ago, and that a rescaling correction adequately handles the hyper-expanded duplications and tandem repeats present on chimpanzee 2A and 2B but absent from humans.

[E] The second approach dates something else entirely. It asks how old the **duplication architecture** is, from the phylogenetic signature of incomplete lineage sorting across those three segmental duplications — the pattern left when ancestral variation sorts randomly into descendant lineages, which happens when ancestral populations are large. That analysis puts the duplications at more than five million years old, arising early in African great ape speciation.

[F] So one method dates the moment a region stopped being a chromosome end. The other dates the assembly of the repeat scaffolding on which the fusion later occurred. If the scaffolding was in place for millions of years before it finally gave way, both numbers can be correct and the apparent contradiction dissolves into a sequence rather than a conflict. Architecture ancient; event recent.

[O] That reading is tidy and it may be right, but nobody has demonstrated it, and the 2025 paper frames its result as challenging the 0.9-million-year estimate rather than complementing it. Establishing precisely what each clock measures, and whether they reconcile or whether one is wrong, is an open and publishable problem. It is currently the sharpest unresolved question about the fusion.

[E] One constraint holds under either date. The fusion is fixed in every living human, and archaic genomes assemble against a fused chromosome 2, placing it before the divergence of Neanderthal and Denisovan lineages from our own. That sets a floor of several hundred thousand years and is compatible with both estimates, which is to say it does not help us choose.

5. Third Failure: The Chromosome Should Not Have Survived

Here is the part of the story that gets skipped, and it is the part that requires the most luck.

[E] Weld two chromosomes end to end and you have not made a viable chromosome. You have made a **dicentric** one, a chromosome with two centromeres. In mitosis spindle fibers attach at both, and if the two are pulled toward opposite poles the chromosome is stretched between them. What follows is well characterized, because it is a signature of cancer genomes and of cells in telomere crisis.

[E] The dicentric persists through mitosis as a DNA bridge — in experimental systems 50 to 200 micrometers of stretched chromatin spanning two separating daughter cells. The nuclear envelope ruptures. The exonuclease TREX1 accumulates on the bridge and chews it down, generating long-lived single-stranded DNA coated in RPA. That single-stranded DNA is substrate for the cytosine deaminase APOBEC3B, which converts cytosines to uracils; uracil glycosylases and endonucleases turn those into strand breaks; and the chromosome shatters. The resulting patterns have names: **kataegis** for the clustered mutation, **chromothripsis** for the fragmentation.

This is the ordinary fate of a dicentric chromosome. It is why dicentrics are the standard cytogenetic biomarker of radiation dose — they are useful precisely because they do not last. Breakage-fusion-bridge cycles destroy them within a few divisions.

[F] So the fused chromosome 2 was, at the moment of its creation, a self-destructing object. For it to exist today a second thing had to happen: one of the two centromeres had to be switched off. And it was. The ancestral 2B centromere was inactivated and most of its alpha satellite deleted, leaving the degenerate block at 2q21 that we read today as the second signature of the fusion.

Fixation required two improbable events in series, not one. First a fusion at a locus primed to fuse. Then the inactivation and partial deletion of a centromere, before breakage-fusion-bridge cycles eliminated the product. The scar at 2q21 is not merely a relic of the merger; it is the evidence of the rescue that made the merger survivable.

[E] And there is a third improbability, which has nothing to do with molecular biology. A fusion heterozygote — one fused chromosome, one pair of unfused ancestral ones — produces some unbalanced gametes at meiosis and pays a fertility cost for it. That cost is selection against the new arrangement. Yet the fusion went to **complete fixation**: not one living human carries the ancestral configuration.

[O] Which reframes the interesting question a third time. Fusions are not rare. Robertsonian translocations, the same class of event, arise de novo in roughly one in a thousand human births, and rob(13;14) alone accounts for about three-quarters of them. Chromosomes fuse constantly. The puzzle was never how one got made. The puzzle is how one reached a hundred percent while carrying a fertility penalty — a question about effective population size, drift, population structure in early *Homo* and possibly meiotic drive. It is answerable with existing population-genetic methods, and appears not to have been properly attempted.

6. Fourth Failure: It Explains Nothing

[F] Now the load-bearing failure. Whatever the fusion did, it did not make us clever, and the argument does not require choosing between the two dates. It works under both, which is what makes it decisive rather than merely suggestive.

Brain expansion in our lineage is not a single event but a sequence with a conspicuous gap in the middle:

stage	date	cranial capacity
Australopithecus	—	~440 cc
Homo habilis — expansion begins	~2.1–1.5 Mya	~640 cc
H. erectus, Java	—	~930 cc
relative brain size static across *Homo*	**1.8–0.6 Mya**	—
H. erectus, China	—	~1,029 cc
relative brain size rises again	after ~600 kya	—
H. sapiens	—	~1,350 cc

[E] Encephalization began with *habilis*, around two million years ago. Then relative brain size held flat for more than a million years, from 1.8 to 0.6 Mya, before rising again.

[F] The 0.9-million-year fusion estimate lands **inside that plateau**. At the moment the chromosomes merged, brain expansion had been underway for roughly a million years and was, just then, not happening. An event cannot trigger a process that began a million years before it and was static when it occurred.

[F] The five-million-year estimate fails in the opposite direction. It puts the fusion three million years or more before any hominin encephalization at all — a cause separated from its alleged effect by three million years of nothing. That is not a cause in any sense that does work.

Both dates fail. Different reasons, same conclusion.

[E] And then the observation that should have settled this decades ago, because the natural experiment is walking around among us. Robertsonian translocation carriers — people carrying a de novo chromosome fusion, roughly one in a thousand births — are **phenotypically normal**. Normal development, normal cognition. Their clinical issue is reproductive: a risk of unbalanced gametes, relevant to fertility counseling and nothing else. The proposition that fusing two chromosomes changes the phenotype is directly testable in living humans, and the answer has been no for as long as anyone has looked. Mammals generally bear this out; house mouse populations carry whole suites of Robertsonian races without cognitive correlates.

[E] The reason is not mysterious. The fusion deleted no genes. What was lost was alpha satellite DNA at the switched-off centromere — structural repeat, not coding or regulatory sequence. The junction itself sits in duplication-rich, gene-poor territory. Two ancestral chromosomes became one chromosome carrying the same genes in the same order. The event changed the packaging and not the contents.

[O] The most sophisticated remaining defense is that the merger reorganized the three-dimensional architecture of the nucleus — chromosome ends occupy distinct nuclear territories, and joining two of them would reposition genes relative to distant regulatory elements. This is not unreasonable in principle, but it remains a hypothesis with no demonstrated instance: no gene has been shown to have changed expression in humans as a consequence of the fusion, and no human accelerated region has been shown to owe its acceleration to it. It should be cited as a proposal, not a finding.

[F] What the fusion plausibly did do is contribute to **reproductive isolation** — the standard evolutionary significance of karyotype rearrangement, operating through gene flow and population structure rather than phenotype. What it demonstrably did is change the local mutational regime at 2q13, when the region stopped being a telomere and its recombination-driven GC bias began to fade. The fusion's clearest legacy is a decaying chemical signature, which is to say the clock we use to date it.

Part III. Where the Answer Lives

7. Five Loci, None of Them on Chromosome 2

[E] Five loci now have experimental support for human-specific cortical expansion. Not one of them is on chromosome 2.

locus	location	the change	what it does
HARE5 / *FZD8*	10p11.21	four human-specific variants in an enhancer of a WNT receptor	amplifies WNT signaling; radial glia self-renew longer, then expand their neurogenic output. Knock-in mice grow **enlarged neocortices with more excitatory neurons**
NOTCH2NL A/B/C	1q21.1	human-specific partial duplications of *NOTCH2*	delays progenitor differentiation through Delta/Notch, expanding neurogenesis. Human genetics corroborates: 1q21.1 deletions give microcephaly, duplications macrocephaly
ARHGAP11B	15q13.3	a duplication, then a single **C**-to-**G** substitution creating a splice donor site	55 nucleotides vanish from the message, the reading frame shifts, and 47 residues of novel human protein appear. Amplifies basal progenitors; in fetal marmoset, enlarges and folds the neocortex
SRGAP2C	1q32.1	duplication at 2.4 Mya, from *SRGAP2B* at 3.4 Mya	binds and inhibits its own ancestor, producing neoteny of spine maturation and higher spine density
TKTL1	Xq28	one lysine-to-arginine substitution; apes and archaics carry lysine	drives the pentose phosphate pathway and lipid synthesis for basal radial glia. **Contested** — a published technical Comment disputes it

[F] Read the third column and a pattern emerges. Every well-supported case is one of two things: a **gene duplicated and then diverged**, or a **regulatory element rewritten**. The duplications matter because a redundant copy is free to acquire a new job without abandoning the old one. The enhancers matter because changing when and where a conserved gene fires is cheaper than inventing a new gene.

[E] The *ARHGAP11B* case deserves a moment, because it is the most elegant thing in this literature. A single base — cytosine to guanine, a transversion — created a new splice donor site. That deleted 55 nucleotides from the messenger RNA, which shifted the reading frame, which generated 47 amino acids of protein sequence existing in no other organism. Reconstruct the ancestral version without that one base change and it does not amplify progenitors at all. One nucleotide, acting through RNA processing rather than through the genetic code, produced a new functional protein domain and a larger brain.

[E] And the timing, unlike the fusion's, lines up. *SRGAP2B* duplicated 3.4 million years ago, *SRGAP2C* 2.4 million years ago — the latter coinciding with the origin of *Homo* and the onset of encephalization in *habilis*. That is the chronological coincidence the fusion conspicuously lacks.

[F] None of this is visible in a karyogram. You cannot stain for an enhancer variant. Four base changes in a stretch of non-coding DNA on chromosome 10 rewired WNT signaling in the developing cortex and left the chromosomes looking exactly as they did before. **The most consequential events in the evolution of the human brain are invisible at the resolution where the fusion is unmissable.** We noticed the fusion first because it is large, and thirty years have gone into making it mean something, while the things that mean something were too small to see.

Part IV. The Silence

8. One Hundred Eighteen Bases on Chromosome 20

[F] The fusion is a solved problem wearing the costume of a mystery. The real mystery is 118 bases long, sits on the long arm of chromosome 20, and has resisted explanation for twenty years.

[E] In 2006, Katherine Pollard and colleagues ranked the human genome for regions highly conserved across vertebrates that then changed abruptly in our lineage. Forty-nine passed a 5 percent false discovery rate. The top-ranked one they called HAR1.

property	value
length	118 base pairs
human-lineage substitutions	**18**
substitutions expected at the prior rate	**0.27**
differences between chimpanzee and chicken	**2 of 118**
fixed in a 24-person diversity panel	all 18
present in	chicken, platypus, opossum, dog, cow, primates
absent in	frog, zebrafish, all invertebrates
paralogues in any amniote genome	**none**

Dwell on the third and fourth rows together. Two bases out of 118 changed between chimpanzees and chickens — across something like 310 million years of separate evolution this sequence held almost perfectly still. Whatever it was doing, it was doing it so exactly that selection would not tolerate variation.

Then, on our lineage alone, eighteen changes, against an expectation of 0.27. Roughly sixty-seven-fold acceleration in a window the width of a sentence, in a sequence that had not moved since before there were mammals. And all eighteen are fixed. There is no human alive carrying the ancestral version.

[E] The changes were not random. HAR1 folds into a structured RNA, and three of its five predicted helices are supported by five **pairs** of human-specific substitutions that preserve base pairing — four pairs of transitions and one pair of transversions, at a probability of 3.95×10^{-8} against chance. Compensatory substitution is the signature of selection acting to maintain a fold: a base changed on one side of a helix, and its partner changed to match.

[E] Chemical probing confirms the fold shifted. Treat the human and chimpanzee RNAs with dimethyl sulfate and read out which bases are protected, and the answer differs between species in a specific way: the ancestral structure carries three extra base pairs in one helix and two fewer in another, while in the human RNA the second helix is extended at the expense of the first. Helix D gained; helix C lost. The eighteen substitutions rebuilt the molecule's shape.

[F] The widely repeated claim that the substitutions convert an unstable hairpin into a stable cloverleaf is an oversimplification and should not be cited in that form. The primary data show a redistribution of pairing

between two named helices, verified chemically, not a fold-versus-no-fold switch. HAR1 is also not a tRNA relative, despite the shared adjective: it has no acceptor stem, no **CCA** end and no aminoacylation.

[E] Where is it expressed? In the developing human neocortex, with a precision that is almost provocative.

gestational week	location
7–9	dorsal telencephalon, the cortical primordium, and nowhere else in the forebrain
7–19	**Cajal–Retzius neurons** of the marginal zone, co-localized with reelin protein
17–24	hippocampal primordium, dentate gyrus, developing cerebellar cortex, olivary complex
24	gone from Cajal–Retzius cells

Cajal–Retzius neurons secrete reelin, the signal that organizes the six-layer architecture of the cortex. They are among the earliest neurons born, and they lay down the coordinate system every later neuron migrates through. HAR1 switches on in exactly those cells, in exactly the window when cortical layering is being specified, alongside reelin itself — and is absent from the other main neuronal population sharing that space.

So: the fastest-evolving sequence in the human genome, frozen for 310 million years, restructured by eighteen fixed substitutions that selection demonstrably shepherded to preserve an RNA fold, expressed in the precise cells and the precise weeks when the human cortex is being laid out.

And nobody knows what it does.

[O] That is not shorthand. There is no knockout phenotype. No binding partner has been identified. No experiment has swapped the human sequence for the ancestral one in any model system and measured a consequence. The RNA matches nothing in Rfam — no known family, no structural homologue, no recognizable catalytic motif, no convincing microRNA precursor. It is a genuinely novel molecule of unknown function. The case for its importance rests on three circumstantial pillars — extreme acceleration, compensatory structural substitution, cell-type-specific expression in a critical window — and on no direct functional result.

Twenty years. The gap has not closed.

[F] This is what an actual mystery looks like, against the fusion's counterfeit version. The fusion is spectacular, inconsequential, and fairly well understood. HAR1 is invisible, plausibly central, and opaque.

9. The Evidence That Erases Itself

There is one more turn, and it is the strangest thing in this material.

[E] Recall the third signature at the fusion site: the localized excess of substitutions from **A** or **T** toward **G** or **C**. **GC-biased gene conversion** is a consequence of how cells repair the mismatches arising during meiotic recombination — the repair machinery preferentially resolves them toward **G** and **C**, regardless of whether that helps the organism. It is a fixation bias with no relation to fitness.

And it is the clock. The whole 0.9-million-year estimate rests on measuring how much of the telomeric **GC** bias remains at 2q13 and inferring how long it has been decaying. Without **GC**-biased gene conversion there is no date.

[H] Now consider what that same process does to other evidence. In Section 5 the dicentric mechanism ran: fusion, bridge, TREX1 exonuclease, single-stranded DNA, APOBEC3B deaminating cytosines, breaks — and the mutational fingerprint of that last step is kataegis, a dense cluster of strand-coordinated changes from **C** to **T**. Ancestral chromosome 2 **was** dicentric. If it passed through a bridge stage, as it must have, the model predicts a kataegis signature in the sequence flanking the fusion site: a cluster of fixed **C**-to-**T** changes, human-specific, absent from chimpanzee and gorilla.

That is a real, testable prediction against genomes already in hand. Except:

[F] A kataegis signature is a cluster of **C**-to-**T** substitutions. **GC**-biased gene conversion drives substitutions **toward** **C** and **G**. The two processes push in exactly opposite directions, and the bias was running hot at this locus — we know that, because the spike it left is how the event is dated.

The process used as the clock is the process that would have wiped the fingerprint.

This is not a paradox, only an unusually clean case of one signal overwriting another. But the consequence is worth sitting with. The most direct available test of *how* the chromosome fused — whether it took the violent bridge-and-shatter route that dicentrics normally take — is probably unrunnable, because the same chemistry that establishes *when* it happened has been erasing *how* for a million years. Several hundred thousand years of ordinary substitution would degrade the clustering on its own, even without the bias.

The fusion site is a crime scene where the clock on the wall is made of the same material as the fingerprints, and it has been slowly consuming them.

[O] A cautious worker would run the kataegis search anyway. Negative results under known low power are worth little, but the analysis is cheap and the upside is a direct window onto mechanism. It should be done and reported honestly as underpowered.

Part V. What Would Crack It

10. Six Tests, Ordered by Cost

An afternoon. Does HAR1 contain a G-quadruplex motif, and did any of the eighteen substitutions create one? The changes are all weak-to-strong, meaning they raised the **GC** content of a 118-base window, and quadruplex potential is **GC**-dependent. Run G4Hunter or QGRS over the human and chimpanzee sequences — *HAR1A* is at chr20:63,102,205–63,104,421 in hg38 — and ask whether four **G**-runs appear in one and not the other. No published analysis appears to have looked. **[H]** Prediction: negative. 118 bases is a tight budget for a canonical quadruplex and the element is **A**/**T**-rich ancestrally. A prediction that costs an afternoon to falsify should be falsified.

A week at a bench. Is HAR1 RNA catalytic? Transcribe the human and chimpanzee versions in vitro, incubate across a divalent cation series, resolve on a denaturing gel, look for self-cleavage. If products appear, characterize the ends for a 2′,3′-cyclic phosphate and a 5′-hydroxyl, the signature of ribozyme chemistry. Size is no objection: the hammerhead ribozyme is 50 to 80 nucleotides, the HDV ribozyme about 85, and mammalian genomes carry a natural small ribozyme in an intron of *CPEB3*. Against it: no Rfam homology. **[O]** A twenty-year-old functional gap deserves the obvious experiment.

A month of analysis. Did the 2q13 region carry PRDM9 binding motifs, or map to a recombination hotspot, in the ancestral population? PRDM9 is the zinc-finger protein that decides where meiotic double-strand breaks happen: it reads a DNA motif, marks the chromatin, and SPO11 cuts there. It is among the fastest-evolving genes in our genome, its hotspots are almost entirely unshared between humans and chimpanzees, and it is the only known mammalian hybrid-sterility gene. Through the biased gene conversion its own breaks trigger, it also determines where **GC**-biased gene conversion acts — which places it upstream of both the HAR acceleration statistics and the fusion clock. **[O]** Nobody claims PRDM9 caused the fusion. The question is whether it chose the address.

Also a month. Search for the kataegis signature flanking the fusion site, knowing in advance that **GC**-biased gene conversion has been working against it. Report the power calculation with the result.

A paper in itself. Reconcile the two clocks. State precisely what the UBCS method dates and what the incomplete-lineage-sorting method dates, and establish whether ancient architecture with a recent event resolves the fivefold gap or whether one analysis is wrong. This is the most tractable unresolved question about the fusion and it requires no new data.

A modeling project. How did a fusion carrying a heterozygote fertility cost reach complete fixation? Effective population size, drift, population structure in early *Homo*, meiotic drive. The methods exist. The question has sat in plain sight for thirty years while attention went to a phenotype that is not there.

11. Coda: The Discipline of Scale

A fusion this conspicuous attracts explanations, and the ones it attracts share a family resemblance worth naming, because the pattern recurs and it is not obvious from inside. Three candidate causes, each built on entirely real science.

Proton tunneling. [E] A proton can tunnel across a hydrogen bond in a G–C pair, generating a rare enol tautomer: occupation probability around 1.7×10^{-4} at body temperature, with tunneling outrunning classical barrier-hopping by five orders of magnitude. **[F]** If such a tautomer survives to replication the result is a mispaired base — **one point substitution**. The phosphodiester backbone is never touched. A chromosome fusion involves hundreds of kilobases of rearrangement and the demolition of a centromere. Between the two lies a factor of roughly a hundred million. Tautomerization is a mechanism of base-pairing *fidelity*; a fusion requires a mechanism of strand *scission*. These are not different magnitudes of one thing. Note also the terminology: G–C is held by three *hydrogen bonds*, not a triple covalent bond, and I–C by two.

Radiation. [E] Radiation unquestionably breaks chromosomes, and dicentrics are the standard biomarker of dose. There is also a real radionuclide record: interstellar ^{60}Fe in deep-sea crusts marks near-Earth supernovae at 1.5–3.2 and 6.5–8.7 million years ago, from sources 90 to 100 parsecs out. **[F]** Neither window overlaps either fusion estimate. But the deeper objection is not the dates: radiation damage is **stochastic in location**, and the fusion happened at a site already loaded with inverted duplications and telomeric arrays. A random-damage mechanism cannot explain an address. Carbon-14 cannot address the question at all — a 5,730-year half-life gives a ceiling near 50,000 years, short of 0.9 million by a factor of about eighteen. And no exotic cause is needed where fusions of this class arise in one birth in a thousand unprompted.

Translation. [E] Mutations in tRNA and in tRNA-modifying enzymes genuinely cause human neurological disease: *ADAT3* variants give intellectual disability and microcephaly, *ELP1* gives familial dysautonomia. **[F]** But translation *reads* the genome; it does not write it. For a decoding defect to reach chromosome structure it would have to act through a named DNA-handling protein, and the argument would have to show the defect degrades that protein specifically, and that the dysfunction produces breaks at subtelomeric repeats rather than everywhere. The decisive observation is that people living with these exact tRNA-modification diseases do not have chromosomal fusions. The natural experiment has run and the predicted karyotype is absent. Note also that 4-hydroxyproline, sometimes invoked in such chains, has no codon, no tRNA and no synthetase: it is installed after translation by an Fe(II)/2-oxoglutarate dioxygenase, which removes it from any tRNA-level process by definition.

[F] Three hypotheses, three real mechanisms, three failures — and all three fail the same way. A process valid at one scale was applied at a scale many orders of magnitude removed. This is not a failure of knowledge; every one of these proposals requires knowing real chemistry. It is a failure of bookkeeping.

The corrective is mechanical. Before building a causal chain, write down the scale of the proposed cause and the scale of the observed effect side by side, in the same units. A single proton against 455 kilobases. A transient mRNA misread against a fixed karyotype. If the gap exceeds two or three orders of magnitude a step is missing, and the honest move is to find it rather than to assert the chain and offer its improbability as the reason nobody else has proposed it.

[F] What survives this discipline is not nothing. The intuition that some rapidly evolving specificity system decided where the genome broke survives as **PRDM9**. The intuition that RNA-versus-DNA chemistry at a locus can cause breakage survives as **R-loops**, and specifically as **TERRA** — the telomeric transcript that invades its own duplex, pairs with the **CCCTAA** strand and displaces the **TTAGGG** strand, making telomeres fragile. The intuition that a deaminase acting on exposed single-stranded DNA can shatter a chromosome survives intact and published, as the APOBEC3B step in the dicentric-bridge pathway — it simply runs *after* the fusion rather than causing it. Each is the original instinct with the scale corrected and the direction checked.

And the two mysteries remain. One chromosome that fused spectacularly and changed nothing we can measure. One hundred eighteen bases that changed more dramatically than any other sequence in our genome, in the cells that build the cortex, in the weeks that matter, and have kept their purpose to themselves for twenty years.

The second one is where I would look.

PART TWO HUNDRED AND FOURTEEN

Color as Meaning

The Berger index applied to a published figure

PP-2026-COLORDEMO-01 v1 · 22 September 2026 · Dr. John Allen Berger, PhD · NovagonDNA · Licensed under CC BY-NC-ND 4.0.

Color Key

color	element	base	where it appears in these figures
RED	hydrogen · H 1	adenine	A, and every H in the NH2, NH and NH3 groups of Fig. 1
BLUE	carbon · C 6	cytosine	C in the motifs and in every protospacer
GREEN	nitrogen · N 7	guanine	G; every ring N and amine N in the structures
ORANGE	oxygen · O 8	hypoxanthine	I, the inosine intermediate; the carbonyl O of I and G
PURPLE	phosphorus · P 15	uracil	
YELLOW	sulfur · S 16	thymine	T in the duplex, the motifs and the protospacers
INDIGO	selenium · Se 34	xanthine	not present in this paper

What the recoding does

[F] Color is a label, not decoration. Every base letter and every atom label carries the color of its element, the mapping is one-to-one, and nothing else on the page carries color at all. The same letter is the same color in Fig. 1, in Fig. 4c, and in every other paper.

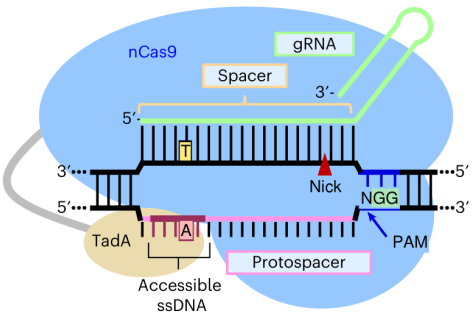
[E] The published figures used color for three unrelated local purposes at once: blue and red for N and O in the structures, a seven-hue rainbow for evolutionary round, and red for mismatched positions in Fig. 4c. Three codes, one palette, none of them portable past its own panel.

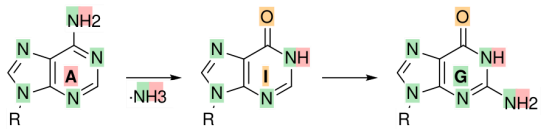
[F] Here the evolutionary round carries no color - the round number carries it, printed in the cell it belongs to - and the mismatches in Fig. 4c are marked with an underline. Nothing is lost. The palette is released to name elements.

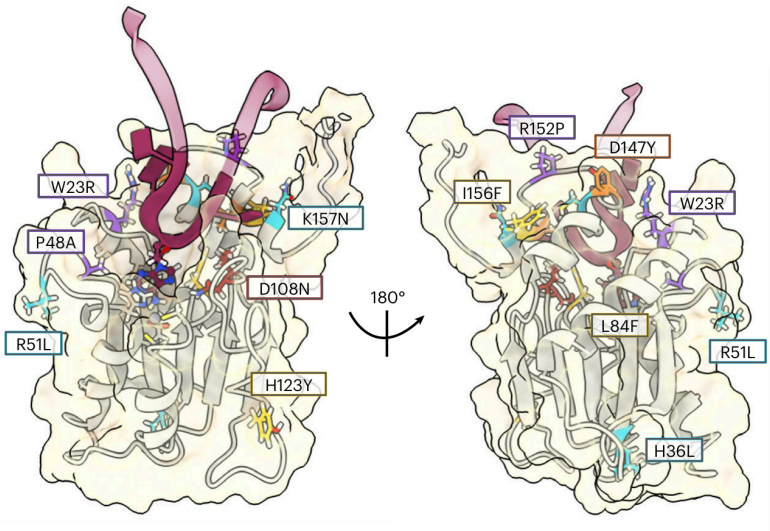
[F] The subject of the paper then reads straight off the page: A·T to G·C is red·yellow to green·blue, hydrogen and sulfur giving way to nitrogen and carbon, and the A to I to G row is red to orange to green, the loss of an amine and the gain of a carbonyl oxygen shown as a color change rather than described in a caption.

[E] Nothing depends on color alone. Every field sits behind a letter that already names the base or the atom, and the key names each element and its atomic number.

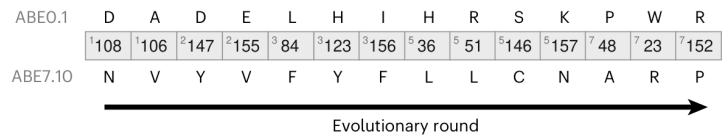
Part 1. Figure 1, recoded to the index







Evolutionary round	Selection pressure target sequence motif(s)	Relative stringency
1	TA$_6$GT	+
2	TA$_6$GT	++
3	TA$_6$TT, TA$_8$GG	++
4	GA$_6$TG	++
5	GA$_6$TG, TA$_9$GT	+++
6	GA$_6$TG	++
7	TA$_6$TT, TA$_7$AC	+++



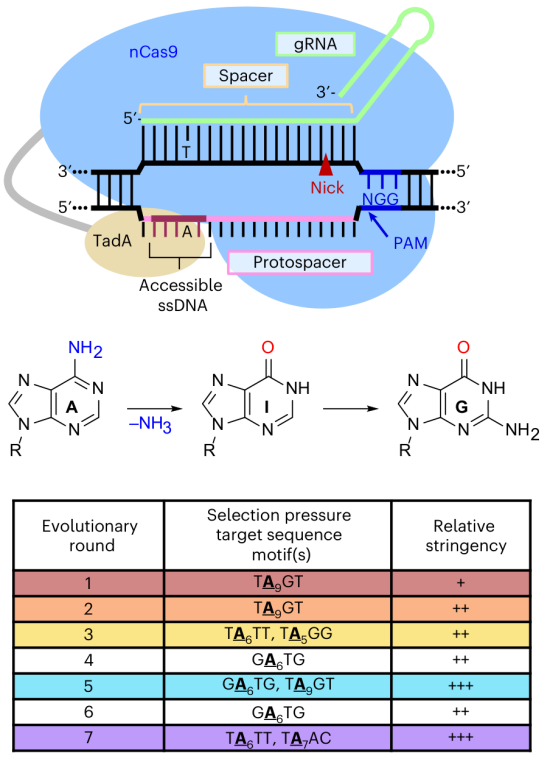
[F] Panel a. The target base is a red A and the base opposite it a yellow T - hydrogen and sulfur. The two G's of the NGG protospacer-adjacent motif are green. The labels that were red and blue for emphasis are now black, so that red and blue mean only hydrogen and carbon.

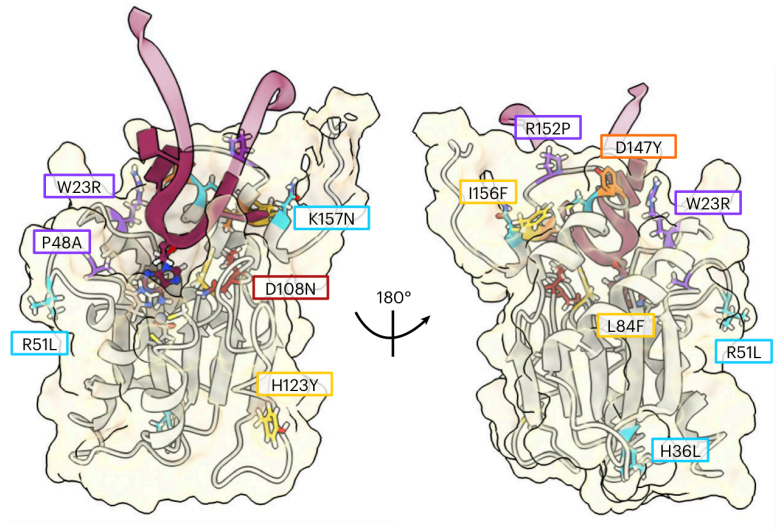
[F] Panel b. Adenine to inosine to guanine, atom by atom. Every ring nitrogen is green, the exocyclic amine is green with red hydrogens, the carbonyl oxygen that appears at C6 is orange, and the bold base letter carries its own color: red A, orange I, green G. The deamination is visible as the disappearance of a green-and-red group and the arrival of an orange one.

[F] Panel c. The selection-pressure motifs are fully coded - T yellow, A red, G green, C blue - and the evolutionary round carries no color at all, only its number.

[E] Panel d. The ribbon diagrams and the residue row below them carry no color from the index. Amino-acid residues are not on the table: the C of a cysteine side chain is an amino-acid symbol here, not the base cytosine, and coloring it would make the code mean two things. The round-coded outlines are gray for the same reason, and the rainbow strip that encoded evolutionary round is now a plain cell per residue: the position number in black, the round as a small superscript. Rounds 1 to 7 carry no color anywhere in this figure. Where the edit occurs is shown in panels a and b, not here.

Part II. The same figure, as published





Evolutionary round	Selection pressure target sequence motif(s)	Relative stringency
1	T**A**$_9$GT	+
2	T**A**$_9$GT	++
3	T**A**$_6$TT, T**A**$_5$GG	++
4	G**A**$_6$TG	++
5	G**A**$_6$TG, T**A**$_9$GT	+++
6	G**A**$_6$TG	++
7	T**A**$_6$TT, T**A**$_7$AC	+++

[E] As printed, color in this figure means evolutionary round in panel c and panel d, element in panel b (blue N, red O - the CPK convention, which disagrees with this index), emphasis in the Nick and PAM labels, and nothing at all in panel a's bases, which are left black. A reader cannot carry any of it to the next figure.

[H] Applied across a whole paper, a fixed index should let a reader compare figures by eye - to see that the same base is under discussion in Fig. 1 and Fig. 4 without reading either caption. That is the claim this recoding is meant to test.

Part III. Figure 4c, the sequence tables

As published

Target A position

c

On-target site	On-target gRNA sequence	Off-target site	Off-target predicted sequence	Off-target source and previous references
H2.0	GAAC **A**CAAAGCATAGACTGC	H2.0 Off-T1	GAAC**A**CAA**T**GCATAGA**T**TGC	Gaudelli (2017); Tsai (2015)
		H2.0 Off-T3	CCAA**A**CAAAA**C**ATAGACTGC	Chen (2022); Kuscu (2014)
H3.0	GGCCC **A**GACTGAGCACGTGA	H3.0 Off-T1	CACCC**A**GACTGAGCACGTG**C**	Gaudelli (2017 -H3.0_OffT1); Tsai (2015 -H3.0_OffT2)
		H3.0 Off-T2	GACAC**A**GAC**C**GGGCACGTGA	Gaudelli (2017); Tsai (2015)
Hi.0	GAAG **A**CCAAGGATAGACTGC	Hi.0 Off-T1	AAAG**A**CCAAGGATAGACTG**A**	Cowan (2025); Hsu (2013)

[E] Black for every base, red for a mismatched position, bold for the most editable A. Color appears once, for one local distinction, and carries no chemistry.

Recoded to the index

Target A position

c

On-target site	On-target gRNA sequence	Off-target site	Off-target predicted sequence	Off-target source and previous references
H2.0	GAAC **A**CAAAGCATAGACTGC	H2.0 Off-T1	GAAC**A**CAA**T**GCATAGA**T**TGC	Gaudelli (2017); Tsai (2015)
		H2.0 Off-T3	CCAA**A**CAAAA**C**ATAGACTGC	Chen (2022); Kuscu (2014)
H3.0	GGCCC **A**GACTGAGCACGTGA	H3.0 Off-T1	CACCC**A**GACTGAGCACGTG**C**	Gaudelli (2017 -H3.0_OffT1); Tsai (2015 -H3.0_OffT2)
		H3.0 Off-T2	GACAC**A**GAC**C**GGGCACGTGA	Gaudelli (2017); Tsai (2015)
Hi.0	GAAG **A**CCAAGGATAGACTGC	Hi.0 Off-T1	AAAG**A**CCAAGGATAGACTG**A**	Cowan (2025); Hsu (2013)

[F] Every base in both sequence columns now carries its element. The mismatches keep their meaning as underlines; the bold A is still bold. The reader gains the composition of each protospacer at a glance and loses nothing that was on the page before.

[O] Open: whether the run-length patterns that the color makes visible here - the red A tracts, the yellow T tracts - track editing efficiency across the 27 sites in this paper. The color raises the question; it does not answer it.

Primordial - Atomic to Molecular to Cellular - Biology, Chemistry, Genetics

The hydrogen that holds every base pair is 13.8 billion years old

PP-2026-COSMOS-01 v11 · 22 September 2026 · Dr. John Allen Berger, PhD · NovagonDNA · Licensed under CC BY-NC-ND 4.0.

Color Key

color	element	base	where it appears in this paper
RED	hydrogen · H 1	adenine	Big Bang nucleosynthesis, the first minutes. Not made since; stars consume it
BLUE	carbon · C 6	cytosine	triple-alpha fusion in the cores of evolved stars
GREEN	nitrogen · N 7	guanine	the CNO cycle, where it is the catalytic intermediate that accumulates
ORANGE	oxygen · O 8	hypoxanthine	helium and carbon burning in massive stars
PURPLE	phosphorus · P 15	uracil	neon and oxygen burning in massive stars; scarce relative to the rest of the set
YELLOW	sulfur · S 16	thymine	oxygen burning in massive stars, dispersed by core collapse
INDIGO	selenium · Se 34	xanthine	past iron: fusion cannot reach it. Neutron capture only, slow and rapid
INDIGO	magnesium · Mg 12	orotate	carbon and neon burning in massive stars; an alpha-process nuclide from the same shells as phosphorus and sulfur

The magnesium row is new to the index. It takes indigo, and it is set on the line below selenium, which keeps indigo as well. The fourth column in this paper is not scoped to a figure. It is scoped to an epoch. Read down the table, which is ordered by ascending atomic number as it always is, and the column gives the order in which the universe learned to make each element.

Abstract. The index has always been ordered by atomic number, on the ground that the order is the design and not a palette. This paper reports what that order corresponds to. Hydrogen was made in the first minutes after the Big Bang and has not been made since; carbon, nitrogen and oxygen in stellar interiors; phosphorus and sulfur in the burning shells of massive stars and scattered by their collapse, magnesium alongside them; selenium past the iron limit, where fusion cannot reach and only neutron capture will do. Four distinct epochs, encountered in sequence, by atomic number. The paper then follows the chain down: the eight bases built from four elements and nothing else, the pairing rule as a count of hydrogen bonds, the heavier elements entering only in the apparatus and not in the sequence, and the code carrying a recoded stop codon for the one element that fusion could not make. It states precisely in what sense the first minutes of the universe are still present in a living body: not as history and not as metaphor, but as nuclei, because no chemical process has ever changed one.

Part I. The order of the index is a chronology

1. Hydrogen, and the first minutes

[E] Big Bang nucleosynthesis, in roughly the first twenty minutes, produced hydrogen, deuterium, helium-3, helium-4 and a trace of lithium-7. It produced nothing heavier, because the expanding universe cooled through the relevant temperature range before heavier nuclei could form.

[E] That epoch is dated at approximately 13.8 billion years before the present. Stars consume hydrogen. They do not make it. Every route by which a star generates energy from hydrogen converts it into something else, and no known astrophysical process runs the other way at any significant rate. The hydrogen in a body is therefore primordial: it dates from the first minutes and there has been no source since.

[F] This is the strongest statement in the paper and it is the least speculative. The red row of the index is the row of the oldest matter in the body.

2. Deuterium is the clean case

[E] Deuterium is produced only in Big Bang nucleosynthesis and is destroyed wherever it is exposed to stellar interiors, being consumed readily in fusion. It has no significant production channel anywhere in the later universe. Its measured abundance is used as a direct probe of the baryon density of the cosmos for exactly this reason: what is observed now is what was left over.

[F] A human body contains deuterium at the natural isotopic abundance of hydrogen. Every one of those nuclei has existed since the first minutes and cannot be replaced. It is not that the deuterium is old. It is that there is no other kind.

3. Carbon, nitrogen, oxygen

[E] Carbon is assembled by the triple-alpha process in the cores of evolved stars, three helium nuclei to one carbon. Oxygen follows from helium capture on carbon and from later burning stages. Nitrogen is the element that accumulates as the catalytic intermediate of the CNO cycle, which is the dominant hydrogen-burning path in stars more massive than the sun.

[F] These three rows of the index, blue and green and orange, are stellar interiors. They are second-generation matter: none of them existed until stars had formed, lived and processed the primordial gas.

4. Phosphorus and sulfur
