This introduction is the ark and frame of the book.

Introduction

Dr. John Allen Berger, PhD, NovagonDNA

In the first minutes after the Big Bang. The universe cooled enough for protons and neutrons to be formed and bond. The products were hydrogen, helium and lithium. Hydrogen composes about three quarters of the mass of the universe. Helium is approximately one quarter, with trace amounts of lithium. Hydrogen is the first atomic element on the standard atomic periodic chart. It is the first of the six organic elements (HCNOPS) which form 97.5 percent of the mass of a eukaryote cell. The other five are Carbon, Nitrogen, Oxgyen, Phoshorous and Sulfur.

A star fuses hydrogen into helium in the triple alpha process. Seen through chemistry,hydrogen is the beginning of the 118 elements of the latest periodic table. Seen through biology, is the fundamental structure of molecular biology which combine atoms to form the molecular structures of compound in every cell. Seen through genetics, it is the source of the hydrogen bonds that form the bases, sugars, and phosphates of DNA to RNA to Proteins. Crick and Watson's central dogma hypothesis. Each of the six atoms (HCNOPS) forms a fixed number of bonds. Hydrogen is the self-identity bond of every atomic molecular compound.

This Arc of this book the Big Bang to atoms to molecules to cellular organelles to the cell.At each step, the same events are described three different ways. At the chemical layer, the biological layer, and the informational genetic layer.

About 13.8 billion years ago, in the first minutes after the Big Bang, the universe cooled enough for protons and neutrons to bind. The products were hydrogen, about three-quarters of the mass of all atoms, helium, about one-quarter, and traces of lithium. Hydrogen is the first of the six elements that form most of the mass of a cell. The other five, carbon, nitrogen, oxygen, phosphorus and sulfur, were made inside stars. A star fuses hydrogen into helium. In the triple-alpha process, three helium-4 nuclei fuse into one carbon-12 nucleus. Adding one more helium-4 nucleus to carbon-12 gives oxygen-16. Nitrogen-14 builds up through the carbon-nitrogen-oxygen cycle of hydrogen fusion. Phosphorus-31 and sulfur-32 form in the carbon-, neon- and oxygen-burning stages of stars above about eight solar masses, and supernova explosions release these elements into space, where stars and planets form from them.

Seen through biology, it is the source of the atoms in every cell. Seen through genetics, it is the source of the atoms that form the bases, sugars and phosphates of DNA and RNA. Each of the six forms a fixed number of bonds at fixed angles. Hydrogen forms one bond. Oxygen forms two; in water, H_2O, they meet at 104.5 degrees. Nitrogen forms three; in ammonia, NH_3, it also holds one unshared pair of electrons, which lets ring nitrogens in DNA bases accept hydrogen bonds. Carbon forms four bonds arranged as a tetrahedron; in methane, CH_4, each angle is 109.5 degrees. Phosphorus in phosphate, PO_4^{3-}, sits at the center of four oxygen atoms, also arranged as a tetrahedron. Sulfur, below oxygen in group 16 of the periodic table, forms two bonds in hydrogen sulfide, H_2S, at about 92 degrees, and its oxidation state ranges from −2 in H_2S to +6 in sulfate, SO_4^{2-}. None of the six is flat. Each one points into space. At 2.4 billion years ago, the great oxidation event occurred. Which transitioned the sulfur economy into the oxygen economy. Is where RNA world turned into the DNA world through the sulfur enzyme of ribonucleotide reductase. The great event, the great divide in Earth's history, which changed sulfur to oxygen and water-based economies, which accelerated the evolution of eukaryote species. The great

© 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

divide between organic and inorganic chemistry.

At the molecular level these bond angles determine which molecules can bind to which. Water is the first matrix: the liquid in which the molecules of a cell dissolve and react. Because the molecule is bent, it carries a partial positive charge on the hydrogen side and a partial negative charge on the oxygen side, so it dissolves salts, carries ions and holds proteins in their folded shapes. The human body has the same water base. Water makes up about 60 percent of adult body weight. The vitreous humour of the eye, a gel, is about 99 percent water. About 99 percent of the body's calcium is stored in bone and teeth as hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$. The four tissue types, epithelial, connective, muscle and nervous, are built in water.

Before the great oxidation event, Earth's atmosphere contained almost no O_2, and organisms obtained energy from reactions of sulfur and iron compounds. Hydrogen sulfide served as an electron donor, and iron-sulfur clusters, such as the [4Fe–4S] cluster of ferredoxins, carried electrons between proteins. Cyanobacteria, using oxygenic photosynthesis, released O_2 as a by-product, and O_2 accumulated in the atmosphere between about 2.4 and 2.3 billion years ago. Sulfur isotopes in rocks record the change: mass-independent fractionation of sulfur isotopes, which forms only when atmospheric O_2 is below about 0.001 percent of the present level, disappears from the rock record at this time. Oxidative weathering then carried sulfate into the oceans.

Ribonucleotide reductase makes the building blocks of DNA from the building blocks of RNA. It removes the hydroxyl group at the 2′ carbon of the ribose sugar, turning a ribonucleotide into a deoxyribonucleotide. Every known class of the enzyme does this with a sulfur radical: a thiyl radical on a cysteine. In the class Ia enzyme of *Escherichia coli*, a radical on tyrosine 122 is generated at a di-iron center that requires molecular oxygen. The radical is transferred about 35 angstroms to cysteine 439, which removes a hydrogen atom from the 3′ carbon of the sugar. Two further cysteines supply the electrons and form a disulfide bond. The enzyme grips the ribonucleotide, carries out the chemistry and releases a deoxyribonucleotide. The anaerobic class III enzyme instead uses a glycyl radical made with S-adenosylmethionine and an iron-sulfur cluster. The author's hypothesis is that this sulfur enzyme is the step at which cells changed from storing genes in RNA to storing them in DNA, and that the oxygen-requiring class I enzyme links that step to the great oxidation event.

Carbon divides organic from inorganic chemistry. Organic chemistry is the chemistry of carbon compounds; by convention, carbonates, carbon dioxide and cyanides are treated as inorganic. In 1828 Friedrich Wöhler made urea, an organic compound, from ammonium cyanate, an inorganic salt, showing that an organic compound can be made from an inorganic starting compound.

The mitochondrion uses all six elements. It descends from an alphaproteobacterium taken up by a host cell, and the eukaryotic cell, with its nucleus and mitochondria, appears in the fossil record after the great oxidation event. The respiratory chain passes electrons through iron-sulfur clusters to oxygen, which is reduced to water. The released energy is stored as a proton gradient across the inner membrane, and that gradient drives ATP synthase. ATP synthase works by grip, turn and release: the proton flow turns its rotor, and each of its three catalytic sites in turn binds ADP and phosphate, forms ATP and releases it, giving about three ATP per 360-degree turn. Human mitochondrial DNA is a circle of 16,569 base pairs carrying 37 genes.

In the cell, protein synthesis starts at an AUG codon, which codes for methionine, a sulfur-containing amino acid; bacteria start with its formylated form, N-formylmethionine. Comparing ribosomal RNA

sequences, Carl Woese and colleagues in 1990 divided cells into three domains: bacteria, archaea and eukaryotes. The arc of the book begins with sulfur and ends in the eukaryote domain. The layers of tissues, organs, organ systems, and the human are not covered in this book.

Sulfur as the first principles layer

The Scientific Arc of Man's Evolution from the Big Bang to the Human Genome

A First-Principles Exploration of Sulfur Across Biochemistry, Molecular Biology and Biomedicine — the Genetic Code Letters (ATGCU) and the Eight Nucleotides of Actual Metabolism (IXGAUOCT)

PP-2026-MASTER-01 v332 · September 2026

The evidence volume, full length

Published by NovagonDNA, Naperville, Illinois.

First edition, 2026. Printed and distributed by the author.

What this book is, and who it is for

This volume is written from first principles rather than from the top down. Every argument is carried to the level of the atom and the bond, and no abstraction is

treated as adequate merely because it is standard. Where the literature says a codon, this book asks what a codon is made of, and then what that is made of, and does not stop until it reaches something that cannot be taken apart any further.

That method is the contribution this volume offers. The findings in it — the sulfur inventory across every level of organization, the case for eight nucleotides where the code prints four, the orientation asymmetry at the wobble, the sulfur and magnesium partnership at the carriers, and the four ways a modern editing tool is aimed by a notation that omits the chemistry — are what the method produced. The findings are offered for checking. The method is offered for use.

The book expects scientific literacy but not specialist standing in any one field. A structural biologist can read the metabolism, a clinician can read the chemistry, a geologist can read the biology, and no reader is expected to be at home in all of it. What its readers have in common is not a credential but a question: whether a four-letter description is sufficient to carry what the molecules are actually doing.

Twenty words this book cannot do without, in plain English

Some technical words in this volume cannot be replaced, because they are the names of the things themselves and a reader who wants to check a claim against the literature will need them. Every one of them is defined here, once, in ordinary language. Nothing else in the book requires a specialist vocabulary.

the word	the meaning
canonical	The standard four. When this book says the canonical bases it means A, T, G and C — the ones with letters. Everything else in a cell is real and has no letter.
de novo	Built from scratch, atom by atom, starting from small molecules. The opposite is salvage, which means taking apart something that already exists and re-using the pieces.
salvage	Recovering a base or a nucleotide that has already been made once and putting it back into service instead of building a new one.
degeneracy	More than one codon spelling the same amino acid. Six different codons all mean leucine. The code has spare spellings.
topology	The shape a long molecule takes when it is twisted, coiled or knotted, as distinct from the order of its letters. Two identical sequences can be wound differently, and the winding changes what can reach them.
supercoiling	DNA wound tighter or looser than it would sit on its own. Cells keep their DNA underwound, and how tightly a stretch is wound changes how easily anything can pry it open.
wobble	The third letter of a codon, where the pairing rules are loose. One transfer RNA can answer two or three different codons at that position, and which ones depend on

the word	the meaning
	chemistry the letters do not show.
anticodon	The three-letter stretch on a transfer RNA that pairs with a codon on the message. It is the tRNA's own address label.
residue	One amino acid after it has been joined into a protein chain. Chemists say residue rather than amino acid once it is part of a chain, because joining it removed a water molecule.
thioester	A bond between a carbon and a sulfur that stores a great deal of energy and gives it up readily. Acetyl-CoA is the famous one. An ordinary ester uses oxygen instead and holds on much more tightly.
phosphodiester	The bond that links one nucleotide to the next along a strand of DNA or RNA. It is the backbone, and it is made of phosphorus and oxygen.
deamination	Removing an amino group — an NH2 — from a base. It is a subtraction, and it changes what the base is: cytosine becomes uracil, adenine becomes inosine.
isomer	Same atoms, arranged differently. Pseudouridine has exactly the same atoms as uridine, rotated, and the cell treats them as different molecules.
chirality	Handedness. A molecule and its mirror image can be as different to an enzyme as a left glove is to a right hand.
cofactor	A helper the enzyme needs but is not made of. Magnesium, iron and the vitamins are cofactors. The enzyme cannot work without them and does not contain them permanently.
coordinated	Held in place by attraction rather than joined by a shared pair of electrons. A metal in an enzyme is coordinated. A carbon in a sugar is bonded. The difference decides whether the atom can leave.
covalent	Joined by a shared pair of electrons — a real bond that has to be broken to come apart. The seven colored atoms in this book are covalently part of the molecules they appear in.
in vitro, in vivo, in silico	In a tube, in a living thing, and in a computer. Results from the three are not interchangeable and this volume says which one it means.
ensemble	A molecule that folds does not have one shape. It has a population of shapes it moves between, and the ensemble is that whole population. A drug may bind one member of it and not another.
promiscuity	An enzyme or a drug binding to more things than it was supposed to. It is the usual cause of a side effect.
pseudogene	A gene that was working once and has been broken by a mutation. The sequence is still there and can still be read; the protein is never finished. Human uricase is one.

A note on the color index

Every shaded word in this volume is a hyperlink to the color index. One color, one element, one base, throughout. The colors are one-to-one labels assigned by mapping, not by measurement; spectral order carries no meaning. Hydrogen = red is the single assignment with a physical basis, the Balmer-alpha line at 656 nanometers. Element symbols appear alongside the colors so that no figure depends on color alone.

A note on the method

Every Part of this volume ends by stating the conditions under which it would be wrong. Where a finding was not reproduced, where a trial missed its endpoint, where a mechanism was later revised, and where this volume changed its own mind, the record is printed rather than omitted.

A note on the spelling

This volume uses sulfur throughout. IUPAC standardized on sulfur in 1990 and the Royal Society of Chemistry followed in 1992. The older form is used here by the author's decision, and the etymological record is set out in the Handoff paper: sulfur was never the etymologically correct form, and the ph never stood for phosphorus.

Table of Contents

179 divisions and 1753 numbered sections, listed in full

Parts are listed flush left. The numbered sections within each Part are listed beneath it, indented. Every section in this volume carries a number, and the numbering runs unbroken from one to 1753. The footer of every page carries a live link back to this table, to the Index and to the Color Index.

584. The Question This Part Answers	784
585. The Purine Square	785
586. The Pyrimidine Square	786
587. Where the Correspondence Fails: X Is Inside, O Is Outside	787
588. What Each Gatekeeper Carries: an Atom Kept, an Atom Discarded	788
589. The Third Hydrogen Bond Is Installed by the Detour Through Xanthine	789
590. The Methyl on Thymine Is Not a Hydrogen Bond	790
591. The Left Branch of Both Squares Is the Same Operation	791
592. The Crossing	792
593. Two Graphs on Eight Nodes	793
594. What This Settles About the Color Scheme	794
595. What Is Claimed and What Is Not	795
596. What Would Show This Part Is Wrong	797
Part Eighty-Two · The Wobble Paper	797
597. The Paper, and What It Proposed	798
598. The Five Candidate Pairs, and the One He Ruled Out	799
599. The Geometry: Two Point Five Ångströms	800
600. One Hundred and Twenty-Seven Combinations Reduced to Seven	800
601. Table One	801
602. Inosine Reads Three and Excludes G — Crick's Own Sentence	802
division · section	page
603. The Footnote That Predicts Adenosine Will Not Be There	803

division · section	page
604. The Three Yeast Anticodons, All Beginning with I	805
605. Sanger's Letter: Little Inosine in E. Coli	806
606. What Crick Did Not Know	807
607. What the Volume Takes	808
608. What Is Claimed and What Is Not	809
609. What Would Show This Part Is Wrong	811
Part Eighty-Three · The Branch Point Enzyme	811
610. Where the Volume's Inosine Came from	811
611. The Enzyme at the Branch Point	813
612. Twelve Cell Lines, Two Inhibitors, One Result	814
613. What Happens to the Nucleotide Pool	815
614. The Substrate Accumulates Five-fold	816
615. Guanosine Reverses It, and Only for the First Two Days	817
616. The Compensation: the Cell Makes More of the Enzyme You Are Blocking	818
617. Hypoxanthine in DNA, and the Enzyme That Removes It	819
618. The Repair Enzyme Is Bad at Its Job	820
619. The Human Enzyme Has a Base-pair Preference the Bacterial One Does Not	822
620. P53 Works Through This Enzyme	823
621. What the Three Papers Say Together	824
622. What Is Claimed, What Is Not, and What Would Show This Part Wrong	826
Part Eighty-Four · The Immortal Strand	828
623. Two Enzymes, Two Papers, One Letter	829
624. The Stem Cell Hypothesis, and the Thousand-fold	829
625. Xanthosine Runs the Switch Backward	830
626. The Transfectant Experiment: Hold the Enzyme Up and P53 Cannot Act	831
627. The Sensitivity, Recomputed	832
628. The Nci60 Result, and the Control That Came Out Backward	834
629. Four Editors from One Gene	835
630. The Alu Cassette Inside the Editor	836
631. But the Alu Is Not the Active Part	837
632. Which Isoform Edits Which Site	838
633. Chromosome 21, and Who Paid for It	839
634. What the Two Papers Say Together	840
635. What Is Claimed, What Is Not, and What Would Show This Part Wrong	842

division · section	page
Part Eighty-Five · The Glutamate Receptor	844
636. The Paper in Full, and a Correction to Part Eighty-Four	844
637. Two Recoding Events, Two Codon Positions	845
638. What the Amino Acid Change Does to the Channel	846
639. The Accuracy Analysis: Eighteen Clones, Site by Site	847
640. The Sites Edited in Vitro That Are Not Edited in the Brain	848
641. All Five Enzymes Bind Identically	849
642. Sixty Percent of the Transcripts Encode a Dead Enzyme	850
643. The Alu, and What the Authors Say About It	851
644. Alu Inside More Than a Dozen Protein-coding Genes	852
645. Two Binding Motifs Against Three, and the Spacing	852
division · section	**page**
646. Salt Sets the Site	853
647. What the Volume Takes	854
648. What Is Claimed, What Is Not, and What Would Show This Part Wrong	855
Part Eighty-Six · The Sanitizer	858
649. The Enzyme This Volume's Author Named in 2000	858
650. How they Found It: a Bead with Itp on It	859
651. Twenty-Nine Nucleotides, and What It Will Not Touch	860
652. The Kinetics, Recomputed: the Diphosphate, Not the Triphosphate	861
653. Nudt16 Against Itpa: Affinity Against Capacity	862
654. Where It Works: the Nucleolus	863
655. One Protein, Two Jobs	864
656. Knock It Down and Inosine Rises in the RNA	865
657. The DNA Breaks, and Only on One Strand	866
658. Inosine in RNA Is Fifty Times More Abundant Than in DNA	867
659. The Mouse and the Human Do Not Agree	868
660. What the Volume Takes	869
661. What Is Claimed, What Is Not, and What Would Show This Part Wrong	871
Part Eighty-Seven · The Ratio	873
662. A Mathematical Model of the Pathway This Volume Is About	874
663. What the Model Is Made of	874
664. Ranking the Causes of Gout	875
665. The Kidney Beats the Enzyme Twenty-Six to One	877
666. Two Thresholds: Two Percent and Nought Point Two Percent	877

division · section	page
667. The Ratio Separates Where the Activity Does Not	878
668. Family P and Family I	880
669. What the Guanylate Pool Does to Nucleic Acid Turnover	881
670. One Metabolite Moves and Nothing Else Does	882
671. Two Diseases, Two Disjoint Sets of Variables	883
672. The Author's Annotations on Scheme One	884
673. What the Volume Takes	885
674. What Is Claimed, What Is Not, and What Would Show This Part Wrong	886
Part Eighty-Eight · Six Hundred and Forty-Two Fold	888
675. The Direct Measurement	889
676. What Was Counted	890
677. Wild Type: Nine Times More Hypoxanthine in RNA Than in DNA	891
678. Six Hundred and Forty-Two Fold	891
679. Xanthine Does Not Move	892
680. The Synergy: Single Mutants Do Almost Nothing	893
681. Yeast Gives the Same Answer	894
682. The Repair Enzymes Make No Difference, and the Authors Say So	894
683. Why Xanthine Is Refused, and a Second Enzyme That Sorts the Purines	895
684. Fifty Percent, and One Person in Six	897
685. The Author's Annotations: Ferredoxin, Thioredoxin, Cysteine	898
686. What the Volume Takes	899
687. What Is Claimed, What Is Not, and What Would Show This Part Wrong	900
Part Eighty-Nine · The Missing Base	903
division · section	page
688. The Enzyme That Deletes the Base It Came to Replace	903
689. What Tgt Does, and the Four TRNAs It Does It to	904
690. How the Damage Was Found	905
691. The Genetics: Tgt Required, PreQ1 Supply Decisive	906
692. The Organisms with No Queuosine Have No Damage	907
693. The Stalled Intermediate, Caught in Vitro	908
694. Stress, and Oxidative Stress Most of All	909
695. Brain, Lung and Spleen	910
696. The Damaged TRNA Is Excluded from the Ribosome	911
697. Four Chemical States, One Letter	912
698. The Sulfur Modifications in the Same Paragraph	913

division · section	page
699. What the Volume Takes	914
700. What Is Claimed, What Is Not, and What Would Show This Part Wrong	915
Part Ninety · The Axis at Thirty-Seven	917
701. The Axis, and What It Connects	917
702. The Energy Bill for One Peptide Bond	918
703. Why Position 37 and Not Position 34	919
704. Lysidine: One Modification, Two Specificities, Both Flipped	920
705. And in Eukaryotes, Inosine Makes the Whole TRNA Unnecessary	921
706. Cysteine 37: the Identity Matters and the Modification Does Not	922
707. M¹G37 and the Two Frameshifts	923
708. Position 37 Governs What Position 34 Can Read	925
709. T⁶A37, and the TRNA That Does the Most Work	926
710. Diet, Stress, and the Enzymes That Install Them	927
711. The Minimal Set	928
712. What the Volume Takes	930
713. What Is Claimed, What Is Not, and What Would Show This Part Wrong	931
Part Ninety-One · Thirty Seconds	934
714. The Measurement	934
715. What Happens in Thirty Seconds	935
716. The Deamination, and a Stoichiometry That Checks Twice	936
717. The Purine That Goes Missing	937
718. The Number That Matches	938
719. And Then, in the Second Five Minutes, It Behaves	939
720. Why the Inosine Monophosphate Will Not Clear	940
721. And Salvage Loses the Race	941
722. Ammonia, and Where the Nitrogen Goes	941
723. What This Part Is and Is Not	942
724. What the Volume Takes	943
725. What Would Show This Part Is Wrong	944
726. What Is Claimed and What Is Not	945
Part Ninety-Two · Forty and Sixty-Five	947
727. The First Paper in the First Issue	947
728. Crick Noticed It, and Holley's Molecule Already Had It	948
729. Where G·u Appears	949
730. The Geometry: Forty Degrees and Sixty-Five	950

division · section	page
division · section	page
731. G·u and U·g Are Not the Same Object	951
732. The Electrostatic Hole, and the Metal That Binds in It	951
733. Nearly as Stable as Watson-crick, and That Is Not Enough	953
734. Conformationally Soft, and Recognized by Induced Fit	953
735. What the Synthetase Actually Touches	954
736. Selection from Ten to the Fourteenth Finds It Anyway	955
737. The Selenocysteine Exception	956
738. What the Volume Takes	957
739. What Is Claimed, What Is Not, and What Would Show This Part Wrong	958
Part Ninety-Three · The Other Oxygen	961
740. The Question That Started This Part	961
741. The Two Pairs, Atom by Atom	962
742. The Other End of the Ring	962
743. And That Is Why the Pocket Is There	963
744. The Angles, Measured a Third Time	964
745. The Rule Generalizes: Purine Down, Pyrimidine Up	965
746. Sixteen Steps, Ten Energies	966
747. The Four That Cannot Escape	966
748. The Wobble Steps	967
749. What Context Is Worth	968
750. The Distinction the Volume Must Not Blur	969
751. The Third Position and the Protein Fold: What Is Not True	969
752. What Is True, and What This Part Claims	970
Part Ninety-Four · Both Faces	972
753. The Six Papers	973
754. The Correction Owed to Part Ninety-Three	973
755. The Amine in the Minor Groove	974
756. Two and a Half Kilocalories, and Why Geometry Is the Variable	975
757. The Amine Works Twice	976
758. The Instrument Is Inosine Carrying a Sulfur	976
759. Which Amines Are Essential	977
760. The Metal, Seen in the Crystal	978
761. The Metal, Seen in Solution	979
762. A Second Correction: Which Atoms Hold the Metal	979
763. The Synthetase and the Ribozyme Read the Same Amine	980

division · section	page
764. One Hundred and Twenty Sites	981
765. What This Part Claims	982
Part Ninety-Five · The Last Purine	984
766. The Paper, and Why It Is Here	984
767. The Model and the Dose	985
768. What Inosine Did to the Damage	986
769. A Purine Restores a Sulfur	987
770. The Enzymes That Do Not Do It	987
771. Inosine Turns on the Eraser	988
772. Protection by Exaggeration	989
773. The Causal Test, and the Honest Split	990
division · section	page
774. What they Looked for and Did Not Find	991
775. The End of the Purine Square Is an Antioxidant	991
776. The Enzyme Is Held Together by Sulfur	992
777. One Atom, Two Phenotypes	994
778. And in Us It Is a Dead End, by Deletion	996
779. The Mutation That Did It Was a Deamination	997
780. What This Part Claims	999
Part Ninety-Six · The Antigen That Isn't There	1001
781. The System, and Why It Is in This Volume	1001
782. There Is No O Antigen	1002
783. One Sugar Is the Whole Difference	1003
784. The O Allele Is a Broken a Allele	1003
785. The Bombay Phenotype: When O Is a Misreading	1004
786. The Simplicity Claim, and Why This Volume Refuses It	1005
787. What the Razor Actually Says	1006
788. Where Economy Does Operate	1007
789. Counting the Substituents on the Purine Ring	1007
790. The First Complete Purine, and Where Its Oxygen Came from	1008
791. The Bare State, Reached from Two Directions	1009
792. Truncation Makes the Bare State	1010
793. What This Part Claims	1011
Part Ninety-Seven · The Door They All Come Through	1013
794. What the Annotation Found	1013
795. The Molecule	1014
796. The Enzyme That Makes It, and Where Its Genes Sit	1015

division · section	page

798. The Fork Is Purine Against Pyrimidine	1016
799. And It Is Not a Symmetric Fork	1017
800. The Correction to the Annotation	1018
801. The Slowest Reaction Life Ever Learned to Hurry	1018
802. The Record, and Who Holds It Now	1020
803. Both Rings Take Their Carbonyl from Bicarbonate	1022
804. Too Much and Too Little	1023
805. The Salvage Enzymes Are All One Reaction	1024
806. Why Ninety-Six Parts Missed It	1025
807. What Is Integrated, and Where	1026
808. What This Part Claims	1027
Part Ninety-Eight · The Empty Cupboard	1029
809. The Annotation in the Checkpoint Figure	1030
810. What Michal's Trigger List Actually Says	1030
811. The Valve on the Supply	1031
812. The 2025 Experiment	1032
813. What the Checkpoint Actually Reads	1032
814. The Cascade, and Where It Stops the Cell	1033
815. The One Inducible Repair Gene Michal Names	1034
816. A Suicide Enzyme That Moves a Methyl Onto a Sulfur	1034
division · section	page
817. The Guardian and Its Failure Rate	1036
818. Two Fidelities, Five Orders of Magnitude Apart	1036
819. The Code as an Error Budget	1037
820. Where This Meets Part Ninety-Five	1038
821. What This Part Claims	1038
Part Ninety-Nine · The Map and the Marks	1040
822. The Source, and What the Annotations Asked	1040
823. Thymine, in RNA	1041
824. The Methyl Comes from the Sulfonium Again	1042
825. And the Other Modification on the Same Loop Is a Rotation	1043
826. The Second Messengers Are Named After the Bases	1044
827. And the Stringent Signal Is a Guanine with Four Phosphates	1044
828. The Color Scheme Extends Without Modification	1045
829. The Four-way Junction	1046
830. Two Ways to Cut the Same Structure	1046

division · section	page
831. The Torsion Arithmetic, and Why the Volume Refuses the Inference	1047
832. The Figure-Eight, Held in Abeyance	1048
833. What Is Omitted	1049
834. What This Part Claims	1050
Part One Hundred · The Shape With No Shadow	1051
835. The Question, and What Was Already Settled	1051
836. There Is No Sixty-Four-cell	1052
837. But Sixty-Four Is the Right Number for Something Else	1053
838. The Same Cube, Re-coordinatized	1054
839. The Labeled Tetrahedron Is Chiral	1055
840. And the Labeled Cube Has Forty-Eight Forms	1056
841. Two Cubes, Offset, Is a Real Crystal	1058
842. Two Cubes, in Four Dimensions, Is the Tesseract	1058
843. The One Figure with No Shadow	1059
844. And Its Vertices Are the Quaternions	1060
845. The Arithmetic, and What Part Seventy Already Printed	1061
846. The Coincidence This Part Refuses	1062
847. What This Part Claims	1063
Part One Hundred and One · The Letters and the Ledger	1065
848. The Distinction That Preceded the Question	1065
849. The Collapse, Counted	1066
850. The Degeneracy Blocks Are Not an Orbit	1067
851. The Second Step Is Not Base Pairing	1068
852. Twenty-Two Does Not Close It	1068
853. The One Amino Acid with No Synthetase	1069
854. And the Twenty-twos Are Different Twenty-twos	1070
855. An Eight-letter Genetic System Exists	1071
856. And It Could Not Use This Volume's Eight	1071
857. Nature's One Attempt Was a Substitution	1073
858. And the Discrimination Was Not in the Polymerase	1074
859. What an Index Is and What a Code Is	1074
division · section	page
860. What This Part Claims	1075
Part One Hundred and Two · The Period Belongs to the Particle	1077
861. What This Part Corrects, and on Whose Instruction	1078
862. The Seven Hundred and Twenty Degrees Is Real, and It Was	1078

division · section	page
Measured	
863. What a Spinor Claim Has to Satisfy	1079
864. The Sugars Fail All Four	1080
865. And the Sugar's Real Rotation Closes at Three Hundred and Sixty	1080
866. What Section 110 Keeps	1081
867. The Torsion Claim Scored Higher, and Was Refused First	1082
868. Where Spin One-half Actually Is in a Nucleotide	1082
869. But Proton Transfer Is Translation, Not Rotation	1083
870. The Methyl Group Is the Exception	1083
871. And Its Number Is Three, Not Seven Hundred and Twenty	1084
872. The Measurement Nobody Has Made	1085
873. What This Part Claims	1086
Part One Hundred and Three · The Mark Decides Where	1087
874. The Claim This Part Refuses, and the One It Makes	1087
875. Both Currencies Are Carried on Sulfur	1088
876. What the Methyl Actually Does to the DNA	1088
877. The Numbers	1089
878. And the Repair That Almost Works	1089
879. The First Worked Example — Uricase	1090
880. The Second — Mocos, at the Other End of the Same Pathway	1090
881. And the Third Example Is This Volume's Own Color Scheme	1091
882. Why This Is Not Lamarck, Stated in Full	1091
883. And Why Off-target Is the Same Problem in Reverse	1092
884. What the Notation Loses Here	1092
885. The Experiment This Part Generates	1092
886. What This Part Claims	1093
Part One Hundred and Four · The Step Where the Chemistry Is Converted	1095
887. The Pipeline, and Where It Is Drawn	1095
888. The Step Where the Chemistry Is Converted	1095
889. The Field's Own Statement of the Problem	1096
890. What Each Modification Becomes	1096
891. And the Error Rates Were Measured	1097
892. The Enzyme Decides the Letter, Not the Molecule	1097
893. Which Makes Detection a Side Effect of a Defect	1098
894. The Correction the Field Has Already Built	1098
895. The Error Is Type Two	1099
896. What This Part Refuses to Claim	1099

division · section	page
897. What the Notation Loses Here	1100
898. The Experiment This Part Generates	1100
899. What This Part Claims	1101
Part One Hundred and Five · The Map Has No Third Dimension	1102
900. What a Metabolic Map Actually Records	1103
901. The Question This Part Answers	1103
division · section	page
902. The Model That Exists	1104
903. And Why It Cannot Be Applied Here	1104
904. The Scale Gap, Measured	1105
905. But Compartmentation Is the Gap That Matters	1105
906. Gravity Does Nothing, and Here Is the Number	1106
907. What Does Dominate Instead	1107
908. And the Sensing the Question Was Reaching for	1107
909. The State of the Field, Stated Plainly	1108
910. What This Part Does Not Claim	1108
911. The Experiment This Part Generates	1109
912. What This Part Claims	1109
Part One Hundred and Six · The Atom That Holds the Charge	1110
913. The Correction This Part Exists to Make	1111
914. The Number That Was Written Down Once	1111
915. The Substrate Is Not ATP	1112
916. The Atom at the Center of the Light	1113
917. The Heat That Is Not a Volcano	1113
918. And the Field That Proves It	1114
919. And the Pacific	1114
920. What Each Atom Can and Cannot Do	1115
921. Why This Volume Is Not a Sulfur-only Volume	1116
922. The Band	1116
923. What This Part Refuses	1117
924. The Experiment This Part Generates	1118
925. What This Part Claims	1118
Part One Hundred and Seven · The Carrier Is Always Adenosine	1119
926. The Question, and Why It Was Asked	1120
927. The Enzyme That Makes the Sulfonium	1120

Part One Hundred and Thirty-Nine · Two Codes in One Cell	1387
1347. Two Dictionaries, One Cytoplasm	1388
1348. The Four Deviations	1388
1349. There Is No Single Genetic Code	1389
1350. Twenty-Two Transfer RNAs for Sixty Codons	1389
1351. And the Seat That Pays for It Is Made of Sulfur	1390
1352. The Enzyme That Installs the Second Sulfur	1390
1353. The Molecular Surgery	1391
1354. What UGA Means, in Three Places	1392
1355. Where the Software Fails	1392
1356. The Contaminant Nobody Has Solved	1393
1357. What the Notation Loses Here	1393
1358. What This Part Refuses	1394
1359. The Experiment This Part Generates	1395
1360. What This Part Claims	1396
Part One Hundred and Forty · The Reader, the Demand, and the Population	1397
1361. Three Things That Were Not in This Volume Yesterday	1398
1362. The Reader	1398
1363. What the Reader Does Not Establish	1399

division · section	page
1364. The Demand	1400
1365. The Population	1400
1366. Thirty Thousand Editing Quantitative Trait Loci	1401
1367. The Direction of the Effect	1401
1368. And the Cell Cycle Stops Without It	1402
1369. The Disease of Inosine in the Wrong Place	1403
1370. The Question the Tunneling Literature Leaves Open	1403
1371. What the Notation Loses Here	1404
1372. What This Part Refuses	1405
division · section	page
1373. The Experiment This Part Generates	1406
1374. What This Part Claims	1407
Part One Hundred and Forty-One · Twenty-One Genes With No Pathway	1408
1375. The Partition	1409
1376. What the Relay Map Is Filed Under	1409
1377. And the Two Maps Do Not Point at Each Other	1410
1378. Twenty-One Genes With No Pathway At All	1410
1379. But KEGG Has Not Overlooked It	1411
1380. And Neither Has Anyone Else	1411
1381. So the Claim Is Narrow	1412
1382. The Organelle That Crosses All Three	1412
1383. What Enrichment Can and Cannot Report	1412
1384. The Arithmetic, and a Prediction That Failed	1413
1385. What the Notation Loses Here	1413
1386. What This Part Refuses	1414
1387. The Experiment This Part Generates	1414
1388. The Remedy Is a Gene Set	1415
Part One Hundred and Forty-Two · The Ring That Decides	1416
1389. The Peptide and the Ring	1416
1390. What the Ring Is Made Of	1416
1391. Change the Topography, Change the Drug	1417
1392. And the Same Result in the Sister Peptide	1418
1393. Where the Literature Disagrees With Itself	1418
1394. One Gene, Two Hormones	1419
1395. And the Same Cell Makes Both	1419
1396. One Receptor Protein, Two Pharmacologies	1419
1397. What the Gepants Do Not Tell Us	1420

division · section	page
1398. What the Notation Loses Here	1420
1399. What This Part Refuses	1421
1400. The Experiment This Part Generates	1422
1401. What This Part Claims	1423
1402. Why This Part Is Short	1424
Part One Hundred and Forty-Three · The Receptor Reached From Both Sides	1424
1403. Twenty-Five Positions, and Only One of Them Matters	1425
1404. The Codon the Brain Does Not Use	1425
1405. What the Notation Records and What the Channel Does	1426
1406. The Same Receptor Family, Reached Through Sulfur	1426
1407. A Thiol Is Not a Strut	1427
1408. The Switch With Three Competing Inputs	1427
1409. Two Strata, Not One Convergence	1428
1410. What the Notation Loses Here	1429
1411. What This Part Refuses	1429
1412. The Six Residue Numbers This Part Will Not Print	1430
1413. What Would Show This Part Is Wrong	1430
1414. The Experiment This Part Generates	1431
1415. What This Part Claims	1432
division · section	page
1416. Why This Part Sits Here	1432
Part One Hundred and Forty-Four · The Bond Was Older Than the Code	1432
1417. The Reaction Happens Without the Machine	1433
1418. The Fragment Reaction	1434
1419. Ten Million Times Faster, and No Catalytic Residue	1434
1420. What the Enzyme Commission Already Knew	1435
1421. Ester to Amide, and Thioester to Ester	1436
1422. Why the Acyl Donor Is a Carbon-Sulfur Bond	1436
1423. Two Strata, and Which One Came First	1437
1424. What the Notation Loses Here	1438
1425. What This Part Refuses	1438
1426. What Would Show This Part Is Wrong	1439
1427. The Experiment This Part Generates	1439
1428. What This Part Claims	1440
1429. Why This Part Comes After the Receptor	1440
1430. The Sentence This Volume Has Been Circling	1441

division · section	page
Part One Hundred and Forty-Five · The Same Two Atoms, Three Times Over	1441
1431. The Acid in the Urine Is a Thioester That Got Away	1441
1432. But Type I Is the Small Door	1442
1433. The Second Gene on That List Is an Acyltransferase	1442
1434. What Is Not Known, and Is Printed Rather Than Smoothed Over	1443
1435. The Pump Is the Cell's Largest Single Customer	1443
1436. And That Pump Is Held Shut by a Thiol	1444
1437. Why a Failing Pump Becomes a Seizure	1445
1438. One Gene Where All Three Meet	1445
1439. The Inosine Family Reaches the Same Clinic by Its Own Road	1446
1440. The Seam: One Drug That Is All Three at Once	1447
1441. What the Notation Loses Here	1448
1442. What This Part Refuses	1448
1443. The Experiment This Part Generates	1448
Part One Hundred and Forty-Six · The Window Was Made of Lipid	1449
1444. Forty-Seven to One	1449
1445. Shape Decides, Not Only Chemistry	1450
1446. The Paper Does Not Ask Why	1451
1447. Seyfried's Lipid	1451
1448. Immature Means Unremodeled	1452
1449. Which Names an Enzyme Already in This Volume	1452
1450. The Prior Art, Before the Argument Goes Further	1453
1451. What Is Still Open	1454
1452. What the Notation Loses Here	1454
1453. The Experiment This Part Generates	1455
1454. What This Part Refuses	1455
Part One Hundred and Forty-Seven · The Nucleotide Decides Where the Nitrogen Goes	1456
1455. A Correction on One Word	1456
1456. Glutamate Dehydrogenase Is a Deaminase	1456
1457. Seyfried Proposes It; the Enzymology Has Measured It	1457
division · section	page
1458. The Duplicate That Escaped the Purine	1458
1459. So the Branch Point Is Upstream	1458
1460. And It Closes Into a Circuit	1459
1461. The Thioester Pays for the Switch	1459
1462. What the Notation Loses Here	1460

I want to say at the outset how the argument in this book was arrived at, because the method is unusual and because a reader is entitled to know what produced the thing he is holding.

It was not planned. There was no outline. I did not set out to write about sulfur and did not know for most of the twenty-nine years that sulfur was what this was about.

It starts with a subject, and then goes down

I begin with a subject I want to understand — in this case the genetic code — and then I do what I have always done, which is to take it apart. I ask what a codon is made of. Then what a base is made of. Then what holds a base together, and what that is made of, and why it takes the shape it does rather than some other shape.

Each answer is a level, and each level has a level beneath it, and I keep going down asking why until I reach a place where the question has no answer to give. Below the quark and the lepton there is nothing further to ask about. There is no next level down. The descent stops there, not because I lost interest but because the floor is the floor.

That floor is what I mean by first principles. Not a slogan and not a style of argument — a literal place where the questions run out, reached by going down until they do.

Then two edges, fixed at the boundaries

Having gone down as far as there is to go, the next question is where the whole thing begins and where the part of it that concerns us begins. Those are two different questions and they gave me two edges.

edge	what it is	why it bounds the work
The beginning of everything	the origin of the universe	the outer boundary; nothing precedes it
The beginning of us	the origin of life on this planet	the inner boundary; the subject of this book starts here
The floor	the quark and the lepton	the lower boundary; no level exists beneath it

On the wall those two edges are physical objects. The origin of the universe is at the upper left. The origin of life on Earth is at the lower left. They were placed there deliberately and they were placed there late — after most of the middle already existed, when I realized the argument needed a beginning at each end and had none.

They are the only two positions on seventy-two square feet that were chosen on purpose. Everything else went wherever there was room.

And then it accretes

Between the floor and the edges, everything else got added by adjacency. Not spatial adjacency — conceptual. I would take something I had just understood and ask what feeds into it and what comes out of it, and those two things would go up next, and then I would ask the same question of them.

If the space to the left was already occupied, the next piece went wherever the wall was open. There is no reading order. Anyone who tries to read that wall from left to right, as though it were a sentence, will construct a narrative that was never there. Two such readings have been attempted and both were wrong.

What the wall has instead of a layout is a topology: a subject at the middle, a floor beneath it, two edges at the boundary, and several thousand elements between them held together by what leads to what. The pictures do that holding. The titles are labels on the pictures. A reader who catalogs the titles and skips the images has copied out the index and missed the book.

It was not a conscious design process. It was built in small steps, one push-back at a time, until a whole appeared that nobody had planned.

Which is how this book was written, and I mean that precisely

Every substantial part of this volume arrived the same way. Something would not sit right, I would push back on it, and the pushing back would open a door I had not known was there.

what it became	where it started	how it got here
Sulfur and oxygen as conjugate partners	was not in any plan	it appeared when the two elements would not stay separate, and the book reorganized around it
Inosine as oxygen's mark on the purine	was not foreseen	it followed from the conjugate framing within an hou the framing existing
The subtractive account of origins	began as an objection	the objection was to a piece of arithmetic and ended eighty years of literature on retrograde evolution
The material-requirement model	began as an irritation	with a diagram that names no atom

None of those were chapters I sat down to write. They are what was left standing after something had been argued with. The book grew the way the wall grew, because the same person made both of them the same way, and I did not notice the

resemblance until somebody pointed at a photograph of the wall and asked me where the center was.

What the center turned out to be

I could not answer that question quickly, which should have told me something. When I did answer it, the answer was a book jacket at the middle of the wall: The Lives of a Cell, by Lewis Thomas, published in 1974.

It was not the first thing I put up. It is where the center turned out to be, visible only once the whole surface could be seen at once. Thomas argues in that book that a cell is not one organism but a community, and that the mitochondrion living inside our cells is a guest rather than a part of us.

A wall about how matter becomes life, grown outward over three decades, with a book about life being collective at the middle of it. I did not put it there for that reason. It ended up there.

Why the Method Is Stated, and Not Just Used

Two things it is fair to hold against this book, and one thing that follows from it

A method like this has a specific weakness and it should be named here rather than discovered by a reader who then wonders why it was concealed.

What accretion is bad at. A structure grown by conceptual adjacency will be strong wherever the author's attention went and thin wherever it did not, and the author is the last person able to see which is which. A designed structure has gaps that can be enumerated because the design says what should be present. An accreted one does not. This is why the volume states its refutation conditions at the front rather than the back, why each part carries a box saying what it does not establish, and why the experimental program is written as instructions somebody else can follow. Those are not modesty. They are the compensations this method requires.

And what it is good at. It crosses boundaries that a planned structure will not, because it follows what leads to what rather than what belongs to which field. The sulfur economy of the cofactors, the wobble position of the adaptor, the isotope record of the Great Oxidation Event and the enzymology of methyl transfer are studied by four sets of people who do not read each other. Nothing in a conventional

research design would have put them in one argument. Adjacency did, because each one is chemically next to the one before it.

The one thing that follows is a request. This book asks to be read the way it was made — by asking of each claim what feeds into it and what comes out of it, and by following that rather than the chapter numbers. The parts are numbered because a book must be, not because the argument runs in a line.

The wall has no reading order and neither, honestly, does the thing it produced. What both have is a floor, two edges, and a great many things that lead to one another.

The Claim, in One Paragraph

Sulfur made life possible. Not helped — made possible. The enzyme that produced the first molecule of DNA is a sulfur enzyme. The molecule that protects every cell in your body from being burned by oxygen is a sulfur molecule. The bonds that hold a protein in its working shape are sulfur bonds. The drugs that treat cancer, ulcers and infection attack sulfur atoms. And the four-letter alphabet that every biology student learns in the first week — A, T, G and C — has no letter for sulfur, no place to write it, and no way to say that it is there.

This paper is about that gap. It argues from first principles that the element is fundamental and the notation is not, and it says what experiments would prove it wrong.

What first principles means here, and why it is the method

First-principles reasoning means this: take a system apart down to the quantities that physics and chemistry actually fix — the electrons, the bond angles, the energies — and rebuild the argument upward from those, rather than accepting what convention says because convention has always said it.

It is the method an engineer uses when he refuses to accept that a battery costs six hundred dollars per kilowatt-hour, prices the raw metals on the commodity exchange instead, and finds a number nobody had computed. The convention was not wrong about what batteries cost. It was wrong about what they had to cost.

Applied here, the question is not what the four letters say. The question is: what atoms must be present before any letter can be read at all? That question has never been asked of the genetic code as a whole, and this paper asks it.

The four letters are not a fact about chemistry. They are a fact about what a laboratory could purify in 1953. This paper starts one level below the letters, at the atoms, and builds up.

The thread that runs the length of this volume

Sulfur has a partner, and the partnership is the plot of this book. Oxygen sits directly above sulfur in the periodic table — same column, same outer-shell arithmetic, same two bonds. They are conjugate: interchangeable in the architecture, never interchangeable in effect. Every place biology uses one, substituting the other changes what happens.

Their behavior is opposite in one crucial respect. Oxygen occupies one state and takes electrons out of circulation; sulfur occupies eight and passes them along. Oxygen is where flows end. Sulfur is how they travel.

That opposition produces three things this volume follows from beginning to end. It produced DNA, when a sulfur atom removed an oxygen from a sugar. It produced the Great Oxidation Event, which is dated not by measuring oxygen but by watching a sulfur isotope signal disappear from the rock. And it produced inosine — because inosine is what happens when an amine leaves adenine and an oxygen takes its place.

Sulfur is the protagonist. Oxygen is the antagonist that shares its face. Inosine is what oxygen leaves behind on the purine, and the cell took that piece of damage and made it into an instrument for reading the code.

PREFACE · THE BAND AND THE WALL

How this volume was built, and how to read it

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The Wall Came First

Nine feet by eight

Before there was a page of this volume there was a wall. Nine feet across, eight feet high, and covered edge to edge with hand-lettered cards, printed figures, photographs, pathway charts and arrows drawn between them.

It was not designed. It was accumulated.

how it grew	
one verified item at a time	nothing went up until it had been checked against a source
placed next to what it touched	position on the wall records relationship, not decoration
arrows added when a connection held	and left off when it did not
nothing removed to make the pattern neater	the contradictions stayed up where they could be seen

The wall was built the way the evidence arrived. Each item was pushed back on before it was pinned up, and each one had to survive contact with the ones already there.

Seventeen photographs of the physical object are reproduced in the plates. They are records of a method, not evidence for a claim, and the distinction is stated again beside them.

And the Book Was Built the Same Way

Accretion, deliberately

This volume was not outlined and then filled in. It was accumulated in the same manner as the wall, over the same years, by the same rule.

a source is read -> a claim is extracted\nthe claim is checked -> against the primary literature\nit survives, or it does not\nwhat survives is written down, with the condition that would refute it\nthe next item arrives and must live beside it

That method produces a particular kind of object. It is long, because the evidence is long. It has no thesis chapter, because the thesis is what remained standing after nine hundred and sixty-two passes. And it can be entered at any section, because each one was built to stand on its own before it was placed.

A literature of this size cannot be read exhaustively by any human being. It can be navigated by recognition — by building a structure dense enough that the right item announces itself when it arrives. That is what the wall is for, and it is what this book is.

The wall is therefore not an illustration of the argument. It is a scale model of the document. Both were made bit by bit. Neither could have been outlined in advance, because neither knew what the next piece would be until it came.

How to Read What Follows

The marching band

Life is not a seated orchestra. An orchestra holds still and plays one shape.

A marching band keeps time while changing formation — every member moving, every interval held, every pivot executed on a count. That is a cell, and no seated ensemble is.

The band this volume borrows is the Ohio State University Marching Band, for one reason above the others.

It is all brass and percussion. No woodwinds and no reeds. Two hundred and twenty-eight members, patterned on the British military brass band, and the largest all-brass band of its kind in the world. A band made entirely of metal and impact.

The First Layer — the Block

The atoms bonded into the molecule

One hundred and ninety-two marchers make the pregame block. They carry the instruments and they are the band.

atom	the section	why
C carbon	51 B-flat trumpets	the largest section, and the skeleton every molecule is built on

atom	the section	why
H hydrogen	12 cornets, 21 flugelhorns	the highest and most numerous voices, as hydrogen is the most numerous atom in a body
N nitrogen	28 mellophones	the middle voice. Harmony is pairing, and every base pair is made at a nitrogen
O oxygen	28 sousaphones	the deepest and the heaviest, and the note a phrase ends on
P phosphorus	21 trombones, 7 bass trombones	the one brass with a continuously variable length. A slide is a backbone that extends
S sulfur	D-Row, the drum major	see below
Se selenium	the sousaphone who dots the i	see below

The drum major

The band's own organization chart settles this without needing a metaphor.

D-Row is the Drum Major, the Assistant Drum Major and the Drum Majors in training. D-Row is not considered part of the block.

Sulfur appears in no canonical base, in no backbone and in no base pair. It carries no instrument and it sets the tempo for everything. The drum major is not in the block.

And the rarest position in the band

To dot the i in Script Ohio a musician must be a sousaphone player in at least a fourth year. One person, one moment, once a performance.

selenocysteine	twenty-five human selenoproteins
its codon	UGA, recoded
its machinery	PSTK and SepSecS, built for it alone — the only amino acid with no synthetase

Rare, ceremonial, and requiring apparatus nobody else needs. And the i-dotter is drawn from the sousaphone ranks, which is exact: oxygen, sulfur and selenium are the same column of the periodic table.

The Second Layer — the Percussion

The atoms that travel as free ions

They carry no melody. They carry pulse — and a pulse in a nerve is a movement of charge.

ion	the row	why
Na^+ and K^+	I-Row, 14 snare drums	an action potential is a sodium and potassium event. Sharp, repeating, and the whole band steps to it
Ca^{2+}	6 pairs of cymbals	the trigger. Calcium release fires muscle contraction and neurotransmitter release
Mg^{2+}	6 bass drums	the low pulse everyone dresses to — and the charge that stops the phosphate backbone repelling itself apart
Cl^-	6 tenor drums	the counterion, moving to balance whatever the others do

The Third Layer — the Specialists

The atoms held at active sites

Never in the block. Measured in milligrams. The show does not happen without them.

metal	the role	why
Fe iron	the featured soloist	the one atom in all three of this volume's stories — heme, the iron-sulfur cluster, and the olivine whose hydration heats Lost City
Zn zinc	the drill designer	plays nothing and sets the shape everyone stands in. Zinc runs no redox; it holds structure
Mn manganese	the pyrotechnics	four manganese atoms in photosystem II make the oxygen the stadium breathes
Mo molybdenum	one specialist	a single atom in a single cofactor, at the end of the purine pathway

metal	the role	why
Co cobalt	the vitamin	one atom, one molecule, and nothing else
Cu copper	the last hand-off	cytochrome c oxidase, the final step before oxygen

What Sorts the Three Layers

Bond type, and nothing else

layer	the criterion	
the block	covalently bonded into the molecule	H · C · N · O · P · S · Se
the percussion	free ions — charge, gradient, folding, signal	Mg · Ca · Na · K · Cl
the specialists	coordinated at an active site	Fe · Zn · Mo · Mn · Co · Cu

Selenium sits in the first layer on this criterion despite being vanishingly rare, because selenocysteine is covalently built into the polypeptide. Magnesium sits in the second and is the most consequential member of it. Iron is coordinated, and is first among the third.

The pyramid is widest at the base because the covalent atoms are approximately ninety-nine percent of body mass; the ions are about one percent; the specialists are milligrams. Widest where there is most matter, narrowest where there is most particular chemistry.

Script Ohio

The one formation that is also a mechanism

a compact triple block -> unwinds into a single continuous line\n-> loops, and writes letters across the field\n-> every musician in continual motion\n-> three and a half minutes, every time

the band	the cell
a folded block	chromatin, condensed
opening into one continuous line	the strand separating
the line writing letters	the transcript
every musician in motion	nothing in a cell is ever still
a fixed duration	a defined rate

And the last sixteen measures

The drum major joins the i-dotter, the two walk to the top of the i, and the drum major points to the spot.

Sulfur and selenium are one row apart in group sixteen, and this volume colors them as a pair. In the closing measures of the most watched drill in American sport, the member who plays no instrument walks the rarest member of the band to the single position that matters and points at it.

The Band Is the Atoms. The Music Is Something Else

the atoms	the band — players, sections, staff
the nucleotides	the music — I, X, G, A, U, O, C and T are the notes
the four-letter code	a score that carries half of them

Which is why inosine is the recurring figure of this book.

Inosine is manufactured deliberately by an enzyme, sits at anticodon position 34, reads three codons where the others read one, and appears nowhere in A, T, G or C. It is the note that gets played and was never written down.

And the epigenetic marks are the markings on the score. Not notes — dynamics, accents, articulation. They change how a note is played without changing which note it is. The two pencils that write them are S-adenosylmethionine and acetyl-CoA, and both of them are sulfur.

The Limits of the Figure

Stated here so the reader is never in doubt

A marching band has a drill designer, a score written before the first rehearsal, and a director who knows how the show ends.

Nothing in this volume is explained by design. Every mechanism recorded here is accounted for by chemistry and by selection.

And the two halves of the title are not in tension. The band plays in time. It is the score that is missing notes — four letters written down where metabolism runs eight.

The band is offered as a way in. It carries no argument, decides no question, and supports no claim. Where this book makes a claim it gives a section number, a primary source, and the condition under which the claim would fail. That structure, and not the figure, is what the volume rests on.

And the Widest True Thing This Volume Says

The periodic table is most likely universal. The same physics assembles the same elements anywhere in a universe of this age.

Which of them life uses is not universal at all.

The chart is given. The choice is not.

This book is a long enquiry into one part of that choice — why sulfur does so much of the work and receives no letter; why there are eight nucleotides in the metabolism and four symbols in the code; why magnesium is required by everything written here and named by none of it.

The Four-Letter Problem

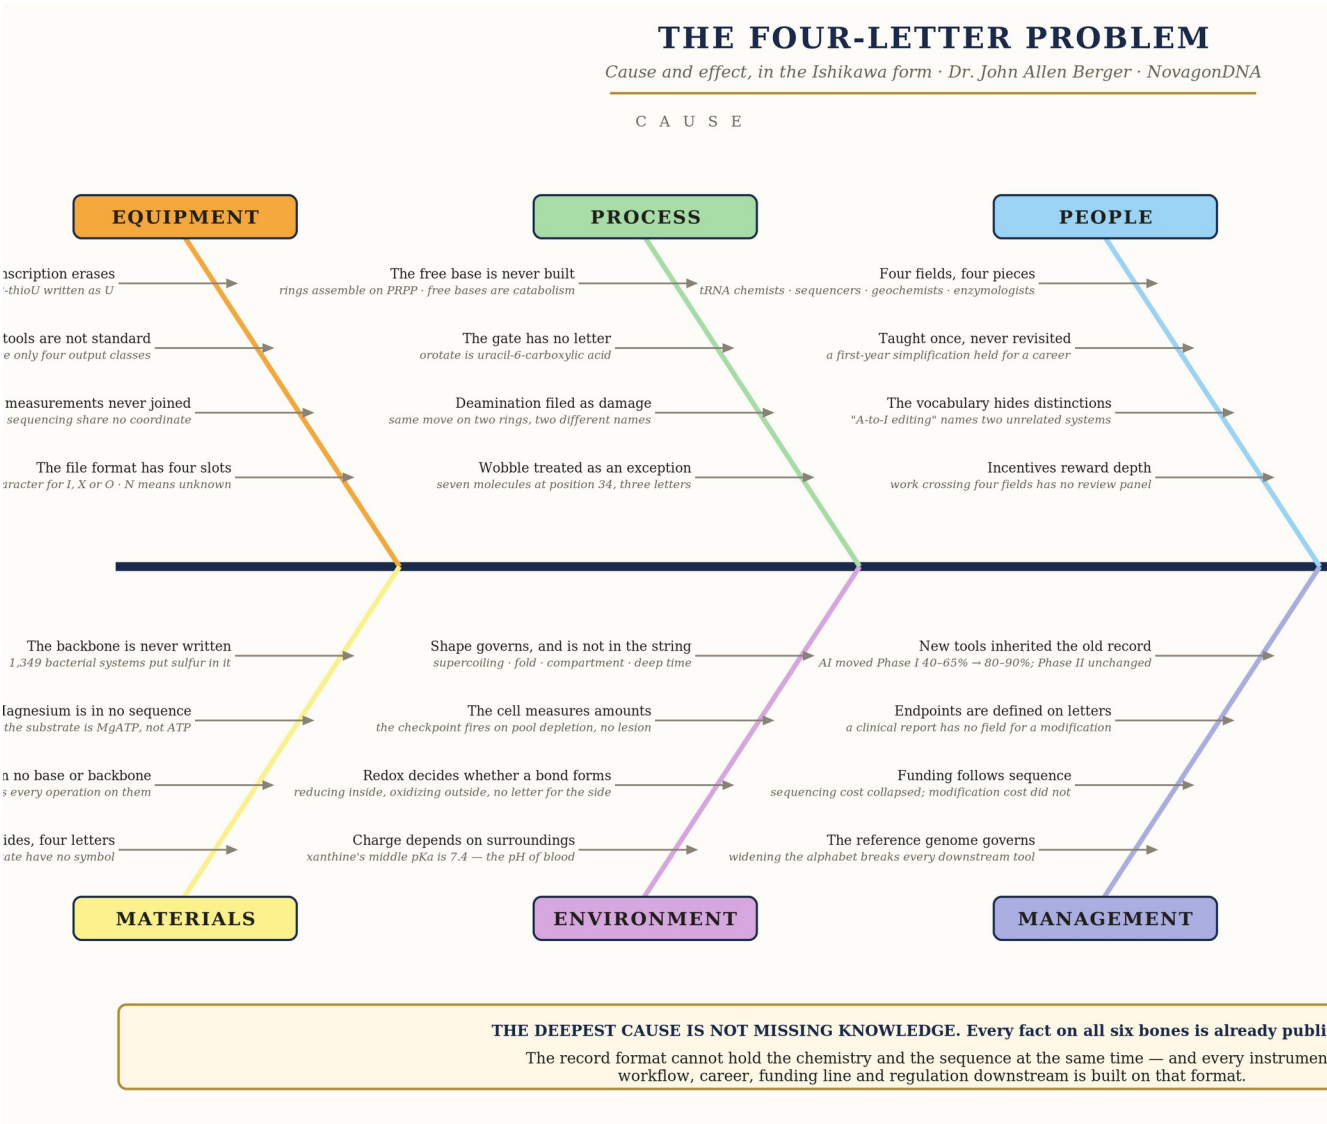
A cause and effect analysis in the Ishikawa form, placed here so a reader meets the problem before the evidence. Every cause on every bone carries the section of this volume where the evidence for it is set out, and every section number is a live link.

The Effect

Genomic problems arise from analyzing genetic code data using purine and pyrimidine base-pair letters ATCGU, which do not reflect the actual biochemical and molecular metabolic pathways and processes used in making RNA and DNA nucleic acids.

That is the head of the fish. The six bones below are what feed it. This analysis works backward through the six standard causal categories of the Ishikawa method, and each category carries its primary causes, each primary cause a secondary cause, and each secondary cause a third-level cause.

The Diagram



Bone colors follow this volume's seven-color index. Orange is oxygen and inosine, green nitrogen and guanine, blue carbon and cytosine, yellow sulfur and thymine, purple phosphorus and uracil, indigo selenium with xanthine and orotate.

Bone One · Equipment

The instruments, and what each of them destroys before a human ever sees the output.

primary cause	secondary cause	third-level cause	in this volume
The sequencing chemistry erases the chemistry	Reverse transcription is the first step	The enzyme reads a modified base and writes a canonical one	§898, §889
		Inosine is written as G, so the record cannot tell a made inosine from an inherited guanine	§972
		2-thiouridine is written as U, and the sulfur is gone at step one	§41, §85
		Methylation is invisible unless a separate, differently prepared assay is run	§346, §362
	Amplification compounds it	Every copy after the first is a copy of the erased version	§894
The instrument that would not erase is not the standard	Nanopore reads the native molecule	Throughput and raw error rate keep it off the routine pipeline	§346, §894
		The basecallers are trained on the four canonical bases and have no output class for what they are seeing	§346, §894
The two measurements are never joined	Modifications are measured by mass spectrometry, sequence by short-read sequencing	The two datasets have no common coordinate system	§45
		No standard file format holds a sequence and its modifications in one object	§33
The file formats have four slots	FASTA permits A, C, G, T, U and N	There is no character for inosine, xanthine or orotate	§29, §59
		N means unknown, not modified — the ambiguity code cannot say ‘known, and not one of the four’	§41, §57
	The reference genome is a consensus string	A string cannot carry a fold, a metal, a charge state or a compartment	§46

Bone Two · Process

The workflow, and the point in it where the chemistry is dropped.

primary cause	secondary cause	third-level cause	in this volume
The build direction	Rings are assembled	Purine synthesis builds onto	§277, §133

primary cause	secondary cause	third-level cause	in this volume
is never the free base	on a sugar phosphate that is already there	PRPP, atom by atom	
	Free bases appear almost only in catabolism	On the 1982 chart they sit inside the two boxes ruled purine and pyrimidine catabolism	§143, §1005
		So the four letters name molecules that, in the direction that builds, occur nowhere on the chart	§143, §1063
Orotate is the gate and has no letter	Orotate is uracil carrying a carboxyl at position six	Its systematic name is uracil-6-carboxylic acid	§595, §1080
	OMP decarboxylase removes that carboxyl and uracil is what remains	A rate enhancement of about 10^17 with no cofactor and no metal	§802, §119
Deamination is filed as damage rather than as a channel	A to I and C to U are the same chemical move on two rings	Both are an amino group leaving and a hydroxy arriving	§41, §18
	One is called editing, the other is called a lesion	The name depends on which molecule it happened to, not on the chemistry	§133, §317
Wobble is treated as an exception	Position 34 is taught as a footnote to base pairing	Seven different molecules occupy that position and three letters exist for them	§133, §34
		Inosine there reads three codon endings with one molecule	§41, §30
The pipeline calls bases, not molecules	Annotation assigns function from sequence similarity	Two identical sequences with different modifications receive identical annotations	§829, §530
		Guanine and isoguanine share the formula and the weight and differ only in arrangement	§133, §18

Bone Three · People

Training, and the walls between the people who hold the pieces.

primary cause	secondary cause	third-level cause	in this volume
Four fields hold four pieces and do not read each other	tRNA chemists, genome analysts, isotope geochemists and enzymologists	Nothing in a conventional research design puts them in one argument	§749
	The genome analysts	They have no field in their	§133, §41

primary cause	secondary cause	third-level cause	in this volume
	hold the sequence data	format for what the chemists measure	
The four letters are taught once and never revisited	They are introduced in first-year biology as the alphabet of life	A simplification taught at the start becomes an assumption held for a career	§29, §59
		The eight nucleotides of actual metabolism are never presented as a set	§198, §199
		Inosine is taught as a curiosity of the wobble rather than as a manufactured base	§38, §1106
The vocabulary hides distinctions	‘A-to-I editing’ names two unrelated systems	ADAT2 and ADAT3 act at one position on transfer RNA	§374, §1105
		ADAR1, 2 and 3 act across double-stranded RNA, mostly inside Alu repeats	§311, §312
	‘Base’ is used for the ring, the nucleoside and the nucleotide	One word covers three molecules with three different chemistries	§133, §41
Incentives reward depth inside a field	Grant review panels are organized by field	Work crossing four fields has no natural panel	§947

Bone Four · Materials

What the notation is made of, and what it therefore cannot contain.

primary cause	secondary cause	third-level cause	in this volume
There are eight nucleotides in metabolism and four letters	Inosine is manufactured deliberately and reads three codons	It has no letter, and sequencing writes it as G	§30, §44
	Xanthine sits at the valve of the purine pathway	Its middle pKa is 7.4, the pH of blood, and it is the only base on the sheet that does	§1088
	Orotate is the origin node of the pyrimidines	The eight are numbered adenine 1 through orotate 8	§1081
Sulfur is in no base, no sugar and no backbone	And it performs every operation on them	Ribonucleotide reductase makes every deoxyribonucleotide from a cysteine radical	§31, §13
		Every methyl comes off a sulfonium and every acetyl off a thioester	§35, §169

primary cause	secondary cause	third-level cause	in this volume
		Iron-sulfur clusters sit in the polymerases, helicases, primase and glycosylases	§31, §1061
		Five proteins in a line move one sulfur atom onto position 34	§85, §89
Magnesium is absent from every sequence	The true substrate of a kinase is MgATP, not ATP	ATP sulfurylase's own systematic name contains the magnesium	§929, §930
	It folds the RNA and runs the ribozyme	Without it the backbone charge prevents folding at all	§41, §913
The backbone is not written at all	The notation records bases and omits the linkage	Bacterial dnd systems put sulfur into that backbone at defined positions	§133, §42
		Hershey and Chase built the founding experiment on a separation that is not absolute	§5
Whole layers of information have no letters	Sulfation patterns on sugar chains are read by proteins as addresses	No gene contains the pattern and no sequencing method reads it	§42, §54

Bone Five · Environment

The conditions that decide what a molecule does, none of which a letter records.

primary cause	secondary cause	third-level cause	in this volume
Charge state depends on the surroundings	Xanthine's middle pKa is 7.4	At body pH it sits half-charged, and the deprotonated form pairs better rather than worse	§200, §1088
		The letter is the same at every pH. The molecule is not	§34, §35
Redox condition decides whether a bond forms	The cytoplasm is held reducing by glutathione	Structural disulfides form outside the cell and not in the cytoplasm	§56, §7
	The membrane is the boundary between two chemical worlds	No sequence says which side of it a cysteine is on	§1118, §1116
Concentration is measured where letters are not	The damage checkpoint fires on pool depletion with no lesion present	The cell commits by measuring an amount	§812, §858
Shape governs, and shape is not in the string	Supercoiling changes what an enzyme can reach	Guide design scores letters against a target whose fold decides the outcome	§962, §967

primary cause	secondary cause	third-level cause	in this volume
	Antisense design does the same	A perfectly complementary sequence fails against a folded site	§1001
Deep time changed the raw materials	Before the Great Oxidation Event sulfate was scarce	Activated sulfate chemistry needs an oxidized world to draw from	§228, §1114
	The event is dated by sulfur, not by oxygen	A signal made only in an oxygen-free atmosphere stops being made, and that is the clock	§14, §53
Compartment changes the meaning	The same letter in nucleus, cytoplasm and mitochondrion	Mitochondrial wobble modification loss produces MERRF and MELAS	§983

Bone Six · Management

The institutions that hold the four-letter schema in place.

primary cause	secondary cause	third-level cause	in this volume
The reference genome is a governance object	It is the coordinate system everything else is reported against	Widening the alphabet would break every downstream tool at once	§301
Funding follows sequence	Sequencing cost fell by orders of magnitude and modification measurement did not	Proposals promising more sequence are cheaper and more certain to deliver	§133
Endpoints are defined on letters	A variant is reported as a letter change at a coordinate	A clinical genetics report has no field for a modification state	§56, §133
		ADAT3 is reported as c.382G>A and the consequence at position 34 is not in the report	§1105
Database and publication standards enforce the schema	Submission requires the sequence in a permitted alphabet	A deposition records the letters and not the modifications of the molecule	§544, §648
The new tools inherited the old representation	AI drug discovery trained on sequence and structure records	Phase I rose to 80–90 percent against a historical 40–65	§938, §948
		Phase II stayed at about 40 percent, which is the historical figure	§947
The economics reward the reduced	A four-letter string compresses, transmits	The representation is optimal for everything except	§18, §933

primary cause	secondary cause	third-level cause	in this volume
representation	and searches efficiently	describing the molecule	

The Six Bones, in One View

bone	the one-line reason it feeds the problem
EQUIPMENT	The instrument erases the chemistry at step one and the file format has no slot to put it back
PROCESS	The workflow names the products of breakdown and not the intermediates of building
PEOPLE	Four fields hold four pieces of the answer and publish in four literatures
MATERIALS	Eight nucleotides, one silent element, one invisible metal, and a backbone that is never written
ENVIRONMENT	pH, redox, concentration, fold, compartment and deep time all decide the outcome and none is a letter
MANAGEMENT	The schema is load-bearing for every institution downstream, so nobody can afford to widen it

What This Analysis Refuses

the claim	the status
that the four letters are wrong	Refused. They assign amino acids to codons and do that correctly
that the code should have eight letters	Refused. This analysis shows what the notation omits, not what should replace it
that any one bone is the root cause	Refused. Six feed one head, and Equipment and Management are the two that make the others durable
that the field is unaware of modifications	Refused. The field measures them well. The failure is that the measurement and the sequence are never joined in one record

The deepest cause on this diagram is not a piece of missing knowledge. Every fact on all six bones is already published. The cause is that no record format holds the chemistry and the sequence in the same object, and every instrument, workflow, career, funding line and regulation downstream is built on that format.

PREFACE · WHERE SULFUR IS NOT THE ANSWER

For the Preface, to be placed before the Wall

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The objection this volume expects, and answers on its first pages

A reader who sees eleven hundred pages about one element is entitled to a suspicion: that the author found a hammer and the world turned into nails. The suspicion is fair. It is answered here, at the front, rather than buried where it would look like a concession extracted late.

Sulfur is the sixteenth element and the subject of this book. It is not the cause of life and this volume does not claim it is.

Six atoms, and what each of them does that sulfur does not

The seven colors of this volume are seven atoms. Six of them are not sulfur.

hydrogen, H1	**the bond that holds the pair, and the proton that every transfer moves**
carbon, C6	the skeleton. Every ring, every chain, every backbone carbon in every sugar
nitrogen, N7	the bases themselves. Every hydrogen bond in every base pair is made at a nitrogen or an oxygen, and none is made at a sulfur
oxygen, O8	the other half of every pair, the phosphate ester, and the atom whose arrival ends the flow
phosphorus, P15	the backbone and the currency. The bond that stores the energy and the linkage that makes a polymer a polymer
selenium, Se34	the residue below sulfur, in the one protein class that could not use sulfur instead

There is no sulfur in a canonical DNA base. There is no sulfur in a canonical RNA base. There is no sulfur in the sugar and none in the phosphate backbone. A reader who opens a structure of the double helix will not find the subject of this book anywhere in it.

And the partners that are not in the seven at all

	what it does, and sulfur does not
magnesium	folds the RNA and runs the ribozyme. Every catalytic RNA needs Mg^{2+} at its active site. It neutralizes the backbone charge that would otherwise prevent folding at all. Without magnesium there is no ribozyme, and without a ribozyme there is no RNA world
iron	the electron carrier of the deep pathways, in heme and in the iron–sulfur cluster — which is named for both atoms and works because of both
montmorillonite and the clays	the first long polymers. Ferris showed that activated nucleotides fed daily onto montmorillonite for fourteen days give oligomers of forty to fifty units, with mild sequence and regio-selectivity. No sulfur is involved at any step
molybdenum, nickel, zinc, manganese, cobalt	the metal centers of the enzymes, including the ones that install sulfur
water	the solvent, the reactant in every hydrolysis, and the medium in which all of it happens
ultraviolet light	the energy. In the carboxysulfitic chemistry this volume records, UV is what does the work

---

What is actually being claimed

Sulfur appears in no canonical base, in no backbone, in no base pair. It is absent from the score and present in every performance.

where sulfur is	
the methyl donor	S-adenosylmethionine, a sulfonium. Every methyl written onto DNA, RNA or a histone
the acyl carrier	acetyl-CoA, a thioester. Every acetyl
the electron router	the iron–sulfur cluster
the folding bridge	the disulfide
the terminal atom	installed by MOCOS onto xanthine oxidoreductase, at the end of the purine pathway
the enzyme that made DNA	ribonucleotide reductase, which runs on a thiyl radical

The claim of this volume is not that sulfur is primary. It is that sulfur is the element the notation loses, and that a system of record which carries four letters, or seven, or twenty-one, carries none of the transactions above.

That is a smaller claim than a claim of primacy, and it is the reason this volume can be checked. A claim that sulfur causes life could not be falsified. A claim that a

notation omits a specific atom in specific reactions can be, and every Part of this book states the condition under which it would be.

The rule this volume is written under

The governing instruction, set by the author before the sulfur chapters were drafted and applied to every Part since:

Focus on sulfur, but not to the detriment of the other atomic elements, cofactors, coenzymes and partners. The truth is what it is.

Where the answer is magnesium, this volume says magnesium — and gives it Parts One Hundred and Six and One Hundred and Seven, and the white band of the color scheme. Where the answer is a clay, this volume says a clay. Where the answer is ultraviolet light, this volume says light. Where a mechanism has been proposed for sulfur and the evidence does not support it, this volume declines the mechanism, and the declined claims are listed at the back where a reader can find them all at once.

A book about one element that never says "not this one" is an advertisement. This one says it on its first pages, and then again at the end of every Part.

PREFACE · THE WALL

There is a wall in a house in Naperville, Illinois. It is nine panels across and eight down. It is made of paper — book jackets, journal covers, plates cut from textbooks, printed figures, a mind map run off a home printer and dated the twentieth of October, two thousand and three. Nothing on it was manufactured for the purpose. Every piece was found, cut out, and placed.

This volume is a transcription of that wall.

Not a summary of it, and not an argument derived from it. A transcription. The Parts that follow were written between 2025 and 2026, and almost every one of them was

already named on the wall, in a hand-typed branch or a cut headline, before any of them was written. Methionine initiates the process. Thioesters. Acetyl coenzyme A. Glutathione. The methyl group donated from S-adenosylmethionine. Disulfide bridges. Iron sulfide. Chromatium. Cyanobacteria. Electron transport. Older than Earth's sun.

The wall was the table of contents. The volume is what happened when a man finally sat down and filled it in.

What a wall can do that a page cannot

A page is sequential. It admits one thing at a time and asks the reader to hold the last thing in memory while the next arrives. It is a good instrument for argument and a poor one for recognition, because recognition is what happens when two things are seen at once.

A wall is simultaneous. Everything on it is present at the same instant, and the eye is free to travel by resemblance rather than by order. A thing pinned beside another thing makes a claim that no sentence has to carry. The claim may be right or wrong, and the wall does not say which — it only holds the two together long enough for someone to notice.

That is why the wall exists, and why it took twenty-three years to become a book. The connections were made by looking. The proving had to be done one sentence at a time, and a sentence is slower than a glance by a factor no one has measured.

The span

Stand back from it and read the edges.

At one edge: interstellar molecules — carbonyl sulfide, carbon monosulfide, hydrogen sulfide, silicon sulfide, nitrogen sulfide, methanethiol. These were made in cold clouds before the sun condensed, and they were identified from Earth by the light they emit. At the same edge, typed onto a branch of the mind map: older than Earth's sun.

Next: rocks and minerals, the making of a planet, a magma ocean, a molten iron core. Then the prebiotic panel, with a Miller-Urey spark apparatus and its table of

products — and in the column of nucleic acid bases, xanthine and hypoxanthine picked out by hand, twenty-three years before either would matter to anything.

Then the great oxidation, dated by the isotopes of a single element. Then Chromatium, the purple sulfur bacterium, labeled on the wall as the first chromosome colony. Then the revised tree of life. Then cells, organelles, tissue, blood, the erythroblast series. Then hominids walking left to right across the bottom of a panel in red. Then Dolly the sheep. Then the first human clone. Then the genome, published.

Thirteen point eight billion years, and it fits on a wall in a house in Illinois.

The scale runs from quarks and leptons at one corner to the human mind at the other, and nothing in between is missing. That is not a small thing to have assembled from cut paper and a glue stick, and it was assembled by one person, alone, without an institution, without funding, and without anyone asking him to.

The thread

The wall has an organizing principle, and it is not decorative. Every panel is a node. Every node has nearest neighbors. And running through all of them, across every scale of the mural, is a single connecting thread — the thing that makes the wall one object rather than seventy-two.

The thread is sulfur.

It is the only element that means the same thing at every level of the picture. At the atomic level it is six oxidation states where oxygen has two. At the molecular level it is seven distinct linkages — thiol, disulfide, thioether, thioester, persulfide, iron-sulfur cluster, sulfonate — each with a different job, all written with the same letter. At the cellular level it is a relay: one donor, cysteine, handing a single atom down a chain of carriers, each passing it by way of its own cysteine. At the organelle level it is the modification that decides whether a compartment works, and a child whose mitochondrial genome is letter-perfect goes into liver failure when it fails to arrive. At the level of the network it is a gasotransmitter, a planetary cycle, and the isotopic record by which the oxygenation of the Earth is dated.

Chemists, biochemists, cell biologists and geochemists do not share a vocabulary. They share this atom. That is what the wall is about, and it is what this volume is for.

The emblem, and its limits

Scattered across the mural are fractals — Mandelbrot and Julia sets, black shapes surrounded by burning filigree, the same form recurring at every magnification.

They were chosen because they look like the thing the wall is doing, and the resemblance is better than the author knew when he cut them out. In 1982 Douady and Hubbard proved that the Mandelbrot set is connected. Every one of those small black islands, at every scale, is joined to the main body by a filament — usually finer than any line that can be printed. They appear isolated. They never are. Whether the set is locally connected, well-behaved all the way down, was conjectured by the same two men in the same year and remains unproven to this day.

A connected structure, self-similar at every scale, whose islands are not islands, and whose finest behavior is still an open question. As an emblem for this work, nothing better could have been chosen.

But it is an emblem. The Mandelbrot set is a fact about iterating a quadratic map in the complex plane. It contains no chemistry and no gravitation. It illustrates the shape of the argument; it does not supply evidence for it. That distinction is made here, in the preface, because it is the distinction this volume is built on and the reader should have it before the first Part rather than after the last.

What is claimed

The wall suggests a great deal. This volume claims only what can be checked.

Where a statement is established, it is cited. Where it is conjecture, it is marked conjecture. Where an arithmetic route fails, the failure is printed rather than omitted. Where a finding was not reproduced, the non-reproduction is named. Where an alternative explanation has not been excluded, it is given its own paragraph. Where the volume has changed its mind — and it has, from seven letters to six, in Part Thirty-Eight — the earlier position is described rather than erased.

Every Part ends with the conditions under which it would be wrong.

And there are things this work does not claim. It does not claim that the fractals depict sulfur. It does not claim a physical connection between complex dynamics and gravitation. And where the wall reaches toward the deepest question it asks —

whether the thread that connects the atoms also connects the minds that contemplate them, what Jung would have called the collective unconscious — the author's own words are the honest ones: that cannot be verified.

He wrote that sentence himself, unprompted, about his own most cherished idea. It is the sentence that makes the rest of the volume trustworthy.

The man in front of it

Twenty-nine years, and for most of them nobody was watching.

There was no laboratory, no grant, no department, no colleague across the hall. There was a wall, a chair, a stack of journals, and the persistence to keep asking the same question of material that kept arriving from unrelated fields. The question never changed: the four letters are a notation — where is the material?

The answer this volume gives is that the material is an atom the notation has no symbol for. It is in the enzyme that opens the purine gate and the enzyme that closes it. It is at the wobble position of a transfer RNA in a mitochondrion. It is on cysteine eighty-four of a cyanobacterial protein, holding the pigment that harvests light. It is in the backbone of every antisense drug ever approved. It is the switch on the sensor that broccoli and garlic each modify at a different residue. It is in the thioester at the center of metabolism, older than phosphate, older than the oxygen it survived.

And it was on the wall in 2003, waiting.

THE BOOK SCRIPT · THE QUATERNION DRAMA

A. The Script, Transcribed From the Author's Hand

One sheet, three nested triangles, and the equation that makes the volume a drama rather than a survey

The forty Parts that follow were not written in the order in which they should be read. This section supplies the order, and it is taken from a single handwritten sheet on which the author set out the shape of the book before the book existed.

The sheet is transcribed here exactly as written.

BERGER BOOK SCRIPT Theory of Threes · Quaternion Process H C N O P S Se ATOMIC → MOLECULAR LEVEL → CELLULAR ORGANELLES I X G A (purine) · U O C T (pyrimidine) BEGINNING → MIDDLE → ENDING Book · Syd Field · Drama, in thirds RESOLUTION → HUMANS · EUKARYOTES · CELLS Human cells: REAL = MOLECULAR · ATOMIC · CELLULAR R = I J K QUATERNION DRAMA · 13.8 BILLION ENDING → 13.8 billion, BIG BANG Prebiotic 2.4 · sulfur → oxidation economics → PRESENT DAY FUTURE OF HUMANS · ORGANIC LIFE · EARTH → RESOLUTION

B. R = ijk, and Why the Volume Is a Drama

Three imaginary axes multiply to one real outcome, and that is the shape of a story

The line at the center of the sheet is the whole architecture: R equals i j k. Three imaginary components, multiplied together, give the real one.

In the quaternions this is an identity. The product of the three imaginary units is minus one — a real number, and the only real number the three of them can produce. The imaginaries are the directions. The real is what they amount to.

> *$i \cdot j \cdot k = -1$ i = the MOLECULAR level j = the ATOMIC level k = the CELLULAR and ORGANELLE level R = the human being, the eukaryote, the cell that is actually alive*

What this licenses and what it does not. Licensed: the use of a four-part structure — three described levels and one lived outcome — as the organizing frame of a book, and the observation that in quaternion algebra the three imaginary units multiply to a real. Not licensed: any claim that a human being is literally the quaternion product of three levels of description. The identity is exact; the mapping onto biology is a structure for the argument, chosen by the author, and it is named here as such.

A survey describes three levels. A drama shows what they produce. This volume is the second kind, and the sheet says so in five characters.

C. The Three Acts, and Where They Fall

Syd Field's thirds, mapped onto forty Parts and two hundred and eighty-eight pages

The script marks BEGINNING, MIDDLE and ENDING and notes the model: drama in thirds. The Parts divide as follows. Page numbers are of the present edition and are approximate to the nearest opening.

act	Parts	what it carries
ACT ONE — THE BEGINNING	Preface through Part Thirteen	the world, the problem, and the missing variable
ACT TWO — THE MIDDLE	Parts Fourteen through Thirty-Two	the machinery, and the complications
ACT THREE — THE ENDING	Parts Thirty-Three through Forty, and the Plates	the geometry, the revision, and the resolution

Act One — the beginning

Opens on the wall. Establishes the world: an element with six oxidation states where oxygen has two, present at every scale, and absent from the notation that runs modern biology. Introduces the antagonist, which is not a person but a convention — the four-letter table. Ends at the arrows of the expanded dogma, with the problem fully stated and no solution yet in sight.

PLOT POINT ONE, at the end of Part Thirteen. The dogma is redrawn with every arrow resolved, and the reader sees that the letters cannot carry what the arrows require.

Act Two — the middle

The long middle, where the machinery is taken apart. The marks, the cofactors, the atomic level, the seed alphabet, recognition, the twenty-two and the twenty-two, the lineage, the experiments. Then the amide bond older than the planet, the theory of three, and the join.

MIDPOINT, at Part Twenty-Two. Twenty-two amino acids and twenty-two nucleic acid components: the two halves of the code counted and found equal. The reader who reaches this page understands that the two languages are the same size, and cannot un-see it.

PLOT POINT TWO, at Part Thirty-Two. The join — the aminoacyl-tRNA synthetases as the one place in the cell where a nucleic acid is covalently bonded to an amino acid, with sulfur at both ends of the adaptor. The two languages are not merely the same size. They are welded together, and the weld is made of the missing element.

Act Three — the ending, and the resolution

The turn, the rotation group, the sugars, the Generator, orotate, and then the revision from seven letters to six — the volume changing its own mind in public. The two companion papers arrive from outside and land on the same six. The Plates close it by showing that all of it was on a wall in 2003.

RESOLUTION, as the script marks it: HUMANS · EUKARYOTES · CELLS. The three imaginary levels resolve into one real organism, and the last question the volume asks is whether that organism has a future.

D. The Cast — Nine Organelles, Chosen for Sulfur

Each compartment earns its place by a named sulfur enzyme, not by importance in general

The script names CELLULAR ORGANELLES as the k axis. The volume needs a specific cast rather than a list, and the criterion for admission is narrow: a compartment is included only where a named sulfur chemistry decides whether it works.

organelle	the sulfur chemistry	what it does in this story
NUCLEUS	chromatin, supercoiling, Lk = Tw + Wr	the archive; the linking number that cannot change without a cut
NUCLEOLUS	rDNA transcription; G-quadruplex	where CX-5461 does its damage, at the rDNA promoter
RIBOSOME	the peptidyl transferase center	a ribozyme; methionine placed first, every time
ROUGH ER	protein disulfide isomerase; Ero1	OXIDATIVE PROTEIN FOLDING — where disulfide bonds are made
ER, second office	FGE / SUMF1	converts one cysteine to formylglycine in every sulfatase there is
GOLGI	tyrosylprotein sulfotransferase; PAPS	tyrosine O-sulfation in the trans-Golgi; about one percent of all tyrosines in secreted and membrane proteins
LYSOSOME	the sulfatases	the divertor; where sulfated cargo is taken apart
MITOCHONDRION	Fe-S clusters; TRMU at U34; ATP synthase	the power, and the disease
PEROXISOME	catalase, hydrogen peroxide	the oxygen counterpart, kept in its own box

The one to watch, and it is not the mitochondrion. Every sulfatase in the human body — the ones in the lysosome that dismantle glycosaminoglycans and sulfatides, and the others besides — carries a cysteine at its active site that must be

converted into formylglycine before the enzyme can work at all. One enzyme performs that conversion: the formylglycine-generating enzyme, FGE, encoded by SUMF1, resident in the endoplasmic reticulum. Lose it and every sulfatase in the cell is born dead. The disease is multiple sulfatase deficiency, and it presents as several storage disorders at once because it is not one enzyme failing but the whole class.

One cysteine, modified once, in every member of an enzyme family. Lose the modification and the family goes with it. That is the thesis of this volume stated as a pediatric diagnosis.

E. The Silver Cord — Sixteen Patterns as the Through-Line

The author's sixteen patterns of life, each answered by a sulfur fact and a Part

Pinned to the wall is a list of sixteen patterns common to all life, annotated in the author's hand. They are the spine on which this volume hangs, and each of them has a sulfur answer somewhere in the Parts.

#	the pattern, as written	the sulfur answer
1	Life builds from the bottom up	the atomic level; six oxidation states before anything is alive
2	Life assembles itself into chains	the thioester; acyl transfer before phosphate existed
3	Life needs an inside and an outside	the sulfonated thylakoid lipid; the membrane that faces water
4	Life uses a few themes to generate many variations	one atom, seven bond types, every level
5	Life organizes with information	and the notation for that information omits the deciding atom
6	Life encourages variety by reshuffling information	ADAR, A to I, at millions of sites
7	Life creates with mistakes	proton tunneling tautomers, deamination — the mutation channel
8	Life occurs in water	and oxygen came from it; the conjugate pair of group sixteen
9	Life runs on sugar	glucose to acetyl-CoA — and acetyl-CoA is a thioester
10	Life works in cycles	the citric acid cycle; the purine nucleotide cycle; the sulfur cycle
11	Life recycles everything it uses	the cysteine desulfurase relay, one atom passed hand to hand
12	Life maintains itself by turnover	the lysosome; the divertor; controlled disposal
13	Life tends to optimize rather than maximize	the wobble position — three codons read by one adaptor

#	the pattern, as written	the sulfur answer
14	Life is opportunistic	hydrogenases that make hydrogen or reduce polysulfide, whichever is offered
15	Life competes within a cooperative framework	the sulfur cycle across species that never meet
16	Life is interconnected and interdependent	which is this volume's own thesis, arriving last on the author's list

Sixteen patterns, and sixteen is the atomic number of the element that answers them. The author did not choose the list, and the coincidence is worth exactly one sentence, which this is.

F. The Twists — Writhe, Linking, and the Eighty-Twenty Rule

A small number of turns carry most of the reversal, and they are all rotations

The author's instruction was to apply the Pareto proportion to the turns: roughly a fifth of the material should carry four fifths of the reversal. Applied honestly to a volume of this length, that means a handful of moments where the reader's picture inverts, and everything else is preparation or consequence.

There are six, and it is not a coincidence that five of them are rotations.

#	the turn	where	what inverts
I	THE NOTATION IS NOT THE MATERIAL	Part One	the premise, stated before it is earned
II	THE CODE HAS A HIDDEN QUANTITY, AND IT TURNS	Part Thirty-One	recognition is decided by orientation, not by sequence
III	THREE HUNDRED AND SIXTY IS NOT ENOUGH	Part Thirty-Six	a spinor needs seven hundred and twenty; one traversal does not bring it home
IV	THE TOPOLOGY CANNOT CHANGE WITHOUT A CUT	the supercoiling material	Lk = Tw + Wr; gyrase changes it in steps of two, which is the same 720°
V	THE VOLUME IS WRONG ABOUT ITS OWN ALPHABET	Part Thirty-Eight	seven letters become six; the author overturns his own framework in public
VI	IT WAS ALL ON A WALL IN 2003	the Plates	the reversal that reframes everything preceding it

Why the twists are rotations

A plot twist and a rotation are the same operation. Both take a fixed object and change the position from which it is read, and in both cases nothing about the object has altered — only the frame. That is why the reversals in this volume are literally

rotational: the syn-anti flip that decides a quadruplex fold, the writhe that converts twist into coil without changing the linking number, the hundred and twenty degree step of ATP synthase, the seven hundred and twenty degrees a spinor needs, the sixty degrees of the hexagon.

Writhe is the plot twist of molecular biology. The sequence does not change. The linking number does not change. What changes is the shape, and the shape is what everything downstream reads.

G. The Resolution — Three Domains and an Uncertain Future

What the three imaginary levels produce, and whether it lasts

The script ends where the volume must end: with the real outcome of the three levels, and with a question rather than an answer.

domain	what sulfur does there	standing
ARCHAEA	the deepest branch; sulfur reducers among the oldest metabolisms	the sulfur economy, still running where oxygen never reached
BACTERIA	hydrogenases that switch hydrogen for polysulfide as the substrate allows	the opportunists; forty-nine genomes from one aquifer, none of them cultured
EUKARYA	the mitochondrion inside the cell; iron-sulfur clusters carrying every respiratory electron	the resolution the script names: HUMANS · EUKARYOTES · CELLS

The three domains are not three answers. They are one answer at three depths of time, and the element is the same in all three. What differs is the economy each one is running: the archaeal branch never left the sulfur world, the bacterial branch learned to switch between economies as conditions offered, and the eukaryotic branch bought the oxygen economy at the cost of depending on a captured organelle that still runs on iron and sulfur.

And the question the volume closes on. The oxidation event that made the eukaryotic bargain possible was itself a catastrophe for the world that preceded it, and it is recorded — datable, still legible — in the isotopes of a single element. Whether the present rearrangement of the same planetary chemistry is survivable by the organism that caused it is not a question this volume can answer, and it is not one it will pretend to. What the volume can say is where to look: the record of the last time the chemistry changed is written in sulfur, and it took two and a half billion years to read.

Prebiotic sulfur. Oxidation economics. Present day. The script's own last line, and the volume's.

H. How to Read the Volume, If Not Straight Through

For the reader who will not read two hundred and eighty-eight pages, and there are many

if you read only one thing	go to	for
The argument in four pages	the Preface	what the book is and what it will not claim
The thesis in one Part	Part Thirty-Two, the join	sulfur at both ends of the adaptor
The best single fact	Part Thirty-Seven and the TRMU material	a letter-perfect genome and a child in liver failure
The moment it changes its mind	Part Thirty-Eight	seven letters become six, in public
The independent confirmation	Parts Thirty-Nine and Forty	two papers, written elsewhere, landing on six
The provenance	the Plates	a wall, dated 2003

The volume is long because the evidence is. The argument is short, and it is on the second page of the Preface.

A note on the spelling

This volume uses SULFUR, the older spelling, throughout. The choice is deliberate. IUPAC standardized on "sulfur" in 1990 and the Royal Society of Chemistry followed in 1992, returning the word to its Latin f. This volume keeps the older form as a standing reminder that what was standardized away from element sixteen was rather more than a letter.

The convention is applied to the name of the element only. Compound names retain their current IUPAC forms — sulfide, sulfate, sulfite, sulfonate, sulfoquinovose, sulfenic, and the rest — because those are chemical naming rather than orthography. Titles of cited works are reproduced exactly as published.

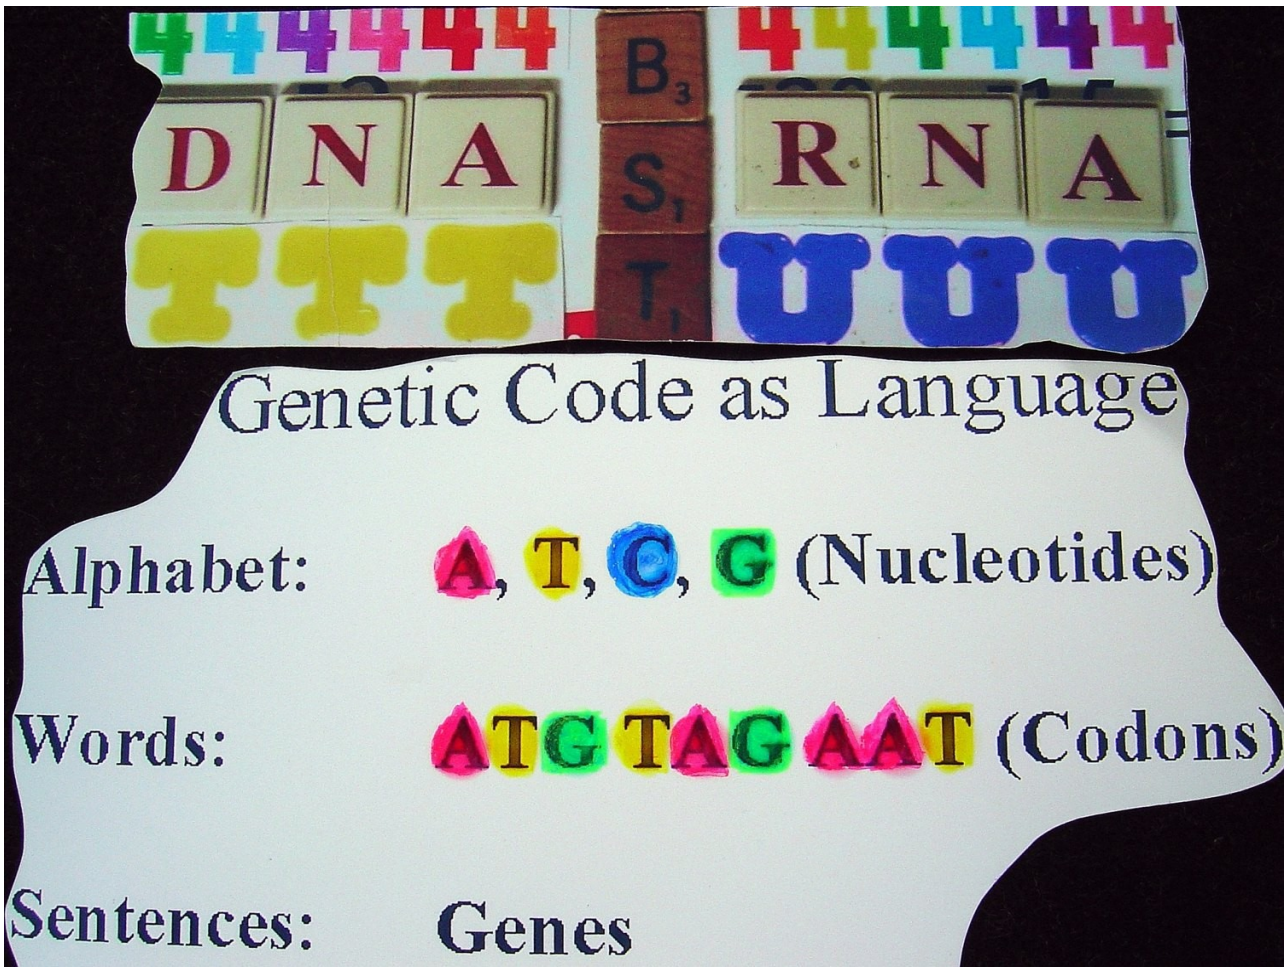


FIGURE 1 · THE GENETIC CODE AS LANGUAGE

The author's own statement of the notation problem, made with letter tiles. Alphabet: A, T, C, G. Words: codons. Sentences: genes. Every level of that analogy is a level of writing, and none of it is a level of matter. This volume is an argument about what the analogy leaves out.

PART ONE · SULFUR, AT EVERY SCALE

1. What Sulfur Is, and Why It Behaves As It Does ↩

Element sixteen, in plain words, from the nucleus outward

Sulfur is the sixteenth element. It sits directly below oxygen on the periodic table, which means it has the same number of outer electrons and forms the same number of bonds. Chemists therefore treat the two as cousins. They are not cousins. They behave differently in ways that decide what life can do, and the differences all come from one fact: sulfur's outer electrons are one shell further out.

The one number that explains most of it

Put two hydrogen atoms on an oxygen and you get water, and the angle between the two hydrogens is 104.51 degrees. Put two hydrogens on a sulfur and you get hydrogen sulfide, and the angle is 92.12 degrees — almost a right angle.

Ninety-two degrees. Sulfur barely bothers to blend its orbitals. It bonds nearly along the raw axes of its own electron clouds, and almost everything sulfur does in biology follows from that.

A right-angle bond is a loose bond. It bends more easily, it stretches further, and it holds its partners at a greater distance. Oxygen is rigid and grasping. Sulfur is large, soft and accommodating, and life uses it wherever something must be held firmly but let go on command.

property	oxygen	sulfur	what it buys
Bond angle to two hydrogens	104.51°	92.12°	sulfur bonds nearly at right angles
Bond length to hydrogen	0.9575 Å	1.3356 Å	sulfur holds its partner further out
Bond to itself	O–O, 1.475 Å, unstable	S–S, 2.055 Å, stable	sulfur chains to itself; oxygen barely can
Twist of the H_2X_2 bridge	119.8°	90.6°	the disulfide's preferred twist is a right angle
Range of oxidation states used in life	about two	eight, from H_2S to sulfate	every step occupied by a named biological molecule

That last row deserves its own sentence. Sulfur can exist in eight different electron-accounting states inside a living cell, and biology uses all of them, from fully reduced hydrogen sulfide to fully oxidized sulfate. Oxygen manages about two. This is why sulfur is the element life reaches for whenever electrons have to be moved, stored, counted or protected.

---

2. Sulfur Before There Was Anything Alive ↩

From stellar nuclei to the early ocean, in order

Sulfur is made inside massive stars by the fusion of silicon and helium, and scattered when those stars explode. It arrives on planets already made. It is the tenth most abundant element in the universe and, on the early Earth, it was everywhere: in volcanic gas, in the ocean as sulfide, in the minerals at hydrothermal vents where iron and sulfur precipitate together.

It also arrives from space in a specific and measurable form. The Murchison meteorite carries a homologous series of alkyl sulfonic acids at roughly forty times the concentration of the corresponding phosphonic acids. Those sulfur compounds carry a fingerprint — an unusual ratio of the sulfur-33 isotope, and a high deuterium content — showing they were formed by ultraviolet light acting on carbon disulfide in cold interstellar clouds, before the solar system existed.

The sulfur in your body was made in a dying star, processed by starlight in a cold cloud, delivered to a young planet, and has been passed hand to hand by living things ever since.

And sulfur is the clock that dates the oxygen

Sulfur has four stable isotopes. Ordinary chemistry sorts them by weight in a predictable way. But ultraviolet light acting on sulfur gas in an atmosphere with no oxygen sorts them in a way that has nothing to do with weight, leaving a signature that cannot be produced any other way. That signature is present in rocks older than about 2.4 billion years and vanishes afterward.

This is how the great oxygenation of the Earth is dated. Not by measuring oxygen — by measuring sulfur. The single most important date in the history of life is read off the element this paper is about.

---

3. Sulfur and the Proton ↩

The smallest scale, where sulfur changes how a proton moves

Chemistry at its finest grain is about where protons sit and how they move. A hydrogen bond is a proton shared between two atoms. Because a proton is light, it does not only climb over energy barriers — it can pass through them, a purely quantum effect called tunneling, and the rate depends steeply on how far it must travel and how heavy it is.

Sulfur changes both. It sits further from its partner than oxygen does, which lengthens the distance the proton must cross. It holds its electrons more loosely, which flattens the barrier. Replace an oxygen with a sulfur in a molecule and you have altered the quantum behavior of the protons around it.

Stated at its correct strength, because this is the most abused subject in the field. That protons tunnel is not in dispute; it has been standard in enzymology since the 1980s and is read from kinetic isotope effects. What is disputed is the

magnitude inside DNA, and the dispute is severe: across five published studies the estimated isotope effect for the guanine-cytosine pair differs by a factor of six, and two experimental studies find no evidence of transfer between bases at all. This paper reports all five rather than choosing one. Any claim here that depends on the absolute size of the effect is marked as such.

Where sulfur enters this cleanly is at the enzyme that opens the purine pathway. Inosine monophosphate dehydrogenase attacks its substrate with a cysteine — a sulfur atom — whose acidity the protein has tuned so that it is ready to react at the pH of the cell. A hydride is then transferred. Whether that transfer tunnels has never been measured, and it is one of the nine experiments listed at the end of this paper.

---

4. Sulfur and the Electron ↩

The other half of the quantum story, and the reason iron-sulfur clusters exist at all

The previous section was about the proton. This one is about the electron, and it is the stronger of the two, because where the proton evidence is disputed the electron evidence is settled.

One property generates most of the rest: sulfur's electron cloud is soft

Oxygen holds its electrons tightly. The cloud is small, dense and hard to deform. Sulfur holds its electrons loosely, one shell further out, and the cloud is large and easily pushed out of shape. The technical word is polarizability, and sulfur has several times more of it than oxygen.

Almost everything that follows is a consequence of that one difference.

property	oxygen	sulfur	consequence for life
Dispersion attraction	weak	strong	van der Waals forces scale with polarizability sulfur sticks to things oxygen does not
Contact radius	1.52 Å	1.80 Å	a larger surface to touch with
Preference in binding metals	hard: magnesium, calcium	soft: iron, copper, molybdenum, zinc	this is why iron-sulfur clusters exist
Holding an unpaired electron	poor	good	a soft cloud spreads a radical and keeps it fro destroying its surroundings
Carrying an electron onward	poor	good	sulfur relays; iron-sulfur clusters are conduits

Hard binds hard and soft binds soft. Iron is a soft metal and sulfur is a soft ligand. That one line of electron theory is why every iron-sulfur cluster in every organism exists, and why there is no iron-oxygen equivalent doing the same job.

This is the first-principles root of the cofactor economy described later in this paper. The cell does not use iron-sulfur clusters because of an evolutionary accident. It uses them because a soft, polarizable ligand is what will hold a soft metal and let an electron pass through.

Sulfur holds a radical still, which is why DNA can be made

A radical is an atom or molecule with one unpaired electron, and radicals are usually violently destructive; they tear hydrogen atoms off whatever is nearest. Ribonucleotide reductase, the enzyme that makes every deoxyribonucleotide, works by deliberately creating one — on a cysteine sulfur — and then using it to remove a hydrogen from the sugar.

That radical has to survive long enough to do its job and be recreated thousands of times without wrecking the enzyme. A soft, polarizable sulfur spreads the unpaired electron over a larger volume and lowers its reactivity. An oxygen in the same position would not hold still.

The enzyme that made DNA possible works by parking a radical on a sulfur atom. It parks there because sulfur's electron cloud is soft. That is a quantum-mechanical property of element sixteen, and the archive of life depends on it.

Electron tunneling, which is where the frontier actually is

Electrons tunnel further and more readily than protons because they are two thousand times lighter. In proteins this is not a curiosity but the ordinary mechanism: electrons move tens of ångströms through the folded chain, hopping between relay points, and iron-sulfur clusters are among the commonest relays. In ribonucleotide reductase the radical character itself travels roughly thirty-five ångströms between subunits along a chain of residues, in a coupled transfer of a proton and an electron together.

Sulfur-containing residues are favored relay points for the same reason they hold radicals: a loose cloud makes a low barrier. Where a paper says an enzyme performs long-range electron transfer, a sulfur is very often on the path.

And sulfur touches without bonding, which is under-appreciated

Not all of sulfur's contribution is covalent. Sulfur atoms make attractive contacts with the flat faces of aromatic rings — a weak interaction individually, but common and cumulative.

A measured case, in a human ion channel. Yeung and colleagues reported that sulfur-aromatic interactions occur in the majority of protein structures, and identified one doing mechanical work: a methionine at position 101 of the human Orai1 calcium channel latches against a phenylalanine gate. Simulations show the latch engaged in open channels and disengaged in closed ones; promoting the bond activates the channel and disrupting it closes the channel. The authors attribute the effect to the particular combination of length, flexibility and chemistry that methionine provides, and note that six such pairs in the hexameric channel contribute substantially to activation. This is a non-covalent sulfur contact operating as a gate.

A second measured case sits inside the methyl donor already discussed. Markham and colleagues examined how the positive sulfonium charge of S-adenosylmethionine shapes the molecule's preferred conformation, and found the sulfonium sulfur in van der Waals contact with a protein heteroatom in four of the structures surveyed — an energetically favorable contact rather than an incidental one.

What the mathematics in this paper does and does not contain

Later parts describe protein backbone conformation using quaternions. It should be stated plainly what that description includes. It is classical rigid-body kinematics: atoms treated as points, bonds as rods with rotatable joints. There is not one electron in it.

The quaternion carries the rotation. The electrons decide which rotations are permitted. Neither can do the other's job, and confusing them is how good arguments go wrong.

The map of permitted backbone angles — the Ramachandran plot every structural biologist works from — is entirely electronic in origin: overlapping electron clouds, electrostatic attraction and repulsion, and the subtler effects of orbital overlap along the chain. The quantum mechanics draws the boundary of the allowed region. The quaternion does exact arithmetic inside it. A disulfide bond is a physical constraint that removes part of the region altogether.

On the uncertainty principle, because it is usually invoked as a gap and is not one. The mathematics of quantum mechanics is complete for chemistry and is used daily: electron clouds are wave functions, molecular orbitals are solutions to the Schrödinger equation, and structures are predicted to spectroscopic accuracy. What remains unsettled is the interpretation — what the wave function is, rather than what it predicts — and chemistry does not wait on that question. Nor is uncertainty an obstacle to the argument of this paper. It is the reason the argument has numbers at all: confining an electron to a small volume forces a large spread in its momentum, and that confinement is why bonds have definite lengths and definite angles. The 92.12 degree bond angle quoted throughout this paper is a quantum-mechanical result.

---

5. Sulfur Is In All Four Kinds of Building Block ↩

Nucleic acids, proteins, sugars, fats — and where sulfur appears in each

Living things are built from four families of small molecules that link into chains. Sulfur appears in all four, in a different bond each time, and the pattern of which bond it makes where is a fact nobody has assembled before.

building block family	bond sulfur makes	where it is found	what it does there
Proteins	S–N and S–S	cysteine, methionine, the sulfenyl-amide switch, every disulfide bond	shape, catalysis, switchi
Sugars	S–N	N-sulfoglucosamine in heparan sulfate	decides which proteins t will bind
Nucleic acids	S–P	phosphorothioate in the DNA backbone; thiolated bases in transfer RNA	redox, gene regulation, r the code
Fats and lipids	S–C, O–S, and S–C(=O) throughout assembly	lipoic acid, two sulfurs on an eight-carbon chain; sulfoquinovosyl diacylglycerol, holding an estimated half the sulfur in the biosphere; sulfatide, 4 to 6 percent of myelin lipid; and the thioester tether at every step of fatty acid synthesis	cofactor catalysis, photo II function, myelin struct carrying the chain durin assembly

All four families carry sulfur. In proteins and sugars it bonds to nitrogen. In nucleic acids it bonds to phosphorus. In fats it makes three different bonds — carbon-sulfur in the sulfolipid and in lipoic acid, a sulfate ester in the sulfatide of myelin, and a thioester at every step of assembly — and holds an estimated half of the element in the living world. Part One Hundred and Nine sets out the lipid row in full.

The one in nucleic acids is the one nobody expected

For fifty-five years the textbooks said sulfur is absent from DNA. The definitive experiment of molecular biology relied on it: in 1952 Hershey and Chase labeled protein with radioactive sulfur and DNA with radioactive phosphorus precisely because the two do not mix, and used the separation to show that DNA carries heredity.

In 2007 it was found that they do mix. Bacterial gene clusters called dnd replace one oxygen of the DNA backbone with sulfur, in a specific sequence and a specific three-dimensional orientation. A later survey found 1,349 such systems spread across many bacterial groups, nearly half of them without the defense machinery that was first thought to explain them. The modification changes the cell's redox balance and changes how efficiently genes are transcribed.

Sulfur is in DNA. It took fifty-five years to find, because it sits on the backbone, and the backbone is the part the four-letter alphabet throws away.

What this does and does not overturn. Hershey and Chase were right about their phage and their conclusion stands. What failed is the generalization the field drew from their choice of tracer: that sulfur and nucleic acid are chemically separate categories. They are not. The convention was adopted because it was true of the system in front of them, and it hardened into a fact about all systems.

---

6. The RNA World Ran On Sulfur, and Sulfur Made DNA ↩

The transition every textbook draws as a change of letter was a change of atom

The standard account says life began with RNA, and DNA came later. It usually explains the change as a swap of one letter, uracil for thymine. That is not what happened. The change is at the sugar, one atom, and one enzyme performs it.

Ribonucleotide reductase removes a single oxygen from the sugar of a ribonucleotide and turns it into a deoxyribonucleotide. There is no other route in any organism that has ever been examined. Every strand of DNA on Earth, in every cell, exists because that one enzyme family removed that one oxygen.

And it is a sulfur enzyme four times over.

sulfur species	what it does in the reaction
S-adenosylmethionine	a sulfur-carrying molecule that is split to start the reaction
An iron-sulfur cluster	the metal-and-sulfur cage that does the splitting
A cysteine radical	a sulfur atom that grabs a hydrogen off the sugar — the committing step
A pair of cysteines	two sulfurs that join to each other, paying the two electrons that strip the oxyge away as water

Take sulfur away and there is no DNA. Not less DNA. None. The archive that holds every genome on Earth was written by a sulfur enzyme.

And the timing rules out the easy story

It is tempting to say oxygen created DNA — the atmosphere oxygenated, chemistry changed, the archive appeared. The dates forbid it. The oxygenation is placed near 2.4 billion years ago. The last common ancestor of all life is placed a billion years or more earlier, and it had DNA. The oxygen-requiring version of ribonucleotide reductase is the late version; the oxygen-sensitive version that runs on iron-sulfur clusters is the early one.

The archive is older than the atmosphere that now maintains it. Oxygen did not create DNA. Oxygen forced the sulfur machine that writes DNA to be rebuilt, and the rebuilt version is the one in your cells.

---

7. Sulfur Folds the Protein and Holds the Shape ↩

From two amino acids to glutathione to the disulfide bond that fixes a rotation

Two of the twenty standard amino acids contain sulfur. Methionine starts nearly every protein. Cysteine does the work.

A cysteine carries a thiol — a sulfur with a hydrogen on it. Two cysteines in a folded protein can lose their hydrogens and bond to each other, forming a disulfide bridge. That bridge is a staple. It holds two distant parts of a chain together and fixes the shape.

Glutathione: three amino acids that keep you from burning

Oxygen is corrosive. Every cell that uses it is continually damaged by reactive fragments of it, and the principal defense is a molecule of three amino acids called

glutathione, whose entire function rests on the sulfur of its central cysteine. That sulfur donates a hydrogen to a damaging radical and neutralizes it, and the spent molecule is recharged using energy from sugar.

This is why glucose-6-phosphate dehydrogenase deficiency — the commonest enzyme defect in the human species, carried by hundreds of millions of people — causes red blood cells to burst under stress. The pathway that recharges the sulfur has failed. Several hundred million people carry a mutation whose consequence is that they cannot keep one sulfur atom in its reduced state under pressure.

The Great Oxidation Event never ended. It happens inside every one of your cells every second, and sulfur is what stands between you and it.

And the disulfide bond fixes a rotation, which can be computed

A protein chain is a series of rotations. Each link can turn, and the shape of the whole is the accumulated result of all those turns. Mathematics has an exact tool for chained rotations in three dimensions — the quaternion, four numbers that compose without error and never gimbal-lock — and it is the tool used inside the best protein structure predictors built to date.

A disulfide bond removes rotational freedom. It ties two points of the chain together and forces a specific twist, and the preferred twist is measurable: hydrogen disulfide, the simplest molecule with a sulfur-sulfur bond, twists to 90.6 degrees, where the oxygen equivalent twists to 119.8. Every cystine bridge in every folded protein has to accommodate that near-right angle.

Sulfur is the element that fixes a rotation. Carbon, nitrogen and oxygen build the chain that turns; sulfur decides where the turning stops.

A note on how this is expressed mathematically, because the temptation is to overreach. It is natural to want to write sulfur as the real component of a quaternion with carbon, nitrogen and oxygen as the three imaginary units. That is not mathematics: a quaternion requires its three imaginary units to be mutually orthogonal quantities of the same kind, obeying $i^2 = j^2 = k^2 = ijk = -1$, and there is no product rule under which carbon multiplied by nitrogen gives oxygen. Written that way the expression cannot be computed and nothing can be derived from it. The legitimate and stronger statement is the one above: the rotations of a protein backbone are genuine quaternions, they compose exactly, and a disulfide bond is a physical constraint on that composition. Source code accompanying this paper

computes them, verifies Hamilton's relations numerically, and confirms that the composition is associative — the property the extension to eight-dimensional numbers loses, and the reason this framework stops at four.

---

8. Sulfur Runs the Traffic Between the Purine Ring and the Cofactors ↩

One donor, every cofactor, and a disease that removes it

A cell needs sulfur in many places at once, and it does not fetch it separately each time. One enzyme takes sulfur off the amino acid cysteine, carries it on its own surface as a reactive chain of two sulfurs, and hands it out.

destination	why it matters
Iron-sulfur clusters	the cages inside the enzyme that makes DNA, and hundreds of others
Thiolated bases in transfer RNA	the modifications that decide which codons get read
Molybdenum cofactor	required by the enzyme that empties the purine ring, and by the enzyme that disposes of sulfite
Thiamine, biotin, lipoic acid	central vitamins of energy metabolism

One donor. Four destinations. Cut the donor and all four stop at once.

And the cofactor that empties the purine ring is built from a purine

Molybdenum cofactor is assembled starting from GTP — a purine nucleotide. An enzyme carrying two iron-sulfur clusters grips the guanine and opens its ring. The finished cofactor is then required by xanthine oxidoreductase, the enzyme that discharges purines at the end of their life.

The enzyme that empties purines cannot work without a cofactor made out of a purine, provisioned with sulfur from the same donor that builds the enzyme that makes DNA. That is a closed loop, and it is not a metaphor.

The disease that proves it

If that account is right, one broken step in cofactor assembly should knock out the purine disposal pathway and the sulfur disposal pathway together, in the same patient. It does, and the disease has a name.

Molybdenum cofactor deficiency destroys three enzymes at once — sulfite oxidase, xanthine oxidase and aldehyde oxidase. Infants present within days with seizures and severe brain injury, and most die within three years. The clinical class is called sulfite intoxication disorders, because it is the accumulated sulfite that destroys the brain, not the lost urate.

disorder	what is lost	which side fails
Xanthinuria type I	one purine enzyme	purine side only; sulfur normal
Xanthinuria type II	two purine enzymes	purine side only; sulfur still normal
Isolated sulfite oxidase deficiency	one sulfur enzyme	sulfur side only; purines normal
Molybdenum cofactor deficiency	all three	both sides, because the shared part is gone

Knock out the purine enzymes and sulfur is untouched. Knock out the sulfur enzyme and purines are untouched. Knock out the part they share and both fail. That is how you know it is a shared part and not a coincidence.

And the methyl donor is a sulfur atom riding on a purine

Every chemical tag placed on DNA or on the proteins that package it — the marks that decide which genes are switched on in which tissue, and which are inherited through cell division — is delivered by S-adenosylmethionine. That molecule is made from the sulfur amino acid methionine and from ATP. Its sulfur carries the tag; its purine carries the sulfur.

The universal sulfate donor, PAPS, is the same design: a purine carrying a sulfur group. So are the thiolated bases of transfer RNA. Three separate sulfur delivery systems in the cell, all built on a purine handle.

---

9. Sulfur in Medicine, Which Is the Argument Nobody Can Wave Away ↩

What modern drug design actually aims at

If sulfur were a minor element, medicine would not be organized around it. It is.

what it is	how sulfur is involved	scale
KRAS G12C inhibitors	a mutation creates one cysteine; the drug bonds to that sulfur covalently	the major oncology advance of the last decade

what it is	how sulfur is involved	scale
Antibody-drug conjugates	the payload is attached through cysteine sulfurs	targeted cancer therapy
Proton pump inhibitors	form disulfide bonds with cysteines in the stomach acid pump	among the most prescribed drugs on Earth
Thiopurines	sulfur-substituted purines; dosing governed by two sulfur enzymes	leukemia and autoimmune disease
Sulfonamides	built on a sulfur-nitrogen bond	the first broadly effective antibacterials
Therapeutic antibodies	folded and held by disulfide bonds	the entire biologics industry

Half of modern pharmacology aims at a sulfur atom. None of it is visible anywhere in A, T, G or C.

What this section is and is not evidence for. That sulfur is central to medicine is not in dispute and is not this paper's discovery; every entry above is standard practice known to the people who do it. It is presented for one reason: to establish that the element the notation cannot express is the element a large fraction of therapeutic chemistry is aimed at. That is a statement about the notation, not about the pharmacology.

---

10. Why This Adds Up to a Case for Changing the Model ↩

Necessary, sufficient, and what those words are doing here

The argument of Part One can now be stated compactly, and it should be stated carefully, because the words necessary and sufficient have precise meanings and this paper claims only one of them.

claim	status	basis
Sulfur is NECESSARY for DNA to exist	yes, and demonstrably	no ribonucleotide reductase, no deoxyribonucleotide, in any organism
Sulfur is NECESSARY for the code to be read accurately	yes	thiolated wobble bases tune decoding; remove them and fidelity degrades
Sulfur is NECESSARY for proteins to hold shape	yes	disulfide bonds fix tertiary structure
Sulfur is NECESSARY for cells to survive oxygen	yes	glutathione, and the disease that follows when fails
Sulfur is SUFFICIENT to explain the code	NO, and no such claim is made	sufficiency would require deriving the codon ta from sulfur chemistry, which nobody can do

Necessary at four separate points, and sufficient at none. That is the honest shape of a first-principles case, and it is strong enough. A claim of sufficiency would be stronger and would be false.

What first principles says the model should become

The central dogma states which information may flow: DNA to RNA to protein, and not backward. It is a claim about direction, framed deliberately in terms of sequence and not chemistry. That precision made it powerful and it is not disputed here.

What it does not state is what must physically be present for any of that flow to occur. It names no atom, no metal, no cofactor. That silence was a reasonable choice in 1958. Sixty-eight years later it is taught as though it were the whole account, and a student learns a diagram in which the element that makes DNA possible does not appear.

The dogma says which information can move. It does not say which atoms must be there for anything to move at all. Both models are needed. Only one is taught.

Part Twenty-One of this paper sets out the second model: every arrow of the diagram annotated with what it cannot proceed without, and what fails when that thing is removed. Sulfur appears in five of the six rows — not as a letter, but as a precondition.

---

11. What Would Show This Is Wrong ↩

Stated here, at the front, because a claim this large is worth nothing without it

One. Demonstrate a deoxyribonucleotide made by any route that does not require ribonucleotide reductase, and the central claim of Part One collapses.

Two. Show that deleting the cysteine desulfurase leaves iron-sulfur assembly, transfer RNA thiolation and molybdenum cofactor synthesis intact, and the shared-supply argument collapses.

Three. Show that the features cataloged in Part Twenty-One can be written in four-letter notation without extending it, and the notational argument collapses.

Four. Show that sulfur's chemical range — the eight oxidation states, the ninety-two degree bond, the stable chain to itself — is matched by another element

available to early life, and the first-principles argument for sulfur specifically collapses into an argument for chemistry generally.

Four ways to be wrong, named before the evidence is presented. A model that cannot be refuted is decoration.

PART TWO · SULFUR AND OXYGEN, THE CONJUGATE PAIR

12. The Same Atom, One Shell Apart ↩

Why these two elements are not neighbors in a list but partners in a mechanism

Everything in this book turns on a relationship between two elements, and the relationship has to be stated before anything else makes sense.

Sulfur and oxygen sit in the same column of the periodic table. Group sixteen. Both have six electrons in their outer shell, both want two more, both form two bonds when they are being simple about it. In the arithmetic of valence they are interchangeable, and biology exploits that interchangeability constantly: serine and cysteine are the same amino acid with one substitution, an ester and a thioester are the same linkage with one substitution, water and hydrogen sulfide are the same molecule with one substitution.

They are conjugate partners. Not similar elements — the same slot in the architecture, filled by a different atom, with different consequences every time.

But the substitution is never neutral, and the differences are all in one direction

Sulfur's extra electron shell puts its outermost electrons further from the nucleus and holds them more loosely. Every difference that matters follows from that.

property	oxygen	sulfur	what it means
Covalent radius	0.66 Å	1.05 Å	sulfur reaches further and makes a longer bond
Electronegativity	3.44	2.58	oxygen pulls electrons hard; sulfur shares
Bond angle to two hydrogens	104.51°	92.12°	near-tetrahedral against near-perpendicul

property	oxygen	sulfur	what it means
Bond to itself	1.475 Å, unstable	2.055 Å, stable in long chains	sulfur catenates; oxygen barely does
Hydride boiling point	+100 °C	−60 °C	oxygen hydrogen-bonds; sulfur does not
Polarizability	low	several times higher	sulfur's cloud deforms and sticks

The bond angle is worth dwelling on, because it is the cleanest illustration of what a conjugate substitution does. Water bends at 104.51 degrees, close to the tetrahedral 109.5, because oxygen's lone pairs occupy hybrid orbitals and crowd the bonding pairs. Hydrogen sulfide bends at 92.12 degrees — close to ninety, which is the angle between unhybridized p orbitals. Sulfur, holding its electrons loosely, does not pay the energetic cost of hybridizing. It uses its p orbitals as they are.

Two atoms in the same column, bonded to the same two hydrogens, seventeen degrees apart. That is what a conjugate substitution costs, and every substitution in this book costs something similar.

---

13. Oxygen Ends Flows. Sulfur Carries Them. ↩

The asymmetry that makes one of them a terminus and the other a conduit

If the two elements were merely similar the story would end there. They are not. In the chemistry life actually runs, they behave in opposite ways, and the opposition is the engine of everything that follows.

Oxygen in biology occupies essentially one state. It arrives as dioxygen at zero, it leaves as water or as a hydroxyl at minus two, and the brief excursion through peroxide at minus one is treated as damage to be cleaned up. Oxygen is where electrons go to stop. It is the terminal acceptor, and the word terminal is doing real work in that phrase.

Sulfur occupies eight states, and moves between them routinely, in ordinary metabolism, without anything being damaged.

species	oxidation state	where it appears
Sulfide, thiol	−2	hydrogen sulfide, cysteine, the persulfide donor
Disulfide	−1	the bond that holds a protein's shape
Elemental sulfur	0	the storage granule in a purple sulfur bacterium
Thiosulfate, inner	+2 (formal)	an intermediate in oxidation and in disposal

species	oxidation state	where it appears
Sulfenic acid	0 to +2	the redox switch on a signaling cysteine
Sulfinic acid	+2	the next oxidation, reversible only by one enzyme family
Sulfite	+4	the intermediate that is toxic if it accumulates
Sulfate	+6	the terminal product, and the universal donor group

Oxygen has one state and a full stop. Sulfur has eight and a ladder. That is why sulfur can be a conduit for electrons and oxygen can only be their destination.

This is the deepest reason the cell is organized the way it is. Any system that has to move electrons over distance, hold them temporarily, hand them off, and reverse the transaction tomorrow needs an element that can occupy intermediate states without being destroyed by them. Only sulfur, among the abundant light elements, does that. Phosphorus does not change state in biology at all — it is always plus five. Nitrogen has a range but is locked into ring systems. Carbon changes state but is the skeleton and cannot afford to move.

And the two of them meet in one reaction, which is the most consequential reaction there has ever been

Ribonucleotide reductase converts a ribonucleotide into a deoxyribonucleotide. What it does, physically, is remove the hydroxyl at the two-prime position of the sugar. It removes an oxygen.

It does this with sulfur. A cysteine thiyl radical abstracts the hydrogen from the three-prime carbon; a pair of cysteines becomes a disulfide and pays the two electrons that carry the two-prime hydroxyl away as water. Four distinct sulfur species in one active site, performing one subtraction.

A sulfur takes an oxygen off a sugar, and DNA exists. The conjugate pair, in a single active site, performing the step that made a permanent archive possible.

Why this is the hinge of the whole argument, stated plainly. The standard account of the RNA-to-DNA transition names a change of base: uracil becomes thymine. That is not what happens first and it is not what defines the molecule. What defines deoxyribonucleic acid is the missing oxygen at the two-prime position of the sugar, and the missing oxygen is missing because a sulfur atom took it. Thymine

arrives afterward, for a separate reason given later in this volume. Any account that leads with the base has described the second event and skipped the first.

---

14. The Great Oxidation Event Is Dated by Sulfur ↩

The element records the arrival of its own displacement

About two and a half billion years ago the atmosphere of this planet acquired free oxygen. It is the largest chemical discontinuity in the history of the Earth, and it reorganized every metabolism then in existence.

The way that date is established is the point of this section. It is not established by measuring oxygen. Oxygen leaves no direct record in rock of that age. The date comes from sulfur.

How the clock works

Sulfur has four stable isotopes. Ordinarily, chemical and biological processes sort them by mass in a strictly proportional way: a reaction that enriches sulfur-34 by some amount enriches sulfur-33 by about half that amount, because the mass differences stand in that ratio. This is mass-dependent fractionation and it is the normal state of affairs.

In an atmosphere without oxygen there is no ozone layer, and short-wavelength ultraviolet light reaches the lower atmosphere and photolyzes sulfur dioxide directly. That photochemical route does not sort isotopes by mass. It produces a signature — an excess or deficit of sulfur-33 relative to what the mass ratio predicts — that no ordinary process can imitate. The technical name is mass-independent fractionation.

state of the atmosphere	what happens to sulfur	what the rock records
Before oxygen	UV reaches the troposphere and photolyzes SO2	mass-independent signal present in sediments
Ozone forms	UV is absorbed high in the atmosphere	the photochemical route is shut off
After oxygen	sulfur cycles through sulfate reduction only	signal absent; ordinary mass-dependent sorting only

The moment oxygen arrived is the moment the sulfur signal disappears from the rock. Sulfur is the clock that records its own displacement.

This is not a figure of speech and it is not an interpretation this volume is placing on the data. It is how the Great Oxidation Event is dated, in the primary literature, by the people who date it. The most important event in the chemical history of the planet is read off the isotopes of the element this book is about.

The date should be held loosely, and this is why. Recent work finds the mass-independent signal globally asynchronous rather than vanishing everywhere at once. It persists in some sections past 2.31 billion years, and the transition is best bracketed between roughly 2.50 and 2.32 billion years rather than fixed at a single date; some authors argue on those grounds that the event needs redefining. None of the argument in this volume depends on a precise date. It depends only on the ordering — that an anaerobic world preceded an aerobic one, and that the machinery of the anaerobic world was built on sulfur.

And the enzyme was rebuilt at the same moment

Ribonucleotide reductase comes in three classes. Class three is oxygen-sensitive: it generates its radical using S-adenosylmethionine and an iron-sulfur cluster, and free oxygen destroys it. Class one requires dioxygen to generate its radical at all. Class three is the anaerobic enzyme and therefore the older one; class one is the aerobic enzyme and therefore the later one.

The archive is older than the atmosphere that now maintains it. Oxygen did not create DNA. Oxygen forced the machine that writes DNA to be rebuilt, and the rebuilt version is the one in your cells.

---

15. Inosine Is Oxygen's Mark on the Purine ↩

The single chemical fact that ties the two threads of this book into one

This section makes a claim that reorganizes the rest of the volume, and it rests on a reaction any biochemistry text will confirm.

Adenine carries an amino group at position six of the purine ring. Remove that amino group by hydrolysis and a keto oxygen takes its place. The base is then hypoxanthine; the nucleoside is inosine. The reaction is a deamination, and it is catalyzed by adenosine deaminase in the nucleoside pool, and by the ADAR family on double-stranded RNA.

$$\textit{adenosine} + H_2O \rightarrow \textit{inosine} + NH_3$$

Inosine is not merely related to adenosine. Inosine is what oxygen does to adenosine. The orange channel of this book's color index is the deamination channel.

The same operation runs on the other purine. Guanine deaminated is xanthine, the base of the indigo channel, one step from disposal. And on the pyrimidine side, cytosine deaminated is uracil.

base	becomes	by	consequence
Adenine	hypoxanthine (inosine)	adenosine deaminase, ADAR	a base that pairs with three, and reads as a fourth
Guanine	xanthine	guanine deaminase	the last stop before urate and excretion
Cytosine	uracil	spontaneous, and APOBEC enzymes	damage in DNA; the reason thymin exists
5-methylcytosine	thymine	spontaneous	damage that the repair machinery cannot see as foreign

And this is where the two threads of the book become one thread

Deamination is oxygen's signature on the nucleobases. Every entry in the table above is an amine leaving and an oxygen arriving. In three of the four rows the product is damage. In one row — the first — the product is a functional molecule that the cell manufactures deliberately, installs in the anticodon of its own adaptors, and uses to read the code.

Now the pyrimidine side. Cytosine deaminates to uracil constantly, by the thousands of events per cell per day. In an RNA molecule, where uracil is a legitimate letter, this is invisible and uncorrectable. In DNA, where the legitimate pyrimidine is thymine, a uracil found in the strand is unambiguously damage and can be excised. Thymine is cytosine's proofreading mark, and its methyl group is what makes deamination detectable.

Orange is the damage. Yellow is the answer to it. Oxygen deaminates the bases; sulfur and thymine hold the line. That is the plot of this book and it runs the entire length of it.

The color index is mechanistic, not decorative. This volume marks adenine and its compounds in red, inosine and its compounds in orange, sulfur and thymine in yellow. Those are not arbitrary groupings. Red to orange is one hydrolysis — the loss of an amine and the gain of an oxygen. Yellow is the element that repairs what that

reaction breaks, together with the base whose methyl group makes the repair possible. A reader who follows only the color can follow the argument.

One consequence, stated now and demonstrated later

If inosine is oxygen's mark on adenine, then the presence of inosine in the anticodon is a record of an oxidative event that the cell has domesticated. The cell takes a damage reaction, performs it on purpose at one position in one molecule, and gets a reader that recognizes three codons instead of one.

The cell took the most common form of purine damage and made it into a decoding instrument. Nothing in the four-letter alphabet can express that, because the alphabet has no symbol for the product and no notation for the operation.

PART THREE · THE MOLECULE WITH NO LETTER

16. Four Measurements, and Inosine Wins All Four ↩

The only part of the prebiotic case that is contested, argued at length because it is contested

The modern position of IMP is settled and is stated once: the ten-step de novo pathway closes at inosine monophosphate, from which adenylosuccinate lyase produces AMP and IMP dehydrogenase produces XMP and thence GMP. This is textbook and is not argued here.

What is contested is the prebiotic claim, and it rests on four measurements made by other people for other reasons.

measurement	result	source class
Glycosylation yield	hypoxanthine + ribose gives measurably higher yield of the nucleoside than adenine or guanine	Orgel and colleagues
Backbone regiochemistry	the inosine product favors the biologically correct linkage	same series
Oligomer chain length	inosine-containing oligomers reach greater length under the same conditions	non-enzymatic polymerization
Copying fidelity	non-enzymatic template copying is more accurate with the inosine pair	non-enzymatic copying studies

The negative half of the argument is the stronger half. Szostak's group has published that efficient prebiotic routes to adenosine and guanosine remain elusive. Sutherland's cyanosulfidic route reaches the pyrimidines cleanly and the purines with difficulty. So the position is not merely that inosine performs well; it is that the two purines the alphabet did select have no demonstrated efficient prebiotic synthesis at all, while the one it did not select does. A reader who rejects everything else in this document should still be uncomfortable with that asymmetry.

Four measurements. Inosine wins all four. It has no seat in the alphabet, and the two purines that do have seats cannot be made efficiently by any demonstrated prebiotic route.

And the cheap route to IMP is one step, not ten

De novo synthesis assembles the purine ring in ten steps from phosphoribosyl pyrophosphate, consuming roughly five ATP equivalents together with two one-carbon units from tetrahydrofolate, two amide nitrogens from glutamine, aspartate, glycine and carbon dioxide.

Salvage is one step. Hypoxanthine-guanine phosphoribosyltransferase condenses hypoxanthine with PRPP to give IMP and pyrophosphate, and that is the whole reaction. Adenine takes a separate enzyme, adenine phosphoribosyltransferase, to AMP.

SEE PART NINETY-SEVEN. The PRPP consumed in this reaction is the shared node of both nucleotide pathways. Section 797 lists every base that enters the nucleotide pool through it, and section 798 shows where the purine and pyrimidine branches divide.

The expensive route makes IMP in ten steps. The cheap route makes IMP in one. Both converge on the same molecule, and the salvage enzyme's substrate is the inosine base.

Tissues differ in which they use. The brain has limited de novo capacity and depends heavily on salvage, which is why complete loss of the salvage enzyme — Lesch-Nyhan syndrome — presents as hyperuricaemia together with severe neurological disease rather than as a purely metabolic disorder. It belongs on the same table of purine defects as the four sulfur enzymes discussed in Part Six.

What this does not establish

It does not establish that inosine was in a primordial alphabet. Prebiotic plausibility is not evidence of prebiotic occurrence, and the measurements above were made under laboratory conditions chosen by experimenters. The claim this document makes is narrower: that the standard account treats the four letters as chemically privileged, that this privilege is not visible in the measurements, and that the discrepancy has gone unexamined because the notation makes it hard to state.

PART FOUR · THE ALGEBRA OF THE PURINE LOOP

17. Four Nucleotides as Hamilton's Quaternions ↩

Not quaternions assigned to nucleotides — the nucleotides as the algebra

Carlevaro, Irastorza and Vericat proposed in 2015 a quaternionic representation of the genetic code, assigning four prime integer quaternions of norm seven to the four bases. Their stated reason for choosing primes is explicit: taking the nucleotide bases as prime quaternions, they write, gives them the character of elemental molecules.

Elemental is precisely what they are not. AMP is IMP plus a nitrogen at C6. GMP is IMP oxidized to XMP and then aminated at C2. Primality is the formal assertion that an object has no factors and comes from nowhere, so their algebra encodes a flat set of four peers where metabolism runs a derivation tree with one root — and the root is not in their set at all.

This paper takes the opposite route. It does not assign quaternions to nucleotides. It makes the four human purine nucleotides the basis of the algebra:

$$IMP = 1 \quad XMP = i \quad GMP = j \quad AMP = k$$

nucleotide	unit	office	enzymology
IMP	1	real unit	Root of de novo synthesis; the ten-step pathway closes here
XMP	i	the gate	IMP dehydrogenase; oxygen from water; obligate passage to guanine
GMP	j	green child	GMP synthetase; nitrogen from glutamine
AMP	k	red child	Adenylosuccinate synthetase and lyase; nitrogen from aspartate

Every result below is a theorem of Hamilton's multiplication table once these four identifications are made, and every one is verified by computation in the accompanying source file.

IMP is the multiplicative identity

$$IMP \cdot q = q \cdot IMP = q \quad \text{for every } q$$

Multiply any purine state by IMP and nothing changes. That is the whole content of calling IMP the parent, and it is now a property of the arithmetic rather than a claim about a diagram. No assignment of four equal-norm primes to four bases can express it, because in that scheme every generator is interchangeable with every other.

Each child squares to the negated parent

$$XMP^2 = GMP^2 = AMP^2 = -IMP$$

No child is its own precursor. None is idempotent. Purine metabolism has no self-sustaining side branch, and the algebra says so without being told.

The loop closes, and it closes as Hamilton's own relation

$$XMP \cdot GMP \cdot AMP = -IMP$$

This is ijk = −1, the relation Hamilton cut into Brougham Bridge in 1843. Under this assignment it says: traverse the gate, then the green child, then the red child, and you arrive back at the parent. The purine loop closing and Hamilton's defining relation are the same equation.

Direction has a sign

forward	result	reverse	result
XMP · GMP	AMP	GMP · XMP	−AMP
GMP · AMP	XMP	AMP · GMP	−XMP
AMP · XMP	GMP	XMP · AMP	−GMP

Reverse the order and the sign flips. This is the most useful property the algebra has, because purine metabolism is directional and standard notation cannot say so. IMP to XMP to GMP runs anabolically through IMP dehydrogenase and GMP synthetase. The reverse arm is catabolic and uses entirely different enzymes — guanase, xanthine oxidoreductase. They are not one reaction run backward, and a commutative representation is forced to pretend they are.

Conjugation is the catabolic arm; the norm is the pool

$$q^* = w\cdot IMP - x\cdot XMP - y\cdot GMP - z\cdot AMP \qquad q \cdot q^* = N(q) \cdot IMP$$

The conjugate holds IMP still and inverts every child. The product of a state and its conjugate is a pure multiple of the root: anabolic times catabolic returns the parent, scaled by pool size. That is turnover in one line, and HPRT, adenosine deaminase and guanase are the machinery that performs the conjugation. The norm $N(q) = w^2 + x^2 + y^2 + z^2$ sums the four pools and is multiplicative under composition — nothing is created.

What is not claimed

The products are not reactions. XMP · GMP = AMP is a fact about Hamilton's algebra and not about a test tube. No enzyme condenses xanthosine monophosphate with guanosine monophosphate to yield adenosine monophosphate, and nothing here says one does. The four nucleotides are basis elements of a state space; the products describe how states compose, not how molecules react.

A reader who takes ijk = −1 as a proposed reaction will reject this on sight, and would be right to.

A spinor structure, unasked for

Unit quaternions are the double cover of the rotation group — the same mathematics that makes an electron require 720 degrees to return to itself. That structure appears here without being added: XMP → −IMP → −XMP → IMP. One traversal of the loop lands on the negated parent; two traversals return the identity. A 360-degree pass through the purine loop is not the identity.

One thing this structure does not permit, tested against 200,000 random unit quaternions: the parent cannot move. Every automorphism of the quaternions fixes the real axis pointwise, so AMP never acquires a real part — largest value observed, 5.55×10^{-17}, which is floating-point zero. No loop of any length promotes a child to root. If AMP became the parent, that would not be this algebra rotated; it would be a different algebra.

---

18. The Encoding, in Full ↩

Four components, four physical facts — and the six-cell lattice as a theorem rather than an observation

The quaternion above is written at the level of the metabolic loop. Underneath it is a finer encoding in which every component names a physical position on the molecule, and from which the pairing chemistry and the lattice count both fall out without being put in.

A nucleotide is written q = (a_0, a_1, a_2, a_3). Nothing is arbitrary.

a_0 — ring class and sugar. Magnitude is the ring count: 2 for a purine, 1 for a pyrimidine. Sign is the sugar: positive for ribo, negative for deoxy.

a_1, a_2, a_3 — the Watson-Crick face, in register. The three contact positions: purine C6 or pyrimidine C4, then purine N1 or pyrimidine N3, then purine C2 or pyrimidine C2. Values are +1 for a donor (exocyclic amine or ring N-H), −1 for an acceptor (carbonyl oxygen or ring nitrogen lone pair), and 0 for no contact.

nucleotide	quaternion	norm	class	note
AMP	(2, +1, −1, 0)	6	purine · ribo	C6 donor, C2 unopened
IMP	(2, −1, +1, 0)	6	purine · ribo	root; C2 unopened
XMP	(2, −1, +1, −1)	7	purine · ribo	gate; both sockets open
GMP	(2, −1, +1, +1)	7	purine · ribo	C2 loaded
ZMP	(2, +1, −1, +1)	7	purine · ribo	2-aminoadenine, phage Z-genome
isoGMP	(2, +1, −1, −1)	7	purine · ribo	never observed in a genome
CMP	(1, +1, −1, −1)	4	pyrimidine · ribo	C4 donor
UMP	(1, −1, +1, −1)	4	pyrimidine · ribo	C4 acceptor
dAMP	(−2, −1, +1, 0)	6	purine · deoxy	= −AMP
dGMP	(−2, +1, −1, −1)	7	purine · deoxy	= −GMP
dCMP	(−1, −1, +1, +1)	4	pyrimidine · deoxy	= −CMP
dTMP	(−1, +1, −1, +1)	4	pyrimidine · deoxy	= −UMP

Thymidine monophosphate comes out as the exact negation of UMP, because the C5 methyl does not touch the Watson-Crick face. The methyl is a repair flag, not an information carrier, and the encoding says so without being told.

dTMP = −UMP. The fifth letter of DNA carries no information the fourth did not.

The canonical four are not primes

Each step of purine metabolism is a single quaternion addition, and the enzyme that performs it is named.

$$AMP = IMP + (2i - 2j)$$

Adenylosuccinate synthetase and lyase, nitrogen from aspartate, paid for in GTP.

$$XMP = IMP - k$$

IMP dehydrogenase, oxygen from water rather than from dioxygen — which is why the ladder runs in an anoxic world.

$$GMP = XMP + 2k = IMP + k$$

GMP synthetase, nitrogen from the amide of glutamine, paid for in ATP. The last line carries the gate: the net displacement from parent to green child is a single +k, but no enzyme performs it. The path is −k and then +2k, through XMP, and the algebra records the difference between a displacement and a route.

The norm counts opened sockets

IMP and AMP have norm 6. XMP and GMP have norm 7. The difference is exactly the C2 socket: unopened in the parent and in the adenine child, opened by IMPDH in everything downstream. The published quaternionic representation assigns all four generators the same norm and calls them prime. Here the norm is a measurement, and the parent is distinguishable from the gate by arithmetic alone.

Deamination is subtraction, and two of the three are the same operator

$$AMP \to IMP \quad \Delta = (0, -2, +2, 0)$$

$$CMP \to UMP \quad \Delta = (0, -2, +2, 0)$$

$$GMP \to XMP \quad \Delta = (0, 0, 0, -2)$$

The claim elsewhere in this paper is that the three deaminations of nucleic acid chemistry are one accounting entry. The algebra sharpens that claim rather than confirming it: A→I and C→U are literally the same operator, and G→X is the same operation applied at the third contact instead of the first two. That is a refinement, and it is stated as one.

Pairing — hydrogen bonds fall out of the dot product

Two nucleotides in Watson-Crick register are compared contact by contact. A product of −1 at a position is a complementary bond, donor facing acceptor. A product of +1 is a clash. Zero is no contact. The hydrogen-bond count is the number of −1 terms. No parameters were fitted.

pair	contact terms	bonds	clashes	observed
G : C	[−1, −1, −1]	3	0	3 ✓
A : U	[−1, −1, 0]	2	0	2 ✓
I : C	[−1, −1, 0]	2	0	2 ✓
Z : T	[−1, −1, −1]	3	0	3 ✓
X : C	[−1, −1, +1]	2	1	2 ✓
isoG : C	[+1, +1, +1]	0	3	0 ✓

Two of these are worth pausing on. The phage Z-genome result — 2-aminoadenine making three hydrogen bonds with thymine where adenine makes two — is not put in by hand; it is what the third contact returns once the C2 socket is loaded. And isoguanine returns zero bonds with three clashes against cytosine, because isoguanine's face is cytosine's own face.

I : C makes two bonds where G : C makes three. That is the inosine prediction, stated in one line of arithmetic.

The six-cell lattice, in full

The purine ring carries two sockets. C6 always bears a substituent and ranges over donor and acceptor. C2 ranges over donor, acceptor, and unopened. Two times three is six, and the count is a theorem of the encoding rather than an observation appended to it.

nucleotide	quaternion	C6	C2	status
IMP	(2, −1, +1, 0)	acceptor	unopened	root — where de novo synthesis closes
AMP	(2, +1, −1, 0)	donor	unopened	child — amination at C6
XMP	(2, −1, +1, −1)	acceptor	acceptor	gate — obligate passage, IMPDH
GMP	(2, −1, +1, +1)	acceptor	donor	child — amination at C2
ZMP	(2, +1, −1, +1)	donor	donor	occupied by phage Z-genomes
isoGMP	(2, +1, −1, −1)	donor	acceptor	never observed in a genome

The sixth cell is not empty for want of chemistry. It is empty because it collides.

Verdict

Six nucleotides, one root, three operators. Every consequence above is computed, not fitted.

Derived, with no fitting and no free parameters

- Six cells, not five or seven — from two socket states times three C2 states.
- Hydrogen-bond counts correct on six of six known pairs.
- dTMP = −UMP, without the methyl being mentioned in the encoding.
- The norm separates the parent and the adenine child from everything past the gate.
- Two deaminations identified as literally the same operator.

Scope, stated plainly

This is a representation, not a mechanism. Nothing here claims a cell performs quaternion arithmetic, and no reaction rate, equilibrium constant or free energy is predicted by it. What it claims is narrower: that a notation whose generators are nucleotides and whose components are physical positions reproduces the pairing chemistry and the lattice count without being told them, and that a notation whose generators are four bases of equal norm cannot express the derivation at all. The encoding is blind to the sugar by construction, since all three contacts sit on the base edge, and the lattice result does not depend on the sugar term.

The quaternion question — what the algebra gives, and what it does not

Ask whether the proton-transfer Hamiltonian can be written as a quaternion and the answer is yes, exactly and without strain. The interesting part is what that buys.

Both the open-quantum-system work and the inelastic-tunneling treatments truncate the proton to two states: localized in the left well, localized in the right. The Hamiltonian of any two-state system is a 2 × 2 Hermitian matrix, and every such matrix expands in the basis of the identity and the three Pauli matrices. For a double well with asymmetry ε and tunneling matrix element Δ:

$$H = \varepsilon\,\sigma z - \Delta\,\sigma x$$

The three Pauli matrices multiplied by the imaginary unit close under multiplication into precisely the algebra of the imaginary quaternions: iσx, iσy, iσz obey the same multiplication table as i, j, k. Hamilton's algebra and the algebra of a spin-half are the same object. So the identification is immediate, the time evolution operator becomes a unit quaternion, the proton's state is a point on the Bloch sphere, and coherent tunneling is a rotation about the axis fixed by Δ. The tunneling splitting is a precession frequency and the well asymmetry is a tilt.

It is a change of notation, not a change of physics. Every prediction is identical to the complex two-by-two formulation, because the two algebras are isomorphic.

Two cautions, and the second is the one that matters.

First, quaternionic quantum mechanics in the strict sense — the program of Finkelstein, Adler and others, in which the Hilbert space itself is built over the quaternions rather than the complex numbers — is a different proposal entirely, and it is not this. It makes predictions that depart from standard quantum mechanics, it has been searched for in neutron interferometry and elsewhere, and nothing has been found. Invoking it would attach a speculative physics program to an argument that does not need one.

Second, and more important: the two-state Hamiltonian is the part of this problem that does not produce the result. The tautomeric occupation figure does not come from the closed system. It comes from the bath — the surrounding water simultaneously decoheres the proton and thermally excites it into eigenstates high enough in the well to tunnel. Decoherence and activation from the same source, which is why an open-system master equation was required and why a closed Hamiltonian in any notation returns the wrong answer. The quaternion form describes the coherent rotation. The physics that generates the number is the dissipative coupling that destroys the coherent rotation.

The elegant object is the one that omits the mechanism. That is worth knowing before building an argument on it.

The other quaternion program, and why it inherits the fault

There is a second and entirely separate use of quaternions in this field, and it must not be confused with the first. The proton-transfer Hamiltonian above is a two-state physical system that happens to be expressible in Hamilton's algebra. What follows is a quaternionic representation of the genetic code itself — a different object, a different justification, and a different verdict.

Carlevaro, Irastorza and Vericat proposed in 2015 a Hamilton-quaternion representation of the standard code. They assign an integer quaternion to each letter, drawn from the prime integer quaternions of norm seven, taking the reduced set of four elements chosen because no two are conjugates. A codon function then maps triplets to amino acids by quaternion products and sums, reproducing the observed degeneracy automatically, with extra quaternions supplied to handle the

six-codon residues. They go on to apply type and order quaternions to protein folding.

The folding application is where quaternions genuinely earn their keep. A polypeptide backbone is a chain of rotations, and rotations are the thing quaternions were invented to compose without gimbal lock or matrix drift. Nothing here argues against that, and the glycine and proline geometry of the β-turn is exactly the regime where such a representation should be tested.

The representation of the code is another matter, and the objection is not to the algebra. It is to what the algebra is built on. Their stated reason for choosing primes is explicit: taking the nucleotide bases as prime quaternions, they write, gives them a certain character of elemental molecules.

Elemental is precisely what the four are not. AMP is IMP with a nitrogen loaded at C6. GMP is IMP oxidized to XMP and then aminated at C2.

Primality in the algebra encodes indivisibility and underivedness. It is the formal assertion that these four objects have no factors and come from nowhere. But two of the four are the parent plus one enzymatic operation, and the parent is not in the set at all. A representation that makes AMP and GMP prime, and omits IMP, has written the wrong topology into its arithmetic — a flat list of four peers where metabolism runs a derivation tree with one root.

The second objection follows from the first. The scheme is presented as preserving the code's degeneracy, and preservation is offered as the criterion of success. On this paper's reading, the degeneracy is an aliasing artifact of a sixty-four-cell grid sampling a forty-adaptor process. A representation that reproduces it faithfully has reproduced the artifact faithfully. It is a more powerful algebra fitted to the projection rather than to the object.

The quaternions are not the problem. The set they were assigned to is.

Which suggests the constructive version rather than the dismissal, and it is Experiment Sixteen. Build the codon function on nucleotides and let the algebra carry what the letters cannot: IMP as the root, AMP and GMP as products of it under named operations, XMP as a gate rather than a symbol, and modification state at anticodon position 34 as an operator applied to a reading rather than a member of the alphabet. In such a representation the degeneracy should not have to be

preserved by fiat. It should fall out of the inosine operator, because that is where it comes from in the cell.

PART FIVE · THE ENCODING

19. A Bond Count That Predicts Structures It Was Not Shown

The strongest formal result here, because it made predictions before it was checked

Each purine presents a Watson-Crick face carrying hydrogen-bond donors and acceptors at three positions. Encode each position as +1 for a donor, −1 for an acceptor, 0 for neither. Nothing else. No geometry, no charge, no sterics, no energy.

base	face	encoding
Adenine	N1 acceptor, C6-NH_2 donor, N7 acceptor	−1, +1, −1
Guanine	N1-H donor, C6=O acceptor, N2-H_2 donor	+1, −1, +1
Hypoxanthine (inosine)	N1-H donor, C6=O acceptor, no C2 substituent	+1, −1, 0
Xanthine	N1-H donor, C6=O acceptor, C2=O acceptor	+1, −1, −1

What it got right without being told

i. Enumerating the encoding over the exocyclic positions produces a six-cell lattice. Biology occupies four of the cells. A bacteriophage occupies a fifth, 2-aminoadenine, reported in Science in 2021 — after the encoding was written. The sixth is synthesizable and has not been found in a natural genome.

ii. The encoding rejects isoguanine as a Watson-Crick partner for cytosine without being given steric information, because isoguanine's face is cytosine's own face inverted.

iii. Applied to the G-tetrad, the encoding predicts that a tetrad-forming base must carry a donor and an acceptor on both the Watson-Crick and Hoogsteen faces simultaneously. Guanine is the only base that does. Inosine fails by exactly one contact — the missing 2-amino group.

An encoding that counts bonds and nothing else predicted a lattice, rejected a base, and identified the unique tetrad former. Three predictions from three integers per base.

And one place it fails, which bounds it precisely. The encoding counts donors and acceptors on neutral species. It has no term for ionization state, so it scores xanthine as a plausible tetrad former and is wrong: xanthine's N3 proton has a pKa near 5.7, so at physiological pH the base is anionic and four anions will not surround a cation channel. Xanthine is excluded by charge, not by bond count. The encoding is a neutral-species approximation, and adding a protonation term is straightforward and has not been done. Source code for the encoding and its verification accompanies this document.

PART SIX · THE PROTON AND THE CARBONYL

20. Where the Proton Goes, and Why the Literature Disagrees ↩

A service to the field rather than a finding: five studies, tabulated, that do not cite each other's disagreement

A mutagenic tautomer forms when a proton moves between paired bases. The proton moves along a hydrogen bond, not along the covalent carbonyl bond — an earlier statement of this argument had that wrong and it is corrected here. The rate-determining step in the guanine-cytosine pair is the asynchronous transfer at N1–H···N3.

The magnitude is disputed. Five studies bear on the same reaction and do not agree with one another.

study	method	reported result
Pohl and colleagues, 2018	NMR deuterium isotope shifts, path-integral MD, isocytosine dimer	inter-base proton transfer does not take place in this system
Slocombe and colleagues, 2022	open quantum system with explicit water bath	tautomer population 1.73×10^{-4}; kinetic isotope effect 30; tunneling dominant
Greer, Doubleday and colleagues, 2025	independent calculation	isotope effect 5.05; zero-point energy raises a second barrier that suppresses tunneling
Gas-phase vibrational spectroscopy	dimer in vacuum	no evidence of inter-base transfer
Consensus on the phenomenon	tunneling in enzymes since Bell 1980	nobody disputes tunneling exists; the dispute is its magnitude inside DNA

Two calculations of the same isotope effect, a factor of six apart, and two experiments finding no transfer at all. Any paper citing one of these as settled is citing a preference.

The prediction that survives the dispute

Guanine-cytosine makes three hydrogen bonds; inosine-cytosine makes two, and the one deleted is a carbonyl contact rather than the rate-determining N-to-N contact. So the tunneling contribution to the inosine pair should differ from the guanine pair by a computable ratio. A ratio computed by one method throughout is insensitive to the absolute scale the five studies dispute. That calculation has never been run — it is Experiment Two.

What sulfur does that oxygen cannot, in one page

Sulfur's valence electrons occupy the third shell. The measured consequences, from gas-phase structures, are more specific than the assertion.

property	oxygen	sulfur	consequence
Bond angle	∠HOH 104.51°	∠HSH 92.12°	sulfur barely hybridizes; close to unhybridized p orbitals
Chalcogen-chalcogen bond	O–O 1.475 Å	S–S 2.055 Å	catenation, and a much longer bridge
Dihedral of X_2H_2	H_2O_2 119.8°	H_2S_2 90.6°	the disulfide's preferred twist is a right angle
Redox span at pH 7	about two units	eight units, H_2S to SO_4^{2-}	every intermediate occupied by a named biological species

The H–S–H angle is 92.12 degrees. Almost everything attributed here to the third shell is visible in that one number.

PART SEVEN · THE ENZYME THAT MADE DNA

21. Every Deoxyribonucleotide Ever Made Was Made by a Sulfur Enzyme ↩

A single-enzyme monopoly, four sulfur species, and a date that forbids the obvious story

There is exactly one route from the ribonucleotide world to the deoxyribonucleotide world, in every organism that has ever been examined: ribonucleotide reductase. It

removes the 2′ hydroxyl. Nothing else does. The archive that carries every genome on Earth exists because one enzyme family performs one subtraction, and the enzyme is a sulfur enzyme four times over.

sulfur species	where it sits	what it does
S-adenosylmethionine	class III activase	sulfonium center, reductively cleaved to generate the initiating radical
[4Fe-4S] cluster	class III activase	cleaves SAM; iron and sulfur, provisioned by cysteine desulfurase
Cysteine thiyl radical	active site	abstracts the 3′ hydrogen — the committed step
Redox-active cysteine pair	active site	becomes a disulfide, paying the two electrons that strip the 2′ hydroxyl off as water

Four distinct sulfur species, in one enzyme, performing one step. Remove sulfur and there is no DNA — not less DNA, none.

And the dates forbid the story that would be convenient

It is tempting to hang the origin of DNA on the Great Oxidation Event: the atmosphere oxidizes, chemistry changes, DNA appears. The dates do not permit it.

event or enzyme	placement	basis
Great Oxidation Event	about 2.4 billion years ago	dated by mass-independent sulfur isotope fractionation
Last universal common ancestor	a billion years or more earlier	and it had DNA, on the standard reading
Class I ribonucleotide reductase	requires dioxygen to generate its radical	the aerobic class, and therefore the late one
Class III ribonucleotide reductase	oxygen-sensitive, radical SAM, [4Fe-4S]	the anaerobic class, and therefore the early one

The archive is older than the atmosphere that now maintains it. Oxygen did not create DNA. Oxygen forced the machine that writes DNA to be rebuilt, and the rebuilt version is the one in your cells.

Two qualifications this argument requires, and one date it should hold loosely. First, whether the last universal common ancestor itself had DNA is genuinely disputed, and the reason is a real observation: the DNA replication machineries of bacteria and archaea are substantially non-homologous. Second, the Great Oxidation Event is not a clean line. Recent work finds the mass-independent sulfur signal globally asynchronous, persisting in some sections past 2.31 billion years and bracketed between roughly 2.50 and 2.32 billion years rather than fixed at one date. Some authors argue the event needs redefining on those grounds. The

argument above needs only that the anaerobic reductase class predates the aerobic one, which is not in dispute; it does not need a precise date, and should not be written as though it did.

Why this sits here rather than in the sulfur part

Because it is the cleanest instance of the pattern the rest of the document argues. The transition from RNA to DNA is universally described as a change of base — uracil to thymine. It is not. It is a change at the sugar, performed by a sulfur enzyme, and thymine arrives afterward for an unrelated reason: cytosine deaminates to uracil, and in a genome whose legitimate pyrimidine is thymine, a uracil found in the strand is unambiguously damage and can be excised. Thymine is a proofreading mark, not the definition of DNA.

An error in earlier versions, corrected, because the correction is instructive.

Earlier versions attributed thymine's methyl group to S-adenosylmethionine. It comes from 5,10-methylene-tetrahydrofolate by way of thymidylate synthase. The one-carbon unit is a folate carbon, not a sulfonium one, and the carbon that becomes thymine's methyl was a serine side chain — leaving glycine behind. The conclusion the error was supporting survives: folate biosynthesis and serine hydroxymethyltransferase are no cheaper than the pathway the error invoked, so thymine still sits far downstream of anything a seed code could assume.

---

22. Three, Six and Nine Are Properties of the Table, Not Impositions On It ↩

One page of arithmetic, included because it is checkable in ten seconds and because it constrains what any geometric reading may claim

Take the sixty-four codons and ask, of each, how many differ from it by one base. Nine — three positions, three alternatives. Now split those nine by the chemistry of the substitution: a transition exchanges purine for purine or pyrimidine for pyrimidine; a transversion crosses the classes.

neighborhood	count	why	graph
Transitions per codon	3	one per position	3-regular
Transversions per codon	6	two per position	6-regular
Single-base neighbors	9	three positions, three alternatives	9-regular

Every one of the sixty-four codons has exactly three transition neighbors and exactly six transversion neighbors. Not on average — every one, without exception.

This is forced rather than discovered. Any four-letter, three-position code has it, so it is not evidence for any particular framework. What it is: the reason a three-and-six decomposition is available at all, and the reason a geometric reading that puts transversions in-plane and transitions along an axis is the only assignment consistent with the degrees. Six is the coordination number of a hexagonal tiling; three is not.

And two corrections to a geometric reading offered elsewhere in this corpus. Sixty-four is not a hexagonal number of any kind. The centerd hexagonal numbers are 1, 7, 19, 37, 61, 91, and 61 and 91 bracket it; the plain hexagonal numbers do not contain it either. Sixty-four is 2^6, 4^3 and 8^2 — a cube and a square, never a hexagon. Any claim of a sixty-four-cell hexagonal lattice fails on a fact a reader checks by counting. What does close without strain is a prismatic reading: sixteen two-base faces, each four codons deep, where the depth is the wobble position and therefore the axis inosine acts on. Separately, the closed end of a honeycomb cell meets at arccos(−1/3) = 109° 28′, which is exactly the tetrahedral angle at sp^3 carbon — but Fejes Tóth showed in 1964 that this rhombic end is about 0.35 percent worse than optimal. The defensible claim is near-optimality reached without computation, which is more interesting than exactness and, unlike exactness, survives.

PART EIGHT · RNA1 TO DNA TO RNA2

23. The Diagram Starts in the Wrong Place ↩

Not DNA to RNA to protein. RNA to DNA to RNA to protein, and the first arrow is the one that was left out.

The central dogma is drawn as DNA to RNA to protein. Every textbook opens with it, and as a statement about which direction sequence information may travel it is not disputed here. But as a diagram of what happens in a cell it begins one step too late, and the step it omits is the one that required the most chemistry.

DNA is not the starting material. DNA is manufactured, and it is manufactured out of RNA. Ribonucleotide reductase takes a ribonucleotide and removes the two-prime hydroxyl. There is no other route, in any organism that has ever been examined. The deoxyribose that defines deoxyribonucleic acid does not exist until a sulfur enzyme makes it from ribose.

DNA is a derived molecule. Ribose came first, deoxyribose was subtracted from it, and the subtraction is the most important chemical event in the history of heredity.

Which means the diagram has four positions, not three

position	what it is	what distinguishes it
RNA1	the ancestral and biosynthetic ribonucleotide world	the material DNA is made from; the pool the reductase draws on
DNA	the archive	stable, double-stranded, proofread, methylated, repairable
RNA2	the transcript	the message and the machinery: mRNA, tRNA, rRNA, the regulatory RNAs
Protein	the product	folded, modified, and doing the work

RNA1 and RNA2 are not the same object and should not carry the same name in a diagram. RNA1 is chemically prior to DNA and is what DNA is built from. RNA2 is chemically posterior to DNA and is what DNA is read into. They are separated by the entire existence of the archive. Writing them both as "RNA" and drawing one arrow between DNA and RNA collapses a manufacturing step and a transcription step into a single symbol, and they have nothing in common except the sugar.

The arrow from RNA to DNA is not Crick's exception for retroviruses. It is the original manufacturing step, and it runs in every cell of every organism, every time a genome is copied.

What the model does and does not claim. It does not claim that the RNA world hypothesis is proven, and nothing here depends on it. The claim is narrower and is about present-day chemistry: in every organism now living, deoxyribonucleotides are made from ribonucleotides by ribonucleotide reductase and by no other route, so the ribonucleotide pool is materially prior to the deoxyribonucleotide pool. Whether that ordering also held four billion years ago is a separate question, argued elsewhere in this volume and not required here.

24. Every Arrow, Expanded Through Four Levels ↩

The alphabet writes the base. The chemistry happens at the other three.

The four letters name bases. But a base is not a functional molecule. Attach a sugar and it becomes a nucleoside; attach phosphate and it becomes a nucleotide; polymerize and it becomes a nucleic acid. Four levels of assembly, and the notation has a symbol only for the first.

level	what is added	examples	what the alphabet can write
Base	the ring system alone	adenine, hypoxanthine, thymine	A, T, G, C — and nothing for the others
Nucleoside	base plus sugar	adenosine, inosine, thymidine	no symbol; ribose and deoxyribose written identically
Nucleotide	nucleoside plus phosphate	AMP, IMP, dTMP	no symbol; mono-, di- and triphosphate indistinguishable
Nucleic acid	the polymer	DNA, mRNA, tRNA, rRNA	the letter string, with every modificatio erased

Every consequential decision in this book is made at level two, three or four. The alphabet operates at level one and reports the result as if it were the whole molecule.

Arrow Zero — RNA1 to DNA

level	what happens on this arrow	the machinery, and what it cannot work without
Base	uracil is retained at first; thymine arrives later, by a separate enzyme	thymidylate synthase, using a folate one-carbon unit
Nucleoside	the two-prime hydroxyl is removed — this is the defining step	ribonucleotide reductase; four sulfur species; n alternative route
Nucleotide	the pool must be sanitized before use	ITPA hydrolyzes ITP and dITP; XTP and dXTP likewise excluded
Nucleic acid	the strand is assembled and proofread	replicative polymerase, two divalent metal ions

Note what the notation records of all that. It records nothing. A and G and C are written identically in the ribonucleotide and the deoxyribonucleotide; the sugar change that is the entire content of this arrow has no symbol. And the sanitization step — the enzyme whose job is to keep inosine triphosphate out of the growing strand — is invisible for the same reason inosine itself is invisible.

Arrow One — DNA to DNA

level	what happens on this arrow	the machinery
Base	5-methylcytosine must be re-established on	maintenance methyltransferase, using S-

level	what happens on this arrow	the machinery
	the daughter strand	adenosylmethionine
Nucleoside	deoxyribonucleoside pools must be balanced	reductase allosteric regulation; imbalance is mutagenic
Nucleotide	triphosphates are selected and pyrophosphate released	the energy of the bond is spent here and recorded nowhere
Nucleic acid	the strand is copied, proofread and repaired	polymerase, mismatch repair, uracil excision

Arrow Two — DNA to RNA2

level	what happens on this arrow	the machinery
Base	adenosine is edited to inosine in double-stranded regions	ADAR; the edit is invisible to the letter string
Nucleoside	ribonucleotides are used; the two-prime hydroxyl returns	no reductase involved; this is the unmodified sugar
Nucleotide	over one hundred and seventy distinct modifications are installed	methylations, thiolations, pseudouridylation, an more
Nucleic acid	transcript is capped, spliced and polyadenylated	and folds while it is being made

Arrow Three — RNA2 to protein

level	what happens on this arrow	the machinery
Base	the anticodon base at position 34 decides how many codons are read	inosine widens; 2-thiouridine narrows
Nucleoside	thiolated nucleosides tune the adaptor	cysteine desulfurase supplies the sulfur for all o them
Nucleotide	the adaptor is charged; the bond is an ester to the terminal adenosine	aminoacyl-tRNA synthetase, one per amino acid
Nucleic acid	the ribosome reads three at a time, and the rate varies by codon	synonymous codons are not synonymous

Sixteen cells in those four tables. The four-letter alphabet can write the contents of one of them, and even there it writes the base without the modification.

PART NINE · WHAT WAS TAKEN AWAY

25. Biology Proceeds by Removal, and the Clearest Case Is DNA ↩

The standard picture assembles life from small parts. A great deal of it is better described as what survived after something was subtracted.

The conventional account of how life's molecules came to be is additive. Simple things combine into complex things: atoms into molecules, molecules into monomers, monomers into polymers, polymers into the machinery of a cell. Each step adds. The story is told as a ladder and every rung is a gain.

A good deal of the actual chemistry runs the other way, and this part collects the cases where it does. The claim is not that everything in biology is subtractive. It is narrower and it is checkable: that several of the most consequential steps in the history of the genetic material are subtractions, that the literature supporting this is eighty years old and substantial, and that the single cleanest example is the one this volume has already spent a hundred pages on.

Ribonucleotide reductase does not add anything. It removes an oxygen. Every deoxyribonucleotide that has ever existed was made by taking something away, and the tool that takes it is a sulfur atom.

The idea is older than most people assume

Horowitz proposed in 1945 that metabolic pathways assembled backward. As a prebiotic substrate pool ran down, the enzyme that made the final product came under selection first; then the enzyme that made its precursor; then the one before that, each recruited in turn as the free supply of its product was exhausted. The pathway grew toward the past, one step at a time, from the end.

The formal name is retrograde evolution, and it is the original statement of the subtractive intuition.

Where retrograde evolution stands today, stated so a reader can discount it.

It is not the consensus. The patchwork model — broad-specificity ancestral enzymes duplicated and recruited to new substrates — explains more of the comparative data, and any argument built on retrograde assembly has to engage Jensen and Ycas directly rather than route around them. Retrograde survives as a live minority position accounting for some ancient routes, histidine biosynthesis and nitrogen fixation among them. This volume cites it as precedent for the direction of reasoning, not as settled fact.

26. The Nucleotide Was Never Assembled From a Pre-Made Sugar ↩

The result that does not reverse the ladder but dissolves it

Part Eight of this volume set out four levels of assembly — base, nucleoside, nucleotide, nucleic acid — and observed that the four-letter alphabet has a symbol only for the first. That framing assumes the levels are built in order. There is now good reason to think they never were.

The textbook prebiotic route makes ribose, makes a nucleobase, joins them into a nucleoside, and phosphorylates it. Every step of that route has a known problem: ribose is unstable and forms in poor yield among a tar of other sugars, and the glycosidic bond between a free base and a free sugar does not form efficiently in water.

Powner, Gerland and Sutherland reported a synthesis that avoids the difficulty by never encountering it. The route to activated pyrimidine ribonucleotides proceeds through arabinose amino-oxazoline and anhydronucleoside intermediates, and it bypasses free ribose and the free nucleobases entirely. The sugar and the base do not meet. They emerge together from shared precursors.

route	how the nucleotide is reached	the consequence
Classical route	ribose, then base, then nucleoside, then phosphate	poor ribose yield; glycosidic bond does not fo in water
Sutherland route	shared precursors to an activated nucleotide directly	free ribose and free base never appear as intermediates
Photoanomerizatio n route	through ribose aminooxazoline, which crystallizes spontaneously	and with enantiomeric enrichment
Wet-dry cycling route	purine and pyrimidine ribonucleotides concurrently, one pot	selective mono- and diphosphate formation, n enzymes

The ladder is not climbed in reverse. There is no ladder. The levels the notation implies are an artifact of how the finished molecule is described, not a record of how it was made.

This is a stronger result than reversal would have been, and it costs nothing to adopt. An argument that the assembly order is inverted still concedes that there is an assembly order. An argument that the intermediates never existed removes the premise.

What this does and does not establish. It establishes that at least one class of nucleotide can be reached prebiotically without free sugar or free base as

intermediates. It does not establish that this is how it happened, and it does not extend automatically to every nucleotide. What it does for the argument of this volume is narrower and safe: it shows that the four-level hierarchy implied by the notation is a description of a finished object, not a history of its manufacture, and that a reader who treats the levels as a sequence is reading the notation rather than the chemistry.

---

27. Sulfur Before Phosphorus ↩

A cryptic core metabolism that needs no phosphate at all, and is enriched for iron-sulfur enzymes

Phosphate is in everything: the backbone of both nucleic acids, the energy currency, the second messengers, the regulatory switch on half the proteome. It is also, on the early Earth, geochemically scarce and poorly soluble. How a molecule that hard to obtain became that central is a real and unresolved problem.

Goldford and colleagues asked the question the other way round. Rather than explaining how phosphate arrived, they used network expansion over the whole of known metabolism to ask what a metabolism could do without it. The answer surprised them.

What the analysis found. Starting from simple prebiotic compounds, they identified a cryptic phosphate-independent core metabolism capable of supporting the biosynthesis of a broad category of key biomolecules. The network is enriched for enzymes using iron-sulfur clusters. And the thermodynamic bottlenecks in it are more readily overcome by thioester couplings than by phosphate couplings. The authors describe the result as a possible metabolic fossil of an early phosphate-free, non-enzymatic biochemistry, corroborating earlier proposals that a thioester-based metabolism predated both phosphate and an RNA genetic system.

A whole metabolism, reconstructed computationally, that runs on sulfur where the modern one runs on phosphorus — and that clears energy barriers phosphate cannot. The thioester was the first currency and the phosphate came later.

This is de Duve's thioester world and Wächtershäuser's iron-sulfur world, arriving from systems biology rather than from bench chemistry, and it is the strongest single result behind the sulfur argument of this volume. It says that the element without a letter was the element the first metabolism ran on.

And the bridge from one currency to the other has been found

Pinna and colleagues report that acetyl phosphate phosphorylates ADP to ATP in water in the presence of ferric iron, at roughly twenty percent yield — and that it phosphorylates no other nucleoside diphosphate. A thioester-derived phosphate donor, selective for adenosine alone. That selectivity is the reason ATP and not some other nucleotide became the universal currency, and it is a chemical answer to a question usually treated as a frozen accident.

The energy economy began in sulfur, transferred to phosphorus through a reaction selective for adenosine, and has run on a purine ever since. Yellow to violet, by way of red.

---

28. Metabolism Before Enzymes ↩

Twenty-nine reactions of glycolysis and the pentose phosphate pathway, running in Archean seawater with no protein present

If the pathways came before the enzymes, the pathways should be able to run without them. That is a hard prediction and it has been tested.

Keller and colleagues reconstructed the ionic composition of a plausible Archean ocean and ran the sugar-phosphate intermediates of glycolysis and the pentose phosphate pathway in it. Twenty-nine reactions proceeded, including the formation of ribose-5-phosphate and erythrose-4-phosphate, driven by ferrous iron and no protein whatever. A later study found the iron acting as both catalyst and co-substrate, with the network's behavior switching on pH: alkaline conditions favor pentose-phosphate-like reactivity, acidic and neutral favor the glycolytic branch.

The network had conditional topology before anything was alive to condition it. A pH change reroutes the chemistry the same way an allosteric enzyme would, and there is no enzyme.

Ribose-5-phosphate is the entry point to purine biosynthesis. It is the sugar that becomes PRPP, and PRPP is what the purine ring is built on. So the metal-driven network in that seawater produces, without instruction, the precursor of the molecule this volume argues was the first nucleotide.

A caution that should be stated rather than left for a referee. These networks build upward from small aldehydes. They do not begin at a hexose and strip it down. Carbon-count reduction is real chemistry within the network — three- to seven-

carbon sugars interconvert freely — but the direction of net assembly is additive. An argument that the sugars arrived by subtraction from larger precursors is not supported by this work and would need its own experiment. The defensible claim is the one made above: that the pathway ran before the catalyst existed, which is a statement about order, not about direction.

---

29. A Note on Notation, and a Case Where Everyone Can See the Error ↩

Why a pattern can be perfectly real and still tell you nothing about the world

This volume argues that the four-letter alphabet is a notation mistaken for a property of nature. That is an uncomfortable claim to make about something taught in the first week of every biology course, and a reader is entitled to ask whether the author would recognize the same error elsewhere. Here is a case where the error is easy to see, and it is worth a page because seeing it once makes the alphabet argument obvious.

Take any whole number and add its digits; repeat until one digit remains. That is its digital root. Now take the doubling sequence — 1, 2, 4, 8, 16, 32, 64 and onward — and write down the digital root of each.

1, 2, 4, 8, 7, 5, 1, 2, 4, 8, 7, 5, … forever

A closed cycle of six, which never touches 3, 6 or 9. And those three form a separate closed system of their own: 3 and 6 double into each other endlessly, and 9 doubles to 18, which has digital root 9, forever. Two disjoint worlds, one of six numbers and one of three.

The pattern is completely real. It is also entirely a consequence of having ten fingers.

The reason is one line of arithmetic: a digital root is the number modulo nine, because ten leaves remainder one when divided by nine. Change the base and the structure survives but the numbers do not.

counting base	the doubling cycle	the numbers outside it
Base 10	1, 2, 4, 8, 7, 5	3, 6, 9
Base 8	1, 2, 4	3, 5, 6, 7
Base 12	1, 2, 4, 8, 5, 10, 9, 7	11

counting base	the doubling cycle	the numbers outside it
Base 16	1, 2, 4, 8	ten other numbers

In base twelve the governing number is eleven. Nothing about matter, energy or life changed; only the notation did. Anyone who builds a physical theory on the specialness of 3, 6 and 9 has built it on the number of human fingers, and the tell is that the theory cannot be stated without first choosing a base.

A real pattern in a notation is still a fact about the notation. That sentence is the whole argument of this volume, and here it is in a case where nobody has anything invested.

Which is exactly the situation with the four letters
A, T, G and C are also a real pattern. Those four bases genuinely dominate the nucleic acids of every organism, and the alphabet built on them genuinely predicts a great deal. It is not a fiction and this volume has never called it one.

But it was fixed by what a laboratory could purify in 1953, and it has no place to write a sulfur atom, a modified wobble base, a sugar difference, a phosphorylation state, or a backbone substitution — every one of which does work in a living cell. The notation is real and the pattern is real and the conclusion that these four are what the genetic material *is* does not follow, for the same reason the conclusion about 3, 6 and 9 does not follow.

The test this volume applies to itself. A claim that some structure is fundamental rather than notational has to survive a change of representation. The 3-6-9 pattern does not: change the base and it evaporates. The sulfur argument does: the ninety-two degree bond angle, the eight oxidation states, the two-point-oh-five-five ångström bond to itself and the requirement for ribonucleotide reductase are the same in any notation, any language and any number system, because they are measurements rather than descriptions. That is the difference the reader should hold onto, and it is the standard every claim in this volume was written to meet.

---

30. Inosine Narrows to One When Read, and Opens to Three When Reading ↩

The same molecule, opposite information operations, decided by which strand it sits on

Inosine appears in RNA2 in two entirely different roles, and the contrast between them is the sharpest illustration in this volume of what the alphabet cannot express.

In the message: inosine collapses to one

When ADAR deaminates an adenosine inside a double-stranded region of a messenger RNA, the resulting inosine is read by the ribosome as guanosine. It is also copied as guanosine by any polymerase or reverse transcriptase that encounters it, which is why edited sites appear in sequencing data as A-to-G discrepancies against the genome.

So in the message, an inosine is one thing. It has been written by an oxidative deamination and it is read as a single letter — and not even its own letter, but somebody else's.

In the message, inosine is a base that the machinery reads as guanosine. Orange, decoded as green. The genome says adenine; the transcript carries inosine; the ribosome hears guanine. Three different answers to the same question, and the letter string can only give one of them.

In the adaptor: inosine opens to three

When the same modification is made at position 34 of a transfer RNA — the wobble position, the first base of the anticodon and the one that pairs with the third base of the codon — the consequence is the opposite. The adaptor now reads three codons where it would otherwise have read one.

pairing	codon base	color	why
Inosine 34 pairs with A	adenine	red	a purine, read by a purine, in the wobble geometry
Inosine 34 pairs with C	cytosine	blue	the pairing inosine shares with guanine
Inosine 34 pairs with U	uracil	violet	the third of the set
Inosine 34 does NOT pair with G	guanine	green	purine against purine will not fit the helix at th position

One inosine reads red, blue and violet — three of the six colors — and refuses green. Eight codon families in the human genome are decoded this way, and there is no letter for the molecule that does it.

The symmetry between the two roles is exact and it is worth stating in one sentence, because it is the kind of thing a diagram of information flow cannot contain.

Inosine narrows to one when it is read, and opens to three when it is reading. Same molecule, same modification, same enzyme family. What changes is which strand it sits on.

And the opposite operation is performed by a sulfur atom, at the identical position

Position 34 also receives 2-thiouridine — a uridine with the oxygen at ring position two replaced by sulfur. Its effect is to restrict which codons the adaptor will accept, sharpening the discrimination between an A-ending and a G-ending codon.

modification	the chemistry, in one phrase	the effect on decoding	the machinery
Inosine 34	an oxygen replaces an amine	reading is widened, one adaptor to three codons	ADAR, TAD/ADAT
2-thiouridine 34	a sulfur replaces an oxygen	reading is narrowed and sharpened	cysteine desulfurase the thiouridylases

Two opposite regulatory acts, at the same position of the same molecule, one performed by adding an oxygen and one by adding a sulfur. The conjugate pair, tuning the genetic code from inside the adaptor. The alphabet has one blank space where both of them belong.

What is established, and what this volume is proposing. That inosine occupies position 34 and expands codon reading to A, C and U is textbook decoding chemistry and is not in dispute. That ADAR-generated inosine in messenger RNA is translated as guanosine is likewise established. That 2-thiouridine at the same position restricts reading is established. What this volume adds is the framing: that these are the same chemical operation — a conjugate substitution at a single ring position — running in opposite directions, and that a notation which cannot represent either one is not a notation for the genetic code but for a projection of it.

PART TEN · ARROW ZERO — RNA1 TO DNA

31. The Enzyme That Made DNA Possible ↩

One reaction, four sulfurs, and the oxygen that forced it to be performed a second way

The central dogma is drawn with three arrows and it needs a fourth. Before DNA can be replicated, transcribed or translated, DNA has to exist — and it did not always. Something converted an RNA world into a DNA one. That conversion is not

reverse transcription, which copies sequence and changes nothing about the chemistry. It is a chemical alteration performed on the monomer, by one enzyme, and on the current evidence it happened before the last universal common ancestor.

Arrow Zero runs once. Everything else in this paper runs continuously, in every cell, forever. This one ran at the beginning and then the question was closed.

DNA is RNA minus one oxygen

The textbook lists two differences between the polymers: deoxyribose instead of ribose, and thymine instead of uracil. They are not of equal weight, and the one that gets the emphasis is the lesser of the two.

Ribose carries a hydroxyl at the 2′ position, sitting immediately adjacent to the phosphodiester linkage. That hydroxyl attacks its own backbone. Deprotonate it and it performs an in-line nucleophilic attack on the adjacent phosphorus, cleaves the chain, and leaves a 2′,3′-cyclic phosphate behind. RNA is a molecule that dismantles itself, and it does so faster as pH rises. Remove that one oxygen and the mechanism has nothing to attack. The half-life of the backbone goes from hours to something on the order of geological time.

Thymine, by contrast, is optional. There exist phage genomes that use deoxyuridine throughout in place of thymidine, and they are perfectly good DNA — replicated, transcribed and inherited. A genome written in uracil on deoxyribose is DNA. A genome written in thymine on ribose would still be RNA and would still cut itself to pieces.

Thymine is not what makes DNA. The missing oxygen is. The archive was created by a subtraction at the sugar, not an addition at the base.

Which relocates the whole question. The RNA-to-DNA transition is not a problem about the alphabet. It is a problem about one hydroxyl group, and it is solved at the level of the free nucleotide rather than on an assembled strand.

Ribonucleotide reductase, and why there is only one route

Every deoxyribonucleotide in every organism on Earth is made by the same reaction: a ribonucleotide is reduced at the 2′ position, the hydroxyl leaves as water, and a hydrogen takes its place. The enzyme is ribonucleotide reductase, and there is no other way in. There is no pathway that builds deoxyribose from scratch and attaches a base to it; the sugar is always modified after the nucleotide already exists.

Reichard states the consequence plainly: the appearance of ribonucleotide reductase was a prerequisite for the transition from the RNA world, where RNA sufficed for both catalysis and information transfer, to the arrangement in which life depends on the interplay of DNA, RNA and protein.

Three classes exist. They differ in almost everything at the surface — primary sequence, quaternary structure, cofactor, how the initiating radical is made — and they agree on the chemistry underneath. All three are radical enzymes. All three regulate their substrate specificity allosterically by the same logic. Retention of critical residues and a similar tertiary fold argue a common origin.

class	radical source	oxygen relationship	cofactor	where it is found
Class I	tyrosyl radical on a diiron center	requires dioxygen	Fe–O–Fe	aerobes, all eukaryotes
Class II	adenosylcobalamin	indifferent to oxygen	vitamin B_{12}	scattered bacteria and archaea
Class III	glycyl radical from SAM	destroyed by dioxygen	[4Fe-4S] cluster	strict anaerobes

Read the oxygen column. One class cannot function without oxygen. One class is destroyed by it. The third does not care. That is not a distribution you would expect from three solutions to a chemistry problem invented independently; it is what a single enzyme looks like after the atmosphere changed underneath it.

Four sulfurs, one reaction

Now look at what the anaerobic enzyme is made of, because the answer is the argument of Part Sixteen arriving in a place nobody put it.

sulfur species	where it sits	what it does
S-adenosylmethionine	class III activase	sulfonium; reductively cleaved to make the initiating radical
[4Fe-4S] cluster	class III activase, NrdD's partner NrdG	cleaves SAM and generates the glycyl radical on the reductase
Cysteine thiyl radical	active site	abstracts the 3′ hydrogen and begins the reaction
Cysteine pair, becoming a disulfide	active site	donates the two electrons that remove the 2′ hydroxyl as water

Four distinct sulfur species, in one enzyme, performing one step. And that step is the creation of the deoxyribonucleotide — which is to say, the creation of the possibility of a genome that does not destroy itself.

The reaction that made DNA is started by a thiyl radical, paid for by a disulfide, triggered by an iron-sulfur cluster, and armed by a sulfonium. The archive is written in sulfur, one oxygen at a time.

Where the disulfide actually is

It is worth being precise about the disulfide, because it is the load-bearing part and because it is easy to put in the wrong place.

In the class I enzyme of Escherichia coli the residues are named. Cysteine-439 initiates the reaction as a thiyl radical. Cysteine-225 and cysteine-462 are the redox-active pair: they begin the cycle as two free thiols and end it as a disulfide, having handed over the two electrons and two protons that convert the 2′ hydroxyl into a water molecule and let it leave. Density functional calculations on the mechanism include a transition state in which an electron is transferred roughly eight ångströms from that disulfide to the substrate. Thioredoxin or glutaredoxin then reduces the disulfide back to two thiols, and the enzyme is ready for the next nucleotide.

Every deoxyribonucleotide in your body was paid for by a pair of cysteines becoming a disulfide. The bond forms, the oxygen leaves, and the bond is broken again so it can be spent twice.

So a disulfide really is at the center of the RNA-to-DNA transition. It is not holding two strands together. It is inside the enzyme, and it is the currency in which the 2′ oxygen is bought.

Oxygen did not create DNA. It forced DNA to be made a second way.

The oxygen question has a published answer and it is not the one an intuition reaches for. Reichard's reading is that the appearance of oxygen on Earth provided the likely driving force for the diversification of ribonucleotide reductase, and that the anaerobic class III enzymes — with their iron-sulfur cluster and their requirement for S-adenosylmethionine to generate a glycyl radical — are the closest surviving relatives of the ancestral enzyme.

Torrents and colleagues, working on the Lactococcus enzyme, reached the same conclusion from the mechanism: ribonucleotide reduction during the transition from an RNA world to a DNA world started with a class III-like enzyme, from which the other reductases evolved when oxygen appeared. And the crystal structure of a class III enzyme led Logan and colleagues to suggest an evolutionary relationship between early deoxyribonucleotide metabolism and primary anaerobic metabolism.

Follow what that means for the class I enzyme. It does not merely tolerate oxygen; it requires it. Its tyrosyl radical is generated by a diiron center reacting with dioxygen. The element that destroys the ancestral enzyme is the reagent the modern one cannot work without.

Oxygen did not break the sulfur world's archive. It forced the machine that writes the archive to be rebuilt around the poison, and the rebuilt version now cannot run without it.

A timeline that does not overreach

The temptation here is to hang the origin of DNA on the Great Oxidation Event, and the dates forbid it. The oxidation is placed near 2.4 billion years ago. The last universal common ancestor is placed a billion years or more earlier. DNA is older than free atmospheric oxygen by a wide margin, and any model that has oxygen creating DNA has the order wrong.

What the oxidation can carry is the diversification, which is exactly what the literature above claims and no more. DNA was first made anaerobically, by a radical enzyme that oxygen destroys. Oxygen then arrived and a class that uses oxygen to make its radical appeared. The archive is older than the atmosphere that now maintains it.

One question this paper does not settle. Whether the last universal common ancestor itself had DNA is genuinely disputed, and the reason is a real observation: the DNA replication machineries of bacteria and archaea — primases, replicative polymerases, ligases — are substantially non-homologous, which some read as DNA replication having been invented twice, independently, after the two domains diverged. If that reading is right, Arrow Zero ran more than once. Nothing in this part depends on the answer, and the answer is not offered.

Where thymine enters, and a correction to Part Seventeen

Thymine arrives after all of this, and for a different reason. Cytosine deaminates spontaneously to uracil. In an RNA world that damage is unreadable, because uracil is a legitimate letter. In a DNA world in which the legitimate letter is thymine, a uracil found in the strand is unambiguously a deamination product, and uracil-DNA glycosylase can excise it. The methyl is a flag, and a flag presupposes a reader.

The methyl comes from folate, not from S-adenosylmethionine. Thymidylate synthase converts dUMP to dTMP, and the methyl donor is 5,10-methylene-tetrahydrofolate. The one-carbon unit is a folate carbon, not a sulfonium one. This

reinforces the argument that thymine sits far downstream of anything a seed code could assume, since methylene-tetrahydrofolate requires folate biosynthesis and serine hydroxymethyltransferase — no cheaper than the methionine pathway it would replace.

The one-carbon unit itself has an origin worth noting. Serine hydroxymethyltransferase strips the hydroxymethyl group from serine and loads it onto tetrahydrofolate, releasing glycine. The carbon that becomes thymine's methyl was a serine side chain, and what is left behind is the simplest amino acid — the one present in every prebiotic inventory ever compiled, and the one whose codon box is the single four-fold box inosine does not read.

Sulfur does still sign DNA's chemistry twice over, and the two places are worth keeping straight. S-adenosylmethionine generates the radical in the ancestral reductase, which is how the sugar loses its oxygen. And S-adenosylmethionine is the methyl donor for DNA methylation — 5-methylcytosine and N6-methyladenine, the marks that regulate and protect the genome. What SAM does not do is make thymine.

What this part claims, and what it does not

Claimed, and conceded by the literature cited: that DNA differs from RNA principally at the 2′ position; that ribonucleotide reductase is the only route to a deoxyribonucleotide; that its three classes share an origin; that the anaerobic class III enzyme uses a glycyl radical generated from SAM and an iron-sulfur cluster and is argued to be closest to the ancestor; that the catalytic mechanism runs through a cysteine thiyl radical and a redox-active cysteine pair that forms a disulfide; and that the appearance of oxygen is the proposed driver of the diversification into three classes.

Not claimed: that this paper has established the order of events, that the class III enzyme is the ancestor rather than its closest relative, or that the prebiotic thioanhydro route to deoxyribose in Part Seventeen and the enzymatic route here are the same route. They are two independent sulfur-dependent paths to the same missing oxygen, and whether the second descends from the first is conjecture and is marked as one.

Two gates, one element. IMP dehydrogenase opens the purine loop with a cysteine thiolate. Ribonucleotide reductase opens the DNA world with a cysteine thiyl radical and a disulfide. Neither of those

was arranged to fit an argument, and both were already in the literature waiting to be put side by side.

PART ELEVEN · ARROW ONE — DNA TO DNA

32. Replication, and a Quantum Effect With Numbers ↩

Slocombe, Sacchi and Al-Khalili, 2022

Watson and Crick proposed in 1953 that base pairs might occasionally flip into rare tautomeric forms that mispair during replication. The idea was argued for fifty years and generally dismissed, on the grounds that such tautomers could not survive long enough to reach the replication machinery.

In 2022 the Surrey group computed it properly, treating the proton as an open quantum system with the surrounding water modeled explicitly — providing both thermal excitation and decoherence. These are their numbers for guanine-cytosine:

quantity	value	comparison
Quantum rates	7.61×10^{5} s^{-1} forward; 1.69×10^{13} s^{-1} reverse	Five orders of magnitude above classical
Tautomer population	1.73×10^{-4} at 300 K	Classical prediction: 5.4×10^{-8}
Timescale	10 fs to 100 ns	Far faster than strand separation
Isotope effect	KIE = 30 at body temperature	Within the range measured for enzyme tunneling

On these numbers, tunneling puts the wrong tautomer of guanine into the replication machinery ten thousand times more often than classical physics allows.

Those are one group's numbers, and they are disputed. Four other studies bear on the same reaction — two of them experimental — and they do not agree with this calculation or with each other. Part Sixteen sets them side by side rather than choosing. The prediction that follows below survives the disagreement, because it is a ratio between two pairs computed by a single method, and a ratio is indifferent to an argument about absolute scale. The magnitude above is not indifferent to it, and should be read as belonging to one calculation among five.

The paper's key move is that lifetime was the wrong variable. What matters is the ratio of tautomeric to canonical forms at equilibrium, and the pair reaches the

helicase already equilibrated. Fifty years of objections were aimed at the wrong quantity.

The inosine prediction

The same literature holds that the adenine-thymine tautomer is fleetingly unstable and does not matter. The effect is not general to base pairs. It belongs to guanine-cytosine — the three-bond pair, with a well deep enough to hold population.

Inosine is guanine minus the 2-amino group. G:C makes three hydrogen bonds: O6 accepting from N4-H, N1-H donating to N3, N2-H donating to O2. I:C makes two — it keeps the central N1-H···N3 contact, which is the proton that tunnels, and loses N2-H···O2. The Surrey mechanism is an asynchronous double transfer in which a second proton moves the opposite way to preserve electroneutrality.

Inosine keeps the proton that tunnels and loses one of the two channels available to the balancing proton.

Prediction: the I:C tautomer population should fall measurably below 1.73×10^{-4}, plausibly toward the A:T regime where the tautomer is too unstable to matter. If that holds, the parent purine is more faithful than either of its children at the level where fidelity is set by quantum mechanics rather than by enzymes.

That inverts the standard reading of inosine as the sloppy, promiscuous base. Pairing promiscuity and tautomeric fidelity are different axes, and conflating them is exactly the error the four-letter notation encourages. A base that accepts three partners at the wobble position and refuses to tautomerize is not sloppy — it has traded specificity, which the first two codon positions supply anyway, for stability against a mutation mechanism operating below the level of chemistry.

This is Experiment Two in Part Twenty-Eight. It is a calculation, not a synthesis.

What the quantum argument can and cannot carry

Two framings were considered for this paper and rejected. The first is that the universe has been quantum-mechanical for 13.8 billion years and carbonyl bonds are quantum objects, so the C=O of hypoxanthine confers a priority of the same order. Every bond in every molecule is quantum-mechanical; an argument establishing inosine's priority on those grounds establishes adenine's equally, and therefore establishes nothing.

Quantum mechanics does not privilege one purine over another. Chemistry does, and the chemistry is already in hand.

The version to make is specific, and it is about that oxygen doing identifiable work at identifiable positions. The C6 carbonyl is why hypoxanthine presents guanine's pairing face minus the 2-amino group, which is why inosine makes two hydrogen bonds instead of three, which is why it pairs with C, U and A, which is why one adaptor reads three codons. The absence of an exocyclic amine is why hypoxanthine has nowhere to glycosylate but N9, while adenine condenses at the wrong nitrogen. The oxygen at C2, delivered by IMPDH from water rather than from dioxygen, is why the discharge ladder runs in an anoxic world. Every one of those is a claim about a specific atom at a specific position producing a measurable consequence, and each is worth more to the argument than any appeal to the age of the universe.

The second is quantum entanglement. Entanglement is not an open problem — Bell inequalities were derived in 1964, loophole-free tests completed in 2015, and the 2022 Nobel Prize awarded for the experimental work. It is also irrelevant here. Everything quantum in this paper is local: proton tunneling is a single particle penetrating a barrier a fraction of an ångström wide, and the Surrey result depends on the water bath decohering that proton rather than preserving coherence. Decoherence in a warm cell runs on femtoseconds. Local quantum chemistry survives it; entanglement does not.

The quantum content here survives precisely because it never leaves the local regime.

PART TWELVE · ARROW TWO — DNA TO RNA2

33. What the Notation Cannot Write Down ↩

The monomer is the nucleotide. The symbol is the base.

Along a nucleic acid strand the sugar and phosphate never vary — only the base does. Information theory therefore assigns the backbone zero bits, and writing just the bases gives the shortest faithful notation for a sequence. That reasoning is correct, and it is why the four-letter convention exists.

It is also conditional, and the condition is never stated: it holds only for a backbone that is already uniform.

The base-as-symbol convention presupposes exactly the thing the origin problem is trying to explain.

The notation cannot distinguish a ribose strand from an arabinose strand. It cannot distinguish a 3′,5′ linkage from a 2′,5′ linkage. It cannot mark 2-thiouridine as anything other than U, or inosine as anything at all. Every one of those distinctions mattered before the backbone settled, and every one is erased by construction. The four-letter alphabet does not merely neglect the prebiotic era — it is a language in which that era cannot be described.

A century-old decomposition that runs backward

The textbook says a nucleoside is a base plus a sugar and a nucleotide is a nucleoside plus a phosphate. That is a retrosynthetic taxonomy — a description of how to take the molecule apart — and it has been read for a century as a description of how one was put together. On current evidence that reading is false. Ribose and cytosine do not condense in water in useful yield; the glycosidic bond is the hardest bond in the entire problem. What works is the cyanosulfidic route, in which sugar and base are built together from cyanamide, cyanoacetylene, glycolaldehyde and glyceraldehyde, with phosphate present throughout as catalyst and buffer.

Base plus sugar plus phosphate is how you disassemble a nucleotide. It is not how one was ever made.

A notation that can carry the chemistry

If the base face is what pairs, encode the base face. Write each nucleotide as $q = (a_0, a_1, a_2, a_3)$ where a_0 is ring class — 2 for a purine, 1 for a pyrimidine — and the three imaginary components name the Watson-Crick contact positions in register: purine C6 or pyrimidine C4, then purine N1 or pyrimidine N3, then purine C2 or pyrimidine C2. Values are +1 for a donor, −1 for an acceptor, 0 for no contact.

nucleotide	quaternion	note
AMP	(2, +1, −1, 0)	C6 donor, C2 unopened
IMP	(2, −1, +1, 0)	root; C2 unopened
XMP	(2, −1, +1, −1)	gate; both sockets open
GMP	(2, −1, +1, +1)	C2 loaded
CMP	(1, +1, −1, −1)	C4 donor
UMP	(1, −1, +1, −1)	C4 acceptor
dTMP	same face as UMP	the C5 methyl does not touch the pairing face

Thymine and uracil share a pairing face exactly. The C5 methyl is a repair flag — it exists so that base-excision repair can distinguish deaminated cytosine from legitimate pyrimidine — and it carries no information the fourth letter did not.

Hydrogen bonds fall out of the dot product

Compare two nucleotides contact by contact. A product of −1 is a complementary bond, donor facing acceptor. A product of +1 is a clash. Zero is no contact. The hydrogen-bond count is the number of −1 terms, and it is computed rather than asserted:

pair	contact terms	bonds	clashes	observed
G : C	[−1, −1, −1]	3	0	3 ✓
A : U	[−1, −1, 0]	2	0	2 ✓
I : C	[−1, −1, 0]	2	0	2 ✓
Z : T	[−1, −1, −1]	3	0	3 ✓
X : C	[−1, −1, +1]	2	1	2 ✓
isoG : C	[+1, +1, +1]	0	3	0 ✓

Six for six, no free parameters. Two are worth pausing on. The phage Z-genome result — 2-aminoadenine making three bonds with thymine where adenine makes two — is not inserted by hand; it is what the third contact returns once the C2 socket is loaded. And isoguanine returns zero bonds and three clashes against cytosine, because isoguanine's face is cytosine's own face.

I : C makes two bonds where G : C makes three. The inosine prediction of Part Eleven, stated in one line of arithmetic.

Why the symbols are bases and not nucleotides

The question is better than it looks, and the textbook has an answer ready that is correct as far as it goes. Along a nucleic acid strand the sugar and the phosphate never vary. Only the base varies. Information theory therefore assigns the backbone zero bits, and the base carries the entire message. If you want the shortest faithful notation for a sequence, you write the bases.

That reasoning is sound. It is also conditional, and the condition is never stated.

The base-as-symbol convention is valid only for a code whose backbone is already uniform. It presupposes exactly the thing the origin problem is trying to explain.

Consider what the notation is structurally unable to write down. It cannot distinguish a ribose strand from an arabinose strand. It cannot distinguish a 3′,5′ linkage from a 2′,5′ linkage. It cannot mark 2-thiouridine as anything other than U, or inosine as anything at all. Each of those distinctions is precisely a distinction that

mattered before the backbone settled — and each is one the four-letter alphabet erases by construction.

So the notation does not merely omit the prebiotic era. It is a formalism in which the prebiotic era cannot be expressed. Any researcher working in A, U, G, C is working in a language whose vocabulary begins after the hard problems were solved, and there is no sentence in that language that describes them being solved.

The origin question was not neglected. It was defined out of the representation, and then the representation is what gets taught, in the textbooks cited here, as though it were the object.

Recognition runs through the phosphate

A modern structural result makes the nucleotide-over-base case independently. Uncoupling protein 1 leaks protons across the mitochondrial inner membrane to generate heat. Purine nucleotides were long held to be its only inhibitors. Jones and colleagues showed in 2025 that pyrimidine nucleotides bind and inhibit it as well, that all binding is pH-dependent, and — their explicit conclusion — that no selection for nucleobase specificity has occurred, the interaction being governed by pH-dependent binding through the phosphate moieties.

A protein that must recognize a nucleotide does it through the phosphate and the protonation state. The base is very nearly along for the ride.

One caution so no reader mistakes the claim: this is proton conductance, the bulk translocation of protons through a membrane protein, and it is not proton tunneling. The two share a particle and nothing else.

PART THIRTEEN · ARROW THREE — RNA2 TO PROTEIN

34. The Redundancy Is Not in the Cell ↩

Sixty-four codons, twenty amino acids, and about forty physical readers

The codon table's most-discussed feature is its degeneracy: six codons for leucine, whole boxes where the third position appears not to be read. Every other recognition event in the cell is exact to the ångström. Then you reach the codon table and the precision dissolves into a shrug.

Ask where the duplication physically is. Escherichia coli carries on the order of forty distinct tRNA species. Each has one anticodon. Each anticodon carries a defined chemical modification state at positions 34 and 37. Each reads a defined set of codons by defined chemistry.

Nothing in that inventory is duplicated. No spare part, no second copy, no redundant reader idling in the cytoplasm.

Now project that forty-member, modification-resolved process onto a table with sixty-four cells and no axis for modification. Inosine at position 34 collapses three codons onto one adaptor. Thiolation at C2 of the wobble uridine narrows a pair that would otherwise be loose. Lysidine — a lysine adduct on cytidine — is what actually distinguishes AUA from AUG in bacteria, and the table cannot say so. Queuosine, the methoxycarbonylmethyl groups, the whole modification inventory: none of it has anywhere to go in a 4 × 4 × 4 grid.

Six codons for leucine is not six ways of saying leucine. It is one process, sampled too coarsely to resolve, and reported as duplication.

That is aliasing in the exact signal-processing sense — structure below the sampling resolution reappearing as spurious pattern above it. Which settles whose flaw it is. Nature did not build a redundant machine. We built a low-resolution instrument, pointed it at a machine, and named the artifact after the machine.

Sixty-four codons for twenty amino acids. Six codons for leucine. Whole boxes in which the third letter appears not to be read at all. Every other recognition event in the cell is exact — enzyme and substrate, antibody and epitope, receptor and ligand, lock and key to the ångström. Then you arrive at the codon table and the precision dissolves into a shrug. It is the one place in molecular biology where the machinery looks careless, and it has been explained away as tolerated slack for sixty years.

It is not slack. It is compression, and the operator is inosine.

The compression operator

Inosine at anticodon position 34 pairs with U, with C and with A. One adaptor reads three codons. Adding inosine does not multiply the codon space — it divides the adaptor space threefold. For a cell with a few dozen tRNAs and not a synthetase to spare, that is not waste. It is the only arrangement that can be paid for.

Count the modern table. Nine four-fold degenerate boxes exist, and eight are read at position 34 by inosine: alanine, arginine, isoleucine, leucine, proline, serine, threonine, valine.

Eight of nine. A doublet code still running inside triplet clothes.

The one box the mechanism does not touch

The ninth is glycine, and the exception dates it. Glycine is the simplest amino acid, present in every prebiotic inventory ever compiled, and it arrives whole inside the purine ring as C4, C5 and N7 — glycine is not merely specified by the purine loop, it is structurally inside it. Its box is not inosine-read because its box is older than inosine's office. It was assigned before there was a wobble to read it with.

Note where the rest of the oldest amino-acid set falls. Proline: inosine-decoded. Alanine: inosine-decoded. Glycine: not. The two residues on either side of that boundary are the two that build the β-turn and the collagen repeat.

The pair that decides where a protein bends sits across the oldest seam in the code.

Twenty-one amino acids from seven nucleotides — a derivation attempted and not obtained

Seven nucleotides taken two at a time give C(7,2) = 21 pairs, excluding self-pairs. A human uses exactly 21 proteinogenic amino acids: twenty plus selenocysteine. The arithmetic coincidence is exact, and it motivated a designed code assigning each pair one amino acid.

The assignment used two orderings fixed independently before being combined: pairs ranked by pairing stability from the face encoding above, amino acids in Trifonov's 2000 consensus order of entry into the code. No per-pair free choices. Glycine, the oldest, landed on the only three-bond pair.

Three computed results argue against it. Only 7 of the 21 pairs form a clean Watson-Crick pair; the rest are purine-purine, pyrimidine-pyrimidine, or clash. Read instead as major-groove signatures — what a DNA-binding protein actually sees — only 14 of 21 are distinguishable, with six collisions. And a permutation test over 20,000 random relabelings gives p = 0.09: the assignment clusters side-chain classes no better than chance.

An arrangement, not a discovery. It is reported here rather than shelved, because the arithmetic is real and someone may find the assignment principle this one lacked.

Degeneracy is aliasing, and the aliasing is ours

Ask where the duplication physically is. Count the adaptors: Escherichia coli carries on the order of forty distinct tRNA species. Each has one anticodon. Each anticodon has a defined modification state at position 34 and position 37. Each reads a defined set of codons by defined chemistry. Nothing in that inventory is duplicated. There is no spare part, no second copy, no promiscuous reader idling in the cytoplasm.

Now project that forty-member, modification-resolved process onto a table with sixty-four cells and no axis for modification. Inosine-34 collapses three codons onto one adaptor. 2-thiolation at C2 of the wobble uridine narrows a pair that would otherwise be loose. Lysidine in bacteria — a lysine adduct at C2 of the wobble cytidine — is what actually discriminates AUA from AUG, and the table cannot say so. Queuosine, methoxycarbonylmethyl groups, the whole modification inventory: none of it has anywhere to go in a 4 × 4 × 4 grid.

Six codons for leucine is not six ways of saying leucine. It is one process, sampled at a resolution too coarse to resolve it, reported as duplication.

That is aliasing, in the exact signal-processing sense: structure below the sampling resolution reappearing as spurious pattern above it. And it settles the question of whose flaw it is. Nature did not build a redundant machine. We built a low-resolution instrument, pointed it at a machine, and named the artifact after the machine. The degeneracy is in the notation's resolution, not in the biology — which is why the redundant hardware has not turned up, and why the search for a reason nature tolerates the waste has produced sixty years of adaptive stories about a phenomenon that may not be in the cell at all.

Nature built no code

The precision paradox dissolves the moment you ask who the symbols belong to

The paradox, stated at full strength: every recognition event in the cell is exact to the ångström. Four billion years of selection produced machinery of a precision no engineer has matched. And then the same nature is supposed to have produced a

symbolic code so loose it spends six symbols where one would do. How can a designer that careful be that careless?

It cannot, and it was not, because nature never built a symbolic code. It built a physical process. The symbols are entirely ours.

There is no lookup table in the cell. Nowhere in a ribosome is there a register holding the string GGN → glycine. What exists is a set of molecules with shapes, charges and binding energies: a tRNA whose anticodon loop presents a particular modified base at a particular geometry, a synthetase that charges it with one amino acid and rejects the others, a decoding center in the small subunit that inspects the geometry of the minor groove of the first two pairs and is deliberately permissive at the third. Every one of those steps is as precise as the enzymology anywhere else in the cell. The precision is intact. It was never missing.

The code — the sixty-four-cell table, the four letters, the arrows — is a description written by human beings between 1961 and 1966 using the reagents and the notation available to them. It is a magnificent piece of work and it is not the object. When the description shows redundancy that the object does not contain, that is information about the description.

The right criticism was never that nature designed the code badly. It is that we transcribed a high-precision physical process into a low-precision symbolic one, mistook the transcription for the process, and then spent six decades explaining the artifacts of our own notation as though they were features of the cell.

PART FOURTEEN · THE MARKS

35. Both Epigenetic Currencies Ride on a Sulfur Atom ↩

Methyl and acetyl, the two marks that decide which genes are on, and where each of them comes from

Which genes are switched on in which tissue, and which of those settings a cell passes to its daughters, is decided largely by chemical marks placed on DNA and on the proteins that package it. There are many such marks. Two of them do most of the work: methyl and acetyl.

Both are delivered by a sulfur atom. Both are carried to the site on an adenine handle. Neither can be written in four letters.

mark	the donor	the sulfur that carries it	what it writes
Methyl	S-adenosylmethionine	a positively charged sulfonium sulfur	5-methylcytosine, histone lysine a arginine methylation, m6A on RN
Acetyl	acetyl coenzyme A	a thioester bond to a terminal thiol	histone lysine acetylation, and eve acetylation in the cell

Yellow carries the mark. Red carries it to the site. Every methyl and every acetyl group placed on a genome came off a sulfur atom, riding on an adenine.

The methyl donor, examined

S-adenosylmethionine is made from the amino acid methionine and from ATP. Methionine contributes a sulfur; ATP contributes the adenosine. The reaction attaches the adenosyl group directly to the sulfur, which gives that sulfur three bonds and a positive charge — a sulfonium center.

$$\textit{methionine} + \textit{ATP} \rightarrow \textit{S-adenosylmethionine} + \textit{phosphate} + \textit{pyrophosphate}$$

The positive charge is the whole point. It makes the methyl group attached to that sulfur electrophilic and therefore transferable. An ordinary thioether will not donate a methyl; a sulfonium will, and does, in more than two hundred distinct human enzymes.

The universal methyl donor is a sulfur atom carrying a positive charge, bolted onto a purine. Remove either half and no gene is marked anywhere.

The acetyl donor, examined

Coenzyme A ends in a thiol. Acetate is attached to it as a thioester, and a thioester is a high-energy linkage — higher than the corresponding oxygen ester — precisely because sulfur's larger, more diffuse orbitals give poor overlap with the carbonyl and therefore little resonance stabilization. The bond is unstable, which is why it can be spent.

Coenzyme A also carries an adenine: it is built on three-prime-phosphoadenosine. So the acetyl donor, like the methyl donor, is a sulfur working end on an adenine handle.

The reason acetyl-CoA is the energy currency of group transfer is that its bond is to a sulfur rather than an oxygen. The conjugate substitution, chosen deliberately, because the weaker bond is the useful one.

The general principle these two cases illustrate. Where the cell needs a group held firmly, it uses oxygen. Where the cell needs a group held ready to be given away, it uses sulfur. The thioester is unstable relative to the ester and that instability is the function. The sulfonium is reactive relative to the thioether and that reactivity is the function. In both cases the design decision is a conjugate substitution, and in both cases the four-letter notation records the mark that gets placed and nothing about the atom that placed it.

---

36. The Methylation Cycle Is a Purine Cycle, and Its Exhaust Is Inosine ↩

Where the methyl donor goes after it has donated, and why that lands in the orange channel

Follow S-adenosylmethionine after it has given up its methyl. What remains is S-adenosylhomocysteine — the same molecule minus the methyl group, and a potent inhibitor of the very enzymes that just used it. It has to be removed, and the route by which it is removed is the reason this section exists.

step	product	enzyme
S-adenosylmethionine donates its methyl	S-adenosylhomocysteine	the methyltransferase, any of over two hundred
S-adenosylhomocysteine is hydrolyzed	homocysteine + ADENOSINE	S-adenosylhomocysteine hydrolase
Homocysteine is re-methylated or committed to cysteine	methionine, or cysteine	methionine synthase; cystathionine beta synthase
Adenosine is deaminated	INOSINE	adenosine deaminase

Every methyl mark placed anywhere in the cell releases one adenosine, and adenosine deaminase turns it into inosine. The epigenetic machine is a purine machine, and its exhaust is the base with no letter.

Two things follow, and both are checkable.

One. The rate of methylation and the size of the inosine pool are coupled, because they are the same pathway seen at two points. A cell methylating heavily is a cell producing adenosine, and therefore inosine, at a matching rate.

Two. The sulfur arm and the purine arm of this cycle are not two pathways that happen to intersect. They are one cycle. Homocysteine goes on to become cysteine, which is the sulfur source for iron-sulfur clusters, for the thiolated wobble bases, and for glutathione. Adenosine goes on to become inosine and then hypoxanthine and then urate. One molecule splits into the sulfur economy and the purine economy at a single hydrolysis.

S-adenosylhomocysteine hydrolase is the enzyme where the sulfur story and the purine story separate. Upstream of it they are one molecule. That is not a metaphor and it is not a coincidence — it is a hydrolysis with two products.

And the same design appears twice more

molecule	made from	what it does	the pattern
S-adenosylmethionine	methionine + ATP	transfers a methyl group	a sulfonium on a purin
PAPS	ATP + sulfate, twice phosphorylated	transfers a sulfate group	a sulfate on a purine
Methylthioadenosine	the by-product of polyamine synthesis	salvaged by MTAP to adenine and methylthioribose	a thioether on a purine

Three separate sulfur delivery systems. All three are a sulfur working group mounted on a purine handle. The pattern is not remarked on in the literature because the sulfur half and the purine half are studied by different people.

A clinical corroboration, because the pattern predicts a vulnerability. Methylthioadenosine phosphorylase, the enzyme that salvages the third molecule in that table, sits beside CDKN2A on chromosome nine and is co-deleted with it in a substantial fraction of human cancers. Cells that have lost it accumulate methylthioadenosine, which inhibits methyltransferases, and become dependent on the enzyme PRMT5 — a dependency now being pursued therapeutically. The point for this volume is narrower: the vulnerability arises because a sulfur-bearing purine cannot be recycled, and it was found by people looking at neither sulfur nor purines but at a deletion.

37. Written by Sulfur, Erased by Oxygen ↩

The conjugate pair, running the epigenome in opposite directions

Marks that cannot be removed are not regulation. They are damage. So for every writer there is an eraser, and the erasers are where the second half of the conjugate pair appears.

Both families of enzyme that remove a methyl group from DNA or from a histone require molecular oxygen.

eraser	what it removes	enzyme class	the oxygen require
TET1, TET2, TET3	5-methylcytosine on DNA	Fe(II) and 2-oxoglutarate dioxygenase	O2 is a substrate; co stoichiometrically
JmjC domain demethylases	methylated histone lysines	Fe(II) and 2-oxoglutarate dioxygenase	O2 is a substrate
LSD1 / KDM1A	mono- and dimethyl histone lysine	flavin-dependent amine oxidase	O2 is the electron ac H2O2 is released

Sulfur writes the methyl marks and oxygen erases them. The conjugate pair, one on each side of the epigenome, and neither is visible anywhere in A, T, G or C.

The acetyl side is a different pairing and the contrast is informative. Acetyl marks are written from a thioester — sulfur again — but removed by two distinct classes: the classical deacetylases, which are zinc enzymes, and the sirtuins, which consume NAD-plus and are therefore coupled to the redox state of the cell. NAD carries an adenine. So even the eraser that is not an oxygen enzyme is a purine enzyme.

What this means for the model this volume argues

The epigenome is usually described in terms of what is written: a methyl here, an acetyl there, a pattern inherited or lost. Described in terms of material prerequisite, it looks different.

operation	what must physically be present
Writing a methyl mark	a sulfonium sulfur, an adenosine, a folate one-carbon unit, and B12 upstre
Erasing a methyl mark	molecular oxygen, ferrous iron, and 2-oxoglutarate from the citric acid cyc
Writing an acetyl mark	a thioester, an adenine handle, and acetyl-CoA from central metabolism
Erasing an acetyl mark	zinc, or NAD-plus and therefore the cell's redox state

Not one of those requirements is a letter. Every one of them is an atom, a cofactor or a metabolite, and every one of them can be removed experimentally to stop the operation.

Why this belongs in a book about the genetic code and not in a book about metabolism. Because the epigenetic layer is the clearest case in modern biology of information that is real, heritable, and consequential, and that the four-letter notation cannot represent at all. Two cells with identical sequence can have opposite phenotypes, and the difference is a set of chemical groups delivered by sulfur and removed by oxygen. If the alphabet were an adequate description of the genetic material, that could not happen. It happens in every tissue of every multicellular organism, continuously.

PART FIFTEEN · THE SULFUR ECONOMY OF THE COFACTORS

38. One Donor, Every Cofactor, and a Disease That Removes It ↩

The best-evidenced claim in this document, and the one a reviewer should attack first

This part is longer than the others because it carries the most weight and because a natural experiment has already been performed on it.

The supply line

Cysteine desulfurase abstracts sulfur from L-cysteine and carries it as a protein-bound persulfide on an active-site cysteine, delivering it to acceptors. From that one donor come iron-sulfur clusters, thionucleoside modifications of transfer RNA, thiamine, biotin, lipoic acid and molybdenum cofactor. These pathways are individually published; assembling them into a single supply argument is the contribution here.

destination	route	why the purine loop cares
Iron-sulfur clusters	ISC and SUF systems	the catalytic core of the ancestral ribonucleotide reductase
Thionucleosides	2-thiouridine at position 34 and others	the modification that narrows wobble decoding
Molybdenum cofactor	MoaA onwards	required by xanthine oxidoreductase and by sulfite oxidase
Thiamine, biotin,	separate transferases	central carbon metabolism

destination	route	why the purine loop cares
lipoic acid		

And the cofactor that empties the purine ring is built from a purine

Molybdenum cofactor biosynthesis begins with GTP. MoaA, a radical S-adenosylmethionine enzyme carrying two [4Fe-4S] clusters, grips the guanine at N1 and N2 and acts at C8 to open the ring and produce cyclic pyranopterin monophosphate. The cofactor that xanthine oxidoreductase requires in order to empty the purine ring is therefore manufactured out of a purine, using iron-sulfur clusters supplied by the same desulfurase.

The enzyme that discharges purines cannot work without a cofactor made from a purine, provisioned with sulfur from the same donor that builds the enzyme that makes DNA. That is a closed loop, and it is not a metaphor.

The distinction that must be kept, because conflating them is a common error.

Molybdenum cofactor (Moco) and the iron-molybdenum cofactor of nitrogenase (FeMo-co) are different molecules with different biosyntheses. Moco is a pyranopterin built from GTP. FeMo-co is a metallocluster. This document concerns Moco. Any argument that slides between them is wrong and is not made here.

The natural experiment: molybdenum cofactor deficiency

If the argument above is right, one lesion in cofactor synthesis should take out the purine discharge ladder and the sulfur disposal pathway together, in the same patient. It does.

According to the clinical literature, molybdenum cofactor deficiencies are inborn errors impairing the cofactor required by three oxidases — sulfite oxidase, xanthine oxidase and aldehyde oxidase. Most patients present with severe neonatal epileptic encephalopathy, hypotonia, poor feeding and apnoea, and death typically occurs within the first three years of life. The clinical class name is sulfite intoxication disorders: it is the sulfite that destroys the brain, not the lost urate.

And the control experiment nature already ran

disorder	enzymes lost	index metabolites	which arm fails
Xanthinuria type I	XDH alone	(hypo)xanthine ↑, urate ↓	purine arm only; sulfur normal
Xanthinuria type II	AO and XDH	(hypo)xanthine ↑, urate ↓	purine arm plus aldehyde

disorder	enzymes lost	index metabolites	which arm fails
			oxidase
Isolated sulfite oxidase deficiency	SO alone	sulfite↑, S-sulfocysteine↑	sulfur arm only; purines normal
Molybdenum cofactor deficiency	AO, XDH and SO	both sets, plus cystine↓ and urate↓	both arms, via the shared cofactor

Knock out the purine enzymes and sulfur is untouched. Knock out the sulfur enzyme and purines are untouched. Knock out the cofactor they share and both fail. That is how you know it is a cofactor and not a coincidence.

Treatment sharpens the point. Cyclic pyranopterin monophosphate — fosdenopterin — treats type A, which lies upstream of the intermediate, and does not help type B, which lies downstream. Isolated sulfite oxidase deficiency has no treatment. In a reported hepatocyte transplantation for type B, sulfite and S-sulfocysteine fell and urate rose, and acute brain injury from sulfite toxicity was still visible on imaging at thirty-five hours of age.

Four rows of a purine table are sulfur enzymes

entry in a standard purine defects table	what the sulfur is doing
Molybdenum cofactor deficiency	AO, XDH and sulfite oxidase fail together
Methylthioadenosine phosphorylase	salvage of a sulfur-bearing purine
S-adenosylhomocysteine hydrolase	the methylation cycle's sulfur hub
Thiopurine methyltransferase	methylates a sulfur-substituted purine drug

Nobody arranged that. They are there because the purine pathway and the sulfur pathway share enzymes, cofactors and substrates.

And the methyl donor is an adenosine wearing a sulfur

Two of the four rows above are the enzymes that gate methylation, and that is not a second coincidence. It is the same one, one level up.

S-adenosylmethionine is not a sulfur compound with an adenosine attached as an afterthought. It is made by methionine adenosyltransferase from methionine and ATP, so every methyl mark placed on every histone and every CpG in the genome is paid for with one adenosine. After the methyl group leaves, what remains is S-adenosylhomocysteine — adenosine plus homocysteine. The polyamine branch

discards methylthioadenosine — adenosine plus methylthioribose. Every intermediate in the methylation cycle carries an adenine.

species	composition	made by	role
S-adenosylmethionine	methionine + ATP	methionine adenosyltransferase	the universal methyl donor
S-adenosylhomocysteine	adenosine + homocysteine	what remains after transfer	product inhibitor of every methyltransferase
Methylthioadenosine	adenosine + methylthioribose	polyamine branch byproduct	inhibits PRMT5
Salvage	adenine + methylthioribose-1-P	MTAP	returns the purine to the p

IMP to AMP to ATP to S-adenosylmethionine. Inosine monophosphate sits three steps upstream of every epigenetic mark in the genome, on the adenine arm rather than the guanine one.

S-adenosylmethionine is not the only sulfur carrier built on a purine. Phosphoadenosine phosphosulfate — PAPS, the universal sulfate donor for every sulfation reaction including the N-sulfation of heparan sulfate discussed in Part Seven — is adenosine carrying two phosphates and a sulfate. The thionucleoside modifications of transfer RNA are a third. Three separate sulfur-delivery systems, all assembled on an adenine.

The cancer result that makes this mechanical rather than rhetorical. Methylthioadenosine phosphorylase lies adjacent to CDKN2A and is frequently deleted along with it as a passenger. Kryukov and colleagues reported in Science in 2016 that MTAP-null cancer cells accumulate methylthioadenosine, that MTA specifically inhibits the arginine methyltransferase PRMT5, and that this creates a selective dependency on PRMT5 and its partner WDR77 across multiple cancer lineages. A purine salvage enzyme, lost by accident, disabling a methyltransferase.

And the result that qualifies it, cited in the same breath because a reader deserves both. Barekatain and colleagues reported in Nature Communications in 2021 that primary human glioblastomas carrying homozygous MTAP deletion do not significantly accumulate MTA in vivo, because MTAP-expressing stromal cells metabolize the secreted metabolite. The in vitro dependency is real; its translation to primary tumors is not established. Any use of this link in a therapeutic argument has to carry that qualification, and this document carries it.

What this adds to the part is one sentence of scope. The sulfur economy argued above provisions the purine loop with iron-sulfur clusters, thionucleosides and

molybdenum cofactor. It also provisions the epigenome, and by the same logic: a sulfonium center delivered on a purine handle. S-adenosylmethionine is where the two supply lines are the same molecule.

Stated at its correct strength, because the temptation here is large. That the methylation cycle runs on adenosine derivatives is textbook biochemistry and is asserted here rather than claimed. That two of the four sulfur entries in a purine defects table are the enzymes gating methylation is an observation about a table, not a mechanism. What this document adds is only that the same shared-supply reasoning applied to cofactors in this part applies unchanged to methyl marks, and that IMP sits upstream of both. Nothing here shows that inosine has any regulatory role in epigenetics, and no such claim is made.

What this part does not establish

Metabolic physicians have measured sulfite and urate in the same patient for decades and know why both are abnormal. Nothing here is news to them. What is offered is that the same shared-cofactor logic runs backward into the origin argument — and that the disease is the test this framework would otherwise have had to design and could not afford.

PART SIXTEEN · THE ATOMIC LEVEL

39. The Carbonyl Is Where the Proton Goes ↩

One bond, one barrier, and a result three groups now dispute

Part Eleven reported the tunneling numbers and moved on to what they imply for inosine. This part goes down one level and asks a question that section skipped: what is the proton actually crossing?

A carbonyl.

Guanine and cytosine meet at three contacts. O6 of guanine accepts from N4-H of cytosine. N1-H of guanine donates to N3 of cytosine. N2-H of guanine donates to O2 of cytosine. Two of the three acceptors are carbonyl oxygens, and the double transfer that produces the rare tautomer moves one proton onto O6.

So the tautomer is not something that happens near a carbonyl. It is the carbonyl. G*:C* is what exists after O6 stops being a ketone and becomes an enol — after a proton lands on that oxygen and stays there long enough to be copied.

The rare tautomer of guanine is a carbonyl holding a proton it has no right to.

A precision this paper owed the reader

That sentence is the one a referee stops at, so it is worth saying exactly what moves and along what.

The proton does not tunnel through the C=O bond. It tunnels along the hydrogen bond. The covalent N-H on the donor side breaks and a new covalent O-H forms on the far side, and the barrier being crossed sits in the non-covalent gap between the two molecules — an asymmetric double-well potential whose width is the N···O separation. The carbonyl oxygen is the destination, not the road. Slocombe and colleagues say so in their opening sentence: proton transfer along the hydrogen bonds of DNA. Every calculation in the table below is a calculation about a hydrogen bond, not about a double bond, and any version of this argument that says otherwise is wrong on the mechanism.

And the carbonyl is not where the rate is decided. The same work reports that the two protons transfer asynchronously, and that the rate-determining process is the transfer of a single proton across the barrier, with the other proton then moving in the opposite direction to preserve electroneutrality. The proton that crosses first travels the central N1-H···N3 contact — nitrogen to nitrogen, with no carbonyl in it at all. The carbonyl carries the second, charge-compensating move. The title of this section survives, because the carbonyl really is where the proton goes. What does not survive is the implication that it is also where the rate is set.

The carbonyl is the destination. The central nitrogen-to-nitrogen contact is the gate.

Adenine-thymine shifts the balance back. It has two hydrogen bonds rather than three, and one of them — N6-H of adenine donating to O4 of thymine — does terminate on a carbonyl. Where guanine-cytosine gives the carbonyl two of three contacts and none of the rate-determining one, adenine-thymine gives it one of two.

Why this bond and not some other

Four properties decide it, and none of them is exotic.

The geometry is already aligned. Carbonyl oxygen is sp^2-hybridized, with two lone pairs in the ring plane about 120° apart. One of them points straight down the pairing axis. Nothing has to rotate, and nothing has to be paid for in entropy before the transfer can begin.

The barrier is a distance. Tunneling probability falls exponentially with barrier width, and the width here is the N···O separation — close to 2.9 Å in a Watson-Crick pair. With an N-H bond of 1.01 Å and an O-H bond of 0.98 Å, the proton has about 0.9 Å of open ground to cross. Change that separation by a tenth of an ångström and the rate moves by an order of magnitude. It is the most sensitive quantity in the whole problem, and it is fixed by the bond lengths of the two rings.

The well has two minima because the two proton affinities are close but unequal. A carbonyl oxygen is a moderate base. Make it much weaker and the second minimum disappears; make it much stronger and the transfer is permanent rather than rare. Carbonyl oxygen sits inside the narrow window where a rare tautomer is possible at all. That window is not wide, and nothing put it there on purpose.

The proton does not start at the bottom. The N-H stretch sits near 3400 cm^{-1}, which is roughly 20 kJ/mol of zero-point energy — energy the proton carries because quantum mechanics forbids it to be at rest. It begins partway up the wall. Substitute deuterium and the stretch falls toward 2500 cm^{-1} and the zero-point energy falls with it. The deuteron starts lower and meets a barrier that is effectively both taller and wider.

Hydrogen and deuterium have identical chemistry. They differ in how far off the floor they stand, and the entire isotope effect comes from that.

The result is contested across five independent studies

Five studies bear on this reaction and they do not agree with one another. The magnitude of the tunneling contribution inside DNA is an open question, and the table below is the state of it.

study	approach	finding
Pohl et al. 2018	NMR deuterium isotope shifts with path-integral MD, isocytosine dimer	Inter-base proton transfer does not take place in this system
Slocombe et al. 2022	Open quantum system, explicit water bath, G:C	Tautomer population 1.73×10^{-4}; KIE 30; tunneling dominant
Botti et al. 2023	Semiclassical vibrational spectroscopy, gas-phase G:C	No evidence of double proton hopping — but the Watson-Crick

study	approach	finding
		structure itself was not detected
Winokan et al. 2023	QM/MM, G:C inside PcrA helicase	Protein environment raises the barrier substantially and shifts the equilibrium
Greer et al. 2025	Semiclassical μOMT with POLYRATE, gas-phase G:C	κ = 1.57; tunneling 36% of the rate at 298 K; KIE 5.05

The sharpest disagreement is the last one. Slocombe reports a kinetic isotope effect of 30. Greer computes 5.05. Same pair, same reaction, a factor of six apart.

And Greer's group found something nobody had predicted. Their minimum-energy path has a single saddle point, as expected. But adding vibrational zero-point energy along that path does not simply lower the effective barrier, which is what the textbook picture says it does. It produces two well-separated barriers. The second is built entirely out of zero-point energy piled up by the curvature of the reaction path, and that purely quantum wall suppresses tunneling. Two quantum effects pulling opposite ways, and in their calculation the suppressing one is not a small correction.

Zero-point energy helps the proton across and builds a second wall in front of it. Which effect wins is an open question.

What is actually unsettled, and what is not

It is worth separating two things that get conflated. Proton tunneling is neither new nor mysterious. It was described in 1927, it has been standard chemical kinetics since Bell's monograph in 1980, and kinetic isotope effects in enzymes have been read as tunneling signatures for forty years. Nobody disputes the phenomenon.

What is disputed is the magnitude inside DNA, and therefore whether it contributes to spontaneous mutation at a rate that matters to anything. One group reports a large effect. Two experimental studies looking for inter-base proton transfer find no evidence of it. One independent calculation finds the effect real but modest. And the same group that reported the large effect then showed that placing the pair inside a helicase — which is where replication actually happens — raises the barrier substantially.

That is the honest state of the question in 2026, and it is a better state for this paper's purposes than a settled one. The inosine prediction in Part Eleven is a comparison between I:C and G:C computed by a single method. A ratio survives a disagreement about absolute scale. What does not survive is the sentence claiming tunneling delivers the wrong tautomer ten thousand times more often than classical

physics allows: that belongs to one calculation among five, and it is now labeled as such.

Three tunneling phenomena, three geometries, one word

The word tunneling is doing three jobs in this literature and they are not the same phenomenon. Separating them is not pedantry. They run on axes at right angles to one another, over distances that differ by an order of magnitude, and only one of the three is disputed.

what tunnels	which direction	over what distance	what it does
Proton transfer	in the plane of the base pair	one hydrogen bond, N···O or N···N, about 2.9 Å	tautomerization, and if the magnitude holds, spontaneous mutation
Electron and hole transport	perpendicular to the pair	the stacked π system, 3.4 Å per step	oxidative damage; holes localize on guanine, preferentially on GG and GGG runs
Proton-coupled electron transfer	along a chain of protein residues	roughly 35 Å, far beyond any single bond	ribonucleotide reductase moving a radical to its active-site cysteine

The second row deserves a sentence of its own, because guanine's part in it is the reverse of its part in the first. Guanine has the lowest ionization potential of the four bases, which makes it the sink for holes rather than the source of protons. Balanikas and colleagues report that guanine quadruplexes photoionize at energies significantly below guanine's own ionization potential, with the peripheral bases interfering in the charge-separation step that precedes electron ejection. That is stack chemistry. It never touches the Watson-Crick edge.

The proton moves sideways across the pair. The charge moves up and down through the stack. The two never use the same bond.

The third row is already in this document, in Part Ten, and was not called tunneling when it was written. Ribonucleotide reductase moves a radical across a distance no hydrogen bond spans, by a coupled proton and electron route through conserved residues. It is the only one of the three about which nothing is contested, and it is the one this paper leans on hardest.

---

40. What Sulfur Does That Oxygen Cannot ↩

One fact about the third electron shell, and the rest follows from it

Sulfur has appeared three times in this argument without ever being explained. 2-thiouridine sharpens the wobble pair. Sulfur metabolism is placed before oxygen metabolism. And the enzyme at the gate of the purine loop, described at length since page one, has never had its catalytic atom named. Three appearances and no account of why sulfur rather than something else.

The account is one line. Oxygen's valence electrons are in the second shell. Sulfur's are in the third.

property	oxygen	sulfur	what it buys
Valence configuration	$2s^2\ 2p^4$	$3s^2\ 3p^4$	Sulfur's electrons are further out and more loosely held
Pauling electronegativity	3.44	2.58	Bonds to sulfur are barely polar
van der Waals radius	1.52 Å	1.80 Å	A larger, softer, more deformable atom
Typical C=X double bond	≈ 1.23 Å	≈ 1.67 Å	The acceptor sits noticeably further from the donor
Side-chain pKa	serine ≈ 13	cysteine ≈ 8.3	A real fraction of cysteine is ionized at pH 7.4

Everything sulfur does in biology descends from that one shell.

It hydrogen-bonds badly. A large, diffuse lone pair is a poor acceptor. This is already this paper's argument for 2-thiouridine — sulfur at C2 refuses guanine's N1-H while leaving the adenine pair intact. That was stated earlier as a fact about fidelity. It is a fact about the third shell.

It is a far better nucleophile. Polarizability makes thiolate soft and reactive, and the low pKa means it is actually available at physiological pH rather than merely reactive in principle. Serine needs an entire charge-relay triad to accomplish unassisted what cysteine does alone.

It spans eight oxidation states. Sulfide at −2 through sulfate at +6. Oxygen realistically manages −2 to 0. That range is why sulfur can serve as electron donor or acceptor as the situation requires, and why sulfur metabolism is so much richer than oxygen metabolism.

It catenates. S–S bonds are stable where O–O bonds are not. Disulfide bridges, polysulfides, and the [4Fe-4S] cubanes that sit in ferredoxins, aconitase, complex I, nitrogenase and every radical SAM enzyme all follow from that single difference.

Sulfur is the catalytic atom at the gate of the purine loop

This paper has said from its first page that IMP dehydrogenase is the gate — the obligate passage from IMP to XMP, the only door to guanine. It has described the covalent mechanism and the E–XMP* intermediate. It has never said what does the attacking.

A cysteine does. Cysteine-331 in human IMPDH type II. Markham and colleagues measured its ionization directly rather than inferring it: the active-site sulfhydryl has a pKa of 7.5 in the enzyme-ligand complex, against roughly 8.3 for free cysteine. The enzyme has tuned its own thiol down toward physiological pH, so that a substantial fraction of it stands as thiolate at the moment of catalysis. That thiolate adds to C2 of IMP before NAD^+ is reduced. It is also what mycophenolic acid exploits — the drug packs underneath the hypoxanthine ring and traps the covalent intermediate the sulfur made.

The gate of the purine loop is opened by a sulfur atom, and the enzyme has adjusted that atom's pKa by nearly a full unit to keep it open.

Why thioesters are high-energy, in one sentence about orbitals

De Duve proposed a thioester world: an energy economy older than ATP, running on acetyl-CoA's thioester bond, which forms far more readily under prebiotic conditions than a phosphoanhydride and sidesteps the problem that making ATP costs ATP. The proposal was never conclusive and remains a live hypothesis rather than a result. But the reason a thioester can play that role at all is the same third-shell fact.

In an oxygen ester, the oxygen lone pair is a 2p orbital facing a 2p orbital on the carbonyl carbon. The overlap is good, resonance delocalizes the pair into the carbonyl, and the ground state is stabilized. In a thioester, sulfur offers a 3p orbital against carbon's 2p. The orbitals are the wrong size for one another, the overlap is poor, and the resonance stabilization largely fails to arrive. The ground state is left sitting high.

A thioester is not high-energy because something was put into it. It is high-energy because the stabilization an ordinary ester enjoys never shows up.

What happens when the carbonyl becomes a thiocarbonyl

Now the two halves of this part meet. Section four established that the proton transfer producing a rare tautomer lands on a carbonyl oxygen. Section five

establishes that sulfur differs from oxygen in every property that event depends on — bond length, atomic radius, electronegativity, proton affinity. So the question writes itself. What does the tautomer do when C=O becomes C=S?

It has been observed, though not in DNA. Khvorostov and colleagues held 2-thiouracil in an argon matrix at low temperature and irradiated it. Before irradiation the molecule was exclusively the oxo-thione form. Under ultraviolet light a proton transferred from N1-H or N3-H onto the sulfur of the C2=S thiocarbonyl, giving oxo-thiol products. The reaction was photoreversible, and prolonged irradiation drove most of the material into the oxo-thiol form and left it there. The corresponding hydroxy tautomer — proton on oxygen rather than sulfur — appeared only as a minor product.

The proton will sit on sulfur. Once there, it stays.

What that does not establish has to be said plainly. This is photochemistry in a frozen matrix at cryogenic temperature, not thermal tunneling in a duplex at 310 K. It shows the thiol tautomer exists and is accessible. It says nothing about the rate or the equilibrium population inside DNA, which is the only quantity that matters for mutation.

What it licenses is a calculation, and the two governing terms point in opposite directions. The C=S bond is roughly 1.67 Å against 1.23 Å for C=O, and sulfur's van der Waals radius is larger by 0.28 Å. The acceptor atom therefore sits further from the donor, the barrier is wider, and tunneling should fall — exponentially, since width is the exponential term. Against that, the matrix work shows sulfur holds the proton once it arrives, which deepens the product well and would raise the tautomer population at equilibrium. Barrier width and well depth are the two terms in the problem, and substituting sulfur moves them against each other.

Replace one oxygen with one sulfur and the two quantities that govern the mutation rate move in opposite directions. That calculation has never been run.

Why this matters to the argument rather than being a curiosity

If 2-thiolation suppresses tautomer formation, then 2-thiouridine is doing fidelity work at two levels simultaneously — refusing the wrong partner on the pairing face, and refusing to tautomerize underneath it. The claim that inosine and 2-thiouridine functioned as paired tolerance controls would acquire a mechanism it does not presently have.

If 2-thiolation raises tautomer formation, that claim is weakened and the modification is doing one job rather than two.

Either result is worth having, which is the test of whether an experiment is worth running. The claim stays in the conjecture column until Experiment Thirteen is run.

A note on how far down this goes

It is tempting to think there is a quantum layer beneath the chemistry that a paper like this has neglected. There is not. Polarizability, orbital overlap, proton affinity, zero-point energy and pKa are quantum mechanics, stated at the resolution where it predicts things. Chemistry is not a coarse approximation sitting on top of the real physics; it is the real physics in the units that do work at 310 K in water.

The one place this paper needed quantum mechanics written as quantum mechanics rather than as chemistry is the tunneling calculation, because there the classical rate is wrong by orders of magnitude and no chemical language captures the discrepancy. Everywhere else the atomic account above is the quantum account, and going further down buys nothing except the appearance of depth.

The atomic level is not a layer above the quantum one. It is the quantum one, described where it earns its keep.

PART SEVENTEEN · THE SEVEN-LETTER SEED

41. A Proposed Initial Genetic Code, Written in Nucleotides ↩

Conjecture, and marked as such from the first line

Everything up to this point described what is. This part proposes what was, and it is therefore a conjecture. What follows is a candidate for the alphabet of the first genetic code: seven monomers, one for each color, chosen on chemical and metabolic grounds and stated in a form that can be argued with.

The unit is the nucleotide, not the base

Every account of the origin of the code that begins with a list of bases has already made an error of category, and the error is worth naming before anything else is proposed.

Bases do not polymerize. A heterocycle in solution is a heterocycle in solution; it has no backbone, no charge, no linkage and no capacity to carry a sequence. The object that polymerizes is the nucleotide — base, sugar and phosphate as one molecule —

and the object a code is written in is therefore the nucleotide. The bases are what the nucleotides are distinguished by. They are not what the code is made of.

This is not pedantry, and the demonstration is already published. Sutherland's 2009 synthesis of activated pyrimidine ribonucleotides succeeded precisely because it stopped trying to join a sugar to a base. Ribose and cytosine do not condense in water in any useful yield; the glycosidic bond is the hardest bond in the whole problem. What works is building the sugar and the base together, part by part, from cyanamide, cyanoacetylene, glycolaldehyde and glyceraldehyde, with phosphate present throughout as catalyst and buffer. The nucleotide arrives whole. It was never assembled from parts that existed separately.

Which disposes, in passing, of the standing objection to cytosine. Cytosine is absent from the Murchison inventory and it is absent for a good reason — free cytosine deaminates readily and does not survive geological time. But the free base was never the intermediate. Cytidine, and specifically its 2′,3′-cyclic phosphate, is a direct product of the cyanosulfidic route. Asking whether cytosine was delivered by meteorite is asking the wrong question about the wrong molecule.

Name the seed alphabet in nucleotides, and cytosine's absence from the sky stops being an argument against its presence in the code.

The seven letters

Seven colors, seven nucleotides. The color scheme was built on elements, not on occupants — which matters more than it appears to, and is the subject of the next two sections.

color	element	modern base	proposed seed nucleotide	office
RED	Hydrogen	Adenine	AMP	weak-pair letter
ORANGE	Oxygen	Inosine	IMP	root monomer; ambiguity-widener
YELLOW	Sulfur	Thymine	2-thio-UMP	fidelity-sharpener; deoxy gateway
GREEN	Nitrogen	Guanine	GMP	strong-pair letter
BLUE	Carbon	Cytosine	CMP	strong-pair letter
INDIGO	Selenium	Xanthine	XMP	pH-gated selector, not a letter
VIOLET	Phosphorus	Uracil	UMP	weak-pair letter

Four purines and three pyrimidines. The seed is purine-heavy and the modern code is not, and that asymmetry is the first thing the proposal has to justify.

Why thymine is not in it, and who sits in yellow instead

Thymine is excluded, and the grounds are four and they converge. It is DNA-specific and absent from RNA. It is absent from the Murchison inventory, in which adenine, guanine, uracil, xanthine and hypoxanthine are all present, so there is no delivery argument for it. Its methyl group is donated by 5,10-methylene-tetrahydrofolate, by way of thymidylate synthase acting on dUMP, which requires folate biosynthesis and serine hydroxymethyltransferase — an apparatus far downstream of anything a seed code can assume. And, decisively, the methyl is a repair flag, whose only function is to make deaminated cytosine distinguishable from legitimate pyrimidine. A flag presupposes a reader. Thymine is unintelligible without uracil-DNA glycosylase and base-excision repair, and a molecule that is unintelligible without a repair system cannot have preceded one.

Thymine is a late solution to a late problem. It belongs to the archive, and the archive came second.

But the yellow chair is not thymine's. It is sulfur's. Thymine is merely who is sitting in it now. Ask instead what sulfur was doing in a pyrimidine before the Great Oxidation Event, and the answer is already in the prebiotic literature and is not speculative.

2-thiouridine — uridine with the C2 carbonyl oxygen replaced by sulfur — is an established intermediate of prebiotic RNA synthesis. It forms on the cyanosulfidic route. It is the clearest instance of a colinear conjugate substitution performed at the pairing face of a nucleotide: one chalcogen for the one below it, at one position, on one ring. And it does three things a seed code needs.

One. It stabilizes the pair it should make and destabilizes the one it should not. s^2U pairs with A more strongly than U does, because 2-thiolation drives the ribose into a C3′-endo pucker, which improves stacking and enforces A-form geometry. It pairs with G much less well than U does, because sulfur is a large, diffuse and poor acceptor for guanine's N1-H. The U:G wobble is the commonest mismatch observed in non-enzymatic RNA copying, and 2-thiolation is the known fix for it. That is a fidelity mechanism available before enzymes, made of sulfur.

Two. It is the chemical gateway to deoxyribose. Phosphorylation of 2-thiouridine gives the 2,2′-thioanhydro derivative; hydrogen-sulfide-mediated photoreduction of that gives 2′-deoxy-2-thiouridine; hydrolysis gives deoxyribose, and reaction with adenine gives 2′-deoxyadenosine. The sulfur

pyrimidine is not merely contemporaneous with the RNA world. It is the documented prebiotic road to DNA.

Three. It survives. 2-thiouridine is still at anticodon position 34 in modern tRNA, doing the same job: restricting the wobble where the wobble must be restricted.

So the yellow chair has had two occupants and one office. In the sulfur economy the occupant was 2-thio-UMP and the office was fidelity. After the oxidation, sulfur at C2 was replaced by oxygen and a methyl was added at C5, and the occupant became thymine and the office became repair. One conjugate substitution and one methylation separate them.

The color did not change, because the color was never the base.

Orange and yellow, and the two tolerance controls

Now put the two chalcogen modifications side by side, because this is the proposal's central structural claim.

Inosine has an oxygen added at C6. Its pairing face is guanine's minus the 2-amino group, so it makes two hydrogen bonds where guanine makes three, and it will pair with cytosine, with uracil and with adenine. Inosine is a widener. It increases the number of partners a position will accept.

2-thiouridine has a sulfur substituted at C2. Its pairing face is uracil's with one acceptor degraded, so it will pair with adenine and refuses guanine. 2-thiouridine is a sharpener. It decreases the number of partners a position will accept.

Both are chalcogen modifications. Both act at the hydrogen-bonding face. Both are single-atom changes. And they act in opposite directions on the same quantity, which is the error rate.

A code cannot be built out of only one of them. A code with no ambiguity needs one adaptor per codon and cannot be afforded; a code with nothing but ambiguity carries no information. What is required is a tolerance control — a way of specifying, position by position, how much slack is permitted. The proposal is that the seed code carried that control in the chalcogen column: oxygen at C6 of a purine to loosen, sulfur at C2 of a pyrimidine to tighten.

Two of the six coded elements are group sixteen — oxygen and sulfur — and selenium is the third chalcogen of biology standing just outside the coded set. The functional reading of that partition is that the chalcogens are not merely the column

that carries the omitted molecules. They are the column that sets the fidelity of the code, and they do it from inside the six and from immediately outside it.

Indigo is not a letter; it is a gate

Xanthosine 5′-monophosphate is in the seed code for reasons that have nothing to do with carrying information. It cannot carry information. The chemistry forbids it, and the number that forbids it is a pKa.

Xanthosine is unusually acidic. The nucleoside deprotonates at N3 with a pKa of about 5.5, and XMP is comparable; at pH 7 the molecule is overwhelmingly a monoanion. An anionic base is a poor hydrogen-bond donor and a bad neighbor to a phosphate backbone, and the consequence is measurable: xanthosine pairs appreciably with adenine at pH 5.5 and appreciably less at pH 7.5. Its pairing is not a property of the molecule. It is a property of the molecule and the medium together.

Which is the definition of a selector: a mechanism in which the primary sequence does not determine the outcome, because something else decides. Selenocysteine's UGA is overruled by a stem-loop. Xanthosine's pairing is overruled by a proton. Indigo carries both, and for the same structural reason.

So xanthosine's membership is not as a fifth or sixth letter. It is as the gate, and it holds that office at both ends of the arc. Anabolically, XMP is obligate: IMP dehydrogenase to XMP, GMP synthetase to GMP, and no route from parent to green child that avoids it. Catabolically, xanthine is the convergence: both children arrive there and xanthine oxidoreductase performs the last oxidation.

The code has six letters and one valve. The valve is indigo.

The pairing lattice

What the seed alphabet can actually do, stated as pairs. Hydrogen-bond counts are on the Watson-Crick face unless noted.

pair	H-bonds	character	office in the seed code
G : C	3	strong, thermally stable	the anchor; present in every code that has existed
A : U	2	weak, meltable	the working pair; opens and closes
A : s²U	2	weak but pre-organized	the working pair with the wobble removed
I : C	2	weak	guanine's pairing without guanine's synthesis
I : U	2	wobble	the deliberate ambiguity; reads a third partner

pair	H-bonds	character	office in the seed code
I : A	2	purine-purine, wide	the Orgel duplex; a homopurine first helix
X : A	2, pH-gated	on below ~pH 6, off above	the valve; a proton-operated switch
X : C	2	weak, anion-suppressed	residual; not load-bearing
s²U : G	2, one poor	wobble suppressed	the mismatch the code is built to decline

Read the column of offices rather than the column of numbers. There is exactly one strong pair, one weak pair, one sharpened version of the weak pair, one substitute for the strong pair that costs less to make, one deliberate ambiguity, one wide purine-purine helix and one switch. That is not a redundant list. It is close to the minimum set of capabilities a replicating, folding, catalyzing polymer would need.

Why the seed was purine-heavy

Four purines against three pyrimidines is the reverse of the modern ratio, and three independent lines point the same way.

The delivery manifest is purine-dominated. Murchison yielded adenine, guanine, hypoxanthine and xanthine — four purines — and uracil. Cytosine is absent. Frozen ammonium cyanide eutectics yield adenine, guanine, hypoxanthine, xanthine and 2,6-diaminopurine alongside the pyrimidines. Whatever was raining on the early Earth, it was raining more purine than pyrimidine.

The glycosidic bond cooperates only with purines. Heating ribose with a purine base in the dry state, with divalent cations or simple sea-salt mixtures, gives nucleosides. Heating ribose with a pyrimidine base under the same conditions gives nothing. Pyrimidine nucleotides have to be built the other way, part by part, which is why Sutherland's route exists and why it took until 2009. If the earliest polymer was assembled from monomers that made themselves, the earliest polymer was purine.

A purine-rich polymer has a geometry worth having. Purine-purine pairs are wide. A helix of them is broad, shallow-grooved on one face and generously open on the other, and it presents a great deal of N7 and O6 to the solvent — the Hoogsteen face, the face that coordinates potassium in a quadruplex and accepts a third strand in a triplex. Poly(I) and poly(A) form a duplex; Orgel's suggestion, recorded by Crick, that the first nucleic acid was an A–I system rests on exactly this.

A homopurine seed helix is not a defective version of the modern one. It is a different instrument, tuned for recognition rather than for storage.

The evidence that inosine went first

The parent's priority in metabolism is textbook and has been since 1960. What is less well known is that inosine's priority in prebiotic chemistry is also documented, in four separate measurements, and that in every one of them it beats adenine and guanine.

Glycosylation. Orgel showed that heating D-ribose directly with hypoxanthine, with magnesium chloride or a seawater salt mixture, gives up to eight percent β-D-inosine. The same reaction with adenine gives a more complex mixture whose major product is the wrong one — condensation at the exocyclic N6 rather than at N9. Hypoxanthine, having no exocyclic amine, has nothing to condense at except the ring nitrogen. The base that lacks the substituent is the base that glycosylates cleanly.

Regiochemistry. Activated monomers oligomerizing on montmorillonite give a mixture of 2′,5′ and 3′,5′ linkages, and only the second is the modern backbone. Adenosine gives 67 percent 3′,5′; uridine and cytidine are predominantly 2′,5′ at 50 to 75 percent; inosine gives 90 percent 3′,5′. Without the mineral, everything gives about 90 percent of the wrong linkage. Inosine is the only monomer on the list that builds the correct backbone essentially unaided.

Chain length. Under the same conditions the phosphorimidazolides of adenosine, inosine, cytidine and uridine give oligomers of ten to fifteen units. Guanosine gives hexamers, the shortest on the list. Guanine makes the best pair and the worst polymer, and that tension is structural rather than accidental — three hydrogen bonds and a strong stacking propensity are exactly what makes a monomer aggregate instead of extend.

Copying. In 2018 Szostak and colleagues reported that inosine supports rapid and accurate non-enzymatic RNA primer extension, both as an activated monomer and in the template, and proposed it as a plausible component of a primordial RNA — while noting that efficient prebiotic routes to adenosine and guanosine remain elusive, and that the pyrimidines and their 2-thio variants are the nucleotides for which good routes exist.

The nucleotides with the strongest prebiotic credentials are inosine, cytidine, uridine and 2-thiouridine. The canonical four are two pyrimidines plus the two purines that are hardest to make.

A seed alphabet chosen on chemistry rather than on tradition does not contain A and G. It contains I and s²U, and A and G arrive afterward, by amination — which is precisely the direction the metabolism still runs in every cell alive.

The loop, and why the seed needed four purines

The metabolic argument for the four-purine seed is an argument about nitrogen. Nitrogen is held in the atmosphere behind a triple bond of 941 kilojoules per mole and is released only by nitrogenase, at sixteen ATP per molecule fixed, or by a Haber-Bosch plant. Fixed nitrogen was the scarce resource of the early biosphere and remains the limiting nutrient of most of the modern one. A purine ring contains four nitrogen atoms. It is, by some margin, the most nitrogen-dense structure a cell routinely builds.

Which makes the purine loop a bank rather than a pathway, and it has the three departments a bank requires.

Deposit. De novo synthesis builds the ring on the sugar in ten steps at five ATP, drawing nitrogen from glutamine twice, from glycine and from aspartate, and it closes at inosine monophosphate. Expensive, and used only when there is surplus.

Withdrawal without loss. Salvage. HPRT takes free hypoxanthine or guanine with PRPP and returns the nucleotide in one step; APRT does the same for adenine. One reaction against ten, and no nitrogen leaves the system. The brain runs almost entirely on this, and Lesch-Nyhan is what a closed loop looks like when the recovery arm is cut.

Disposal. Catabolism. Everything descends through the same funnel to xanthine and is oxidized to urate, which in our species is the terminus because urate oxidase was deleted in the hominoid line. Ammonia — the toxic form of the very element the ring was built to store — is disposed of as a crystalline, nitrogen-dense, ultraviolet-absorbing, antioxidant solid.

Now count the purines the loop requires. IMP to open it. AMP and GMP as the two products whose triphosphates fund each other's synthesis. XMP as the obligate gate between the parent and the green child, and xanthine as the convergence on the way down. Four. Remove any one and the loop does not close: without IMP there is no entrance, without XMP there is no route from parent to guanine, and without both there is no path from AMP to GMP at all except backward to the parent and forward again.

A code whose letters are the currency of the nitrogen bank is a code that pays for itself. That is an argument about economics rather than about information.

The two empty sockets, and what the ring is banking

Count only the exocyclic substituents — the atoms hung on the outside of the ring, not the four nitrogens welded into the bicycle itself. Adenine carries an amino group at C6 and nothing at C2: one exocyclic nitrogen, no oxygen. Hypoxanthine carries a carbonyl at C6 and nothing at C2. Guanine carries a carbonyl at C6 and an amino at C2: one of each. Xanthine carries carbonyls at both.

Hypoxanthine and xanthine are therefore the only two purines in metabolism with no exocyclic nitrogen at all. Whatever nitrogen they hold is structural, built into the ring, and none of it is available. Adenine and guanine each carry one nitrogen atom that is not structural — hung on the outside, at a position from which an enzyme can remove it.

Read the ring, then, as a device with two sockets, at C2 and C6. A socket holding an oxygen is empty. A socket holding a nitrogen is loaded. The four purines of metabolism are four states of charge: IMP with C6 empty and C2 not yet opened; AMP with C6 loaded; XMP with C6 empty and C2 opened and also empty; GMP with C6 empty and C2 loaded.

The enzymes are the charging and discharging circuit, and they name their own nitrogen sources. Loading C6: adenylosuccinate synthetase and lyase, nitrogen from aspartate, paid in GTP. Loading C2: GMP synthetase, nitrogen from the amide of glutamine, paid in ATP. Discharging C6: AMP deaminase in muscle, adenosine deaminase in lymphocytes, ADAR in the nervous system — three different enzymes performing one reaction and releasing ammonia. Discharging C2: guanase, releasing ammonia again.

Every deamination in nucleic acid chemistry is the same operation — a nitrogen withdrawal from a socket, leaving an oxygen behind. A to I. G to X. C to U. Three reactions, one accounting entry.

Two of them are enzymatic, regulated and intended. The third is spontaneous, unregulated and unwanted — and thymine exists because the cell had to flag the one withdrawal it never authorized.

The ladder does not stop at two. Xanthine oxidoreductase opens a third socket, at C8, and leaves an oxygen in it. Uric acid is 2,6,8-trioxopurine: three oxygens, no

exocyclic nitrogen, every socket open and every socket empty. It is the fully discharged purine, and in our species it is the terminus, because we deleted the enzyme that would go further.

One, two, three. Hypoxanthine, xanthine, urate. The oxygen count is the state of the bank.

Why the discharge ladder could run before there was oxygen

The molybdenum hydroxylases are unlike every other hydroxylating system in biology. A monooxygenase takes its oxygen atom from molecular oxygen. Xanthine oxidoreductase does not. The oxygen incorporated into the product is derived from water, transferred from the catalytically labile Mo–OH ligand of the cofactor, with the metal cycling between Mo(VI) and Mo(IV) and two electrons leaving by a separate route.

Read what that permits. Hypoxanthine to xanthine, and xanthine to urate, do not require dioxygen at the point where the oxygen is inserted. They require water, a molybdenum-pterin cofactor and somewhere for two electrons to go — and in the dehydrogenase form those electrons go to NAD^+, not to O_2. The oxidase form that hands them to oxygen and generates superoxide is the later, damaged variant, produced under ischemia by proteolysis or cysteine oxidation. It is not the original.

The nitrogen bank could be charged, read and emptied under an anoxic sulfur economy, long before cyanobacteria learned to split water.

One constraint this argument does not currently acknowledge. Xanthine oxidoreductase requires a molybdenum-pterin cofactor, and molybdenum availability in anoxic oceans is itself contested — under euxinic conditions molybdenum is scavenged as thiomolybdate and drawn down. An argument that the discharge ladder ran pre-oxidation has to survive a metal-availability objection it has not yet been made to face. This is flagged as a weakness rather than answered, and it is the reason the timing claim is conjecture rather than a result.

The same accounting, two scales

Set the intracellular loop beside the planetary one, because the correspondence is exact enough to be worth laying out.

In the atmosphere and soil, nitrogen is banked as N_2 — no oxygen, no availability, locked behind the triple bond. Nitrogenase withdraws it as ammonia, still with no

oxygen attached. Nitrification then oxidizes it in two steps: to nitrite, with two oxygens, and to nitrate, with three. Assimilation draws it back into organic matter; ammonification returns it as ammonia; denitrification returns it to the sky.

In the cell, nitrogen is banked in the purine ring. Amination loads it from aspartate and glutamine. Deamination withdraws it as ammonia. Oxidation opens the sockets in two steps: to xanthine, with two oxygens, and to urate, with three. Salvage draws it back in; catabolism returns it as ammonia and urate; excretion returns it to the environment.

Two oxygens, then three, in both. Ammonia as the released currency in both. And in both, the quantity that records the state of the account is the number of oxygen atoms attached.

There is one asymmetry, and it favors the cell. Nitrification is strictly aerobic — it is the oxidation of nitrogen by oxygen, and it could not operate before the atmosphere had any. Before the oxidation, the planetary nitrogen cycle ran on fixation, denitrification and anammox, the anaerobic route in which ammonium and nitrite are combined directly to N_2. The environmental cycle had no oxidative arm. The purine loop, drawing its oxygen from water, had one.

The reading is that the purine loop is not an analogy to the nitrogen cycle. It is the nitrogen cycle, run at molecular scale, inside a compartment, and running the oxidative arm before the planet could. Whether that is priority or merely parallelism is a conjecture and is marked as one.

Six cells. Biology took four. A virus took a fifth. The sixth has never been looked for.

If the exocyclic positions are sockets, the purine lattice is enumerable. C6 holds either an oxygen or a nitrogen. C2 holds a hydrogen, an oxygen or a nitrogen. Six combinations exist.

C6	C2 = H	C2 = O	C2 = N
= O (empty)	hypoxanthine — used	xanthine — used	guanine — used
= N (loaded)	adenine — used	isoguanine — not used	2,6-diaminopurine — not used by us

Four of the six are the purines of metabolism. Two are not, and the question is why — because both of the unoccupied cells are chemically real and both are prebiotically available. 2,6-diaminopurine appears in the frozen ammonium cyanide

eutectics alongside adenine, guanine, hypoxanthine and xanthine. It is not exotic. It was in the inventory.

And the bottom-right cell — both sockets loaded, maximum nitrogen density, the most nitrogen-rich purine the lattice allows — is not empty in nature. It is empty only in us. In 2021 three papers in Science reported that a widespread family of bacteriophages substitutes 2-aminoadenine for adenine completely, across the whole genome, using a dedicated biosynthetic pathway the phages carry themselves. The substituted base makes three hydrogen bonds with thymine where adenine makes two, and the resulting genome resists host restriction enzymes. That literature calls it the Z-genome.

No more should be made of the designation than it will bear. The letter was chosen by virologists needing a symbol that was not A, T, G or C, and any coincidence with this framework's vocabulary is a coincidence and nothing else. What is not coincidence is the structural fact underneath it: the lattice has an unoccupied cell, the cell is occupiable, and something alive occupies it.

The purine alphabet of terrestrial biology is not the only one that closes. It is the one that was selected.

Which is the honest form of the emergence claim, and it is worth separating from the unfalsifiable form. To say that an outcome is emergent and can be specified only as a probability somewhere between one and ninety-nine percent is to say nothing that could be wrong, and a claim that cannot be wrong cannot be evidence. But to say that the purine lattice has six cells, that biology occupies four of them, that a virus occupies a fifth, and that the sixth is synthesizable and has never been looked for in a natural genome — that is the same intuition stated in a form an experiment can answer.

The sugar axis: arabinose before ribose

Ribose has its 2′-hydroxyl on one face; arabinose is the C2′ epimer with the same formula and that hydroxyl on the other. The chemistry of the sugar axis is a question about which way one oxygen points, and the proposal here is that it pointed the other way first.

In RNA the 2′-hydroxyl projects into the minor groove. In arabinonucleic acid the 2′-substituent is β-oriented and projects into the major groove. Same atom, same formula, opposite face, opposite groove. This is established structurally: ANA duplexes are measurably less stable than the corresponding RNA and DNA hybrids,

and the reason given is steric hindrance from the size and β orientation of that hydroxyl, which causes local unstacking.

Read as a criticism of ANA, that is decisive. Read as a description of what ANA is for, it is the whole argument.

The major groove is where the Hoogsteen face lives — N7 and the C6 substituent of every purine, the atoms that coordinate potassium in a quadruplex, that accept the third strand of a triplex, that a protein reads when it reads a sequence. The minor groove is where the ribose zipper lives, where the 2′-hydroxyl network holds tertiary structure together, and where the polymer is protected. Putting the hydroxyl in the major groove decorates the recognition face. Putting it in the minor groove decorates the storage face.

In a world with no enzymes, dilute reagents and no proofreading, the quantity that limits everything is the probability of a productive encounter, and that probability scales with the size and hydration of the interface, not with the melting temperature of the product. A wide homopurine helix with a hydroxyl-lined major groove is a large target. A large target is easier to hit. Duplex instability is a defect only after replication fidelity has become the thing being optimized — and before that, a duplex that comes apart easily is an advantage, because strand separation is the step with no enzyme to perform it.

So the sequence proposed is: arabinose while the polymer's business is capture, ribose once its business is copying. And the switch has a mechanism that requires no invention. Non-enzymatic copying and extension are themselves selective — they enrich ribonucleotide content relative to arabino and deoxy analogs, because the ribo monomer extends faster and the resulting duplex is compatible. The moment copying begins, chemistry starts paying ribose and stops paying arabinose.

The sugar axis does not need a decision. It needs only for replication to start mattering more than recognition, and then it turns over by itself.

Note that this is the same transition as the base one, arriving on a different axis. The moment fidelity begins to matter is the moment 2-thiouridine's discrimination begins to pay, and the moment cytosine's third hydrogen bond begins to pay, and the moment the arabino hydroxyl begins to cost. Three independent changes, one cause. The prediction is that they should be found to have happened together, and that is a

testable statement about the order of events even though the events are four billion years gone.

What this does to the codon table: the code contracts

The obvious objection to a seven-letter alphabet is arithmetical. Four letters in three positions give sixty-four codons, already more than an early translation apparatus could plausibly have serviced. Seven give three hundred and forty-three, which is absurd.

The objection assumes that adding a letter expands the code. Inosine does the opposite.

Inosine at anticodon position 34 pairs with U, with C and with A. One adaptor therefore reads three codons. Adding inosine to a code does not multiply the codon space; it divides the adaptor space. It is a compression operator, and compression is exactly what a system with very few tRNAs and very few synthetases requires.

Follow the consequence. A code in which the third codon position is read by inosine is a doublet code wearing triplet clothes — the first two positions specify, and the third is read indiscriminately by one adaptor. And that is not a hypothetical arrangement. It is still running. Eight of the nine four-fold degenerate boxes in the modern code are read at position 34 by inosine: alanine, arginine, isoleucine, leucine, proline, serine, threonine, valine.

Which locates the ninth box exactly. Glycine, GGN, is not read by an inosine-bearing tRNA. Glycine is also the simplest amino acid, the one present in every prebiotic inventory ever compiled, the one delivered whole into the purine ring as C4, C5 and N7, and one of the four in the minimal set the Alanine World model proposes for the earliest code. Its box is not inosine-read because its box is older than the mechanism. It was assigned before there was a wobble to be read by.

And note where the other three members of that minimal set fall. Proline and alanine are both inosine-decoded. Glycine is not. The oldest proposed amino-acid repertoire straddles the inosine boundary, and the two residues on either side of it are the two that build the β-turn and the collagen repeat.

What discriminates AUA from AUG, precisely. The AUA discrimination is performed by a modified cytidine — lysidine in bacteria, an adduct of lysine at C2 of the wobble base — and not by a thiolation. The point about methionine is a statement about the amino acid rather than about the modification, and is read that way here.

What is sulfur's is the general office rather than that particular instance. Thiolation at C2 of the wobble uridine is the code's standing mechanism for narrowing position 34. Whether a given s²U-bearing tRNA still reads a G-ending codon turns on what substituent sits at C5, which is a later refinement. The seed code needs only the underlying capability, and the underlying capability is a chalcogen substitution at one atom.

A seven-letter alphabet that needs a dozen adaptors is affordable. A four-letter alphabet that needs thirty-two is not.

The proposal, stated at its proper strength

In one paragraph. The first genetic code was written in nucleotides, not bases. Its alphabet was inosine, cytidine, uridine and 2-thiouridine monophosphates, on a backbone that was arabino before it was ribo; adenosine and guanosine were added by amination of the parent, in the direction metabolism still runs; xanthosine was present throughout as a pH-operated gate rather than as a letter; and thymine did not exist, because the office it holds had not yet been created and the chair it now occupies was sulfur's.

What in that is not conjecture, and should be conceded by anyone: that inosine glycosylates, polymerizes, links 3′,5′ and copies better than adenine or guanine under prebiotic conditions; that 2-thiouridine is prebiotically accessible, sharpens A-pairing, refuses G-pairing and leads chemically to deoxyribose; that xanthosine is a monoanion at neutral pH and pairs pH-dependently; that ANA's 2′-hydroxyl faces the major groove and destabilizes the duplex; that eight of the nine four-fold boxes are inosine-read and glycine's is not; that IMP and XMP stand at the entrance and the exit of the purine loop; that hypoxanthine and xanthine are the only purines in metabolism carrying no exocyclic nitrogen; that the oxygen inserted by xanthine oxidoreductase is derived from water rather than from dioxygen; that the three deaminations of nucleic acid chemistry are one operation performed on three substrates; and that a widespread family of phages runs an entire genome on the sixth purine of the lattice.

What is conjecture, and is marked as such: the seven-letter seed as a historical claim; the arabino-before-ribo sequence; the reading of orange and yellow as paired tolerance controls rather than as two unrelated modifications; the treatment of xanthosine as a member of the code rather than as a metabolite that happens to sit nearby; and the proposal that the base transition and the sugar transition were one event.

The shape of the claim

The canonical table begins one molecule too late. It also begins with the wrong four. The letters everyone learns were selected in the 1950s and 1960s because they were the four that could be purified and polymerized, and the code was then cracked with synthetic polynucleotides made from them. That is a fact about mid-century chromatography. It is not a fact about the early Earth, where the purines outnumbered the pyrimidines, the parent glycosylated and the children did not, the sulfur pyrimidine was on the route to everything, and one oxygen was on the wrong face of the sugar.

Seven colors, seven nucleotides. Four purines because the nitrogen bank has four departments. Three pyrimidines because one anchors, one works and one refuses. Two chalcogen modifications at the pairing face, pulling the error rate in opposite directions. One valve, operated by a proton. And a single hydroxyl that started on the recognition face and moved to the storage face when storage started to matter.

None of it is established. All of it is arguable, and all of it is measurable.

PART EIGHTEEN · THE SULFUR-NITROGEN BOND

42. Two Monomer Classes Out of Four ↩

A pattern that is either a real constraint or an artifact of what has been looked for

Sulfur forms a covalent bond to nitrogen in living systems at three known sites. The bond lengths span a third of an ångström, and length tracks function exactly.

species	S–N length	character	function
HNSO, thionylimide	1.512 Å	cumulated H–N=S=O	interstellar candidate; no biological role
Sulfonamide S(=O)₂–N	≈1.66 Å	shortened by delocalization	the sulfa drugs; designed not to breal
S–N single bond reference	≈1.75 Å	the sulfenamide range	labile
cis-CH₃SNO	1.814 Å	long and weak	homolysis near 32 kcal/mol
trans-HSNO	1.85 Å	weakest of the set	homolysis near 29 kcal/mol

From 1.512 to 1.85 ångströms is a third of an ångström, and it is the difference between a bond that never breaks and a bond whose entire purpose is to break. Biology uses the weak end exclusively.

The three biological sites

In a protein, as a redox switch: the PTP1B sulfenyl-amide. Protein tyrosine phosphatase 1B shuts off the insulin receptor. Its catalytic cysteine is oxidized by hydrogen peroxide during normal insulin signaling, and two groups reported in 2003 that the resulting sulfenic acid converts into a sulfenyl-amide in which the cysteine sulfur is covalently bonded to the main-chain nitrogen of the adjacent residue. The bond forms on oxidation, blocks substrate binding, and is reversed by glutathione. It is a post-translational modification the protein alphabet has no symbol for.

In a sugar polymer, as N-sulfoglucosamine: heparan sulfate. During heparan sulfate biosynthesis, N-deacetylase/N-sulfotransferase enzymes remove the acetyl from glucosamine and install a sulfate on the free amine. The resulting N-sulfation pattern determines which proteins the chain binds and with what affinity, so the sulfur-nitrogen bond is the specificity-determining feature of the polymer rather than decoration.

In signaling, as the S-nitrosothiol. S-nitrosylation attaches nitric oxide to a cysteine sulfur, giving R–S–N=O. It is the longest and weakest bond in the ladder, which is precisely why it works as a carrier: it homolyzes to release nitric oxide on demand.

Proteins and sugars. Not nucleic acids, and not lipids. Sulfur reaches nitrogen in two of the four monomer classes.

And in nucleic acids sulfur reaches phosphorus instead

The statement above is about the sulfur-nitrogen bond specifically, and it needs that qualifier, because sulfur does enter the nucleic acid backbone — at the phosphate rather than at the base or its nitrogen.

Bacterial dnd gene clusters incorporate sulfur into the DNA backbone as a sequence-selective, stereospecific phosphorothioate, replacing a non-bridging oxygen of the phosphate with sulfur. Wang and colleagues described it in 2007 as, to their knowledge, the first physiological modification ever described on the DNA backbone. A later genomic survey by Tong and colleagues found 1,349 such systems distributed sporadically across diverse phylogenetic groups, with nearly half occurring as a solitary modification cluster lacking the restriction counterpart — so

the modification is not merely a defense system. The same work reported that phosphorothioate modification contributes to the overall cellular redox state, that its loss perturbs redox balance and forces metabolic reconfiguration against oxidative stress, and that it alters transcriptional efficiency in vitro.

monomer class	bond sulfur makes	instance	role
Proteins	S–N	sulfenyl-amide, PTP1B	a redox switch, made and unmade
Sugars	S–N	N-sulfoglucosamine, heparan sulfate	the specificity-determining mark
Nucleic acids	S–P	phosphorothioate, dnd clusters	backbone, redox-linked, epigeneti
Lipids	none reported	—	not found in the sources searched

Sulfur reaches nitrogen in proteins and sugars. In nucleic acids it reaches phosphorus. In lipids, nothing has been found. Three classes, two bonds, one absence.

And this is the modification the four-letter alphabet is least able to write. Every other physiological DNA modification — methylation, hydroxymethylation and the rest — sits on the base, where a letter can at least be annotated. Phosphorothioation sits on the phosphate. A, T, G and C do not merely make it awkward to record that a particular phosphate carries a sulfur instead of an oxygen; they provide no place to put it at all. Part Fifteen argues that the alphabet discards the scaffold and the linkage. This is a functional, redox-active, heritable mark living entirely on the discarded part, and it was found only because somebody went looking at the backbone.

This pattern is the weakest inference in the document and is marked as such. An absence in two classes is only evidence if somebody looked. No systematic census of covalent sulfur-nitrogen bonds by monomer class exists in the structural databases, so the pattern may reflect the history of what has been searched for rather than a constraint on chemistry. Experiment Eight is the census, and it is cheap. Until it is run, this part reports an observation and not a finding.

PART NINETEEN · WHERE RECOGNITION ACTUALLY HAPPENS

43. Five Layers, and the Letter Is Only One of Them ↩

Base, sugar and phosphate are all read — for different purposes, by different machines

Ask where a nucleotide is recognized and the textbook answer is the base. That answer is not wrong so much as it is one fifth of the truth. Recognition in nucleic acids is stratified: the phosphate, the sugar and three separate edges of the base are each read, each by a different set of machines, each for a different decision. The alphabet encodes exactly one of the five.

where	what is read there	by what
Phosphate	affinity, and nothing else	sequence-blind backbone contacts; UCP1 binds nucleotides through the phosphate with no preference for the base at all
Sugar, 2′ position	RNA or DNA	the steric gate of polymerases, reverse transcriptase, RNase H, the spliceosome — and the atom ribonucleotide reductase removes
Sugar pucker	A-form or B-form	C2′-endo against C3′-endo sets the groove widths, and therefore everything that reads a groove
Base, minor-groove edge	that a pair is correctly seated	purine N3 and pyrimidine O2 — an acceptor present in all four bases; replicative polymerases hydrogen-bond to it as a fidelity checkpoint
Base, Watson-Crick edge	which letter this is	the complementary base, and the encoding of Part Four
Base, Hoogsteen edge	higher-order structure	N7 and the C6 substituent — tetrads, triplexes, major-groove protein readout, and the MoaA grip of Part Fifteen

The fourth row is the one this paper should have found first

A replicative DNA polymerase checks its own work by hydrogen-bonding into the minor groove, to purine N3 and pyrimidine O2. Look at what is special about those two positions: they present a hydrogen-bond acceptor in an equivalent location in all four canonical bases. A correctly formed Watson-Crick pair puts that acceptor at a fixed distance from the helix axis. A mispair does not.

The polymerase is not reading which letter it is. It is checking that a correctly shaped pair is seated, at a position that is chemically identical in all four letters.

That is a recognition event the alphabet cannot express, performed by the machine this paper has already observed never encounters a base. The letter names the Watson-Crick edge. The enzyme that decides whether the letter was placed correctly reads a different edge entirely, and reads it for a property the letter does not carry.

It also explains a fact that otherwise looks arbitrary. Fidelity in replication is not primarily a matter of hydrogen-bond counting on the pairing face — if it were, the error rate would track pair stability, and it does not. It is a matter of shape, checked at a position blind to identity. Steric complementarity, read in the minor groove, is doing work the pairing energy does not explain.

What this does not claim. That the pairing face is unimportant, or that minor-groove readout is the whole of fidelity. Proofreading exonuclease activity and induced-fit conformational selection both contribute, and disentangling their relative weights is an active field. The narrow claim is that a recognition layer exists at a position the notation cannot name, and that it is the layer the polymerase uses to decide.

---

44. The Tetrad, and the Base That Is Armed on Both Faces ↩

The face encoding predicts a structure it was never shown — and its favorite molecule loses

A G-quadruplex is four strands, stacked tetrads, and a potassium ion threaded between the layers. Each tetrad is four guanines in a cycle, and the bonding pattern is specific: every guanine donates N1-H and N2-H and accepts at O6 and N7, giving N1-H···N7 and N2-H···O6 around the ring. Two hydrogen bonds per edge, eight per tetrad.

Now ask what a base must have to do that, in the vocabulary of Part Four. It must present a donor and an acceptor on its Watson-Crick edge, and a donor and an acceptor on its Hoogsteen edge, at the same time. It must be armed on both faces.

Guanine is the only nucleobase that is. A tetrad is not a guanine preference. It is the only structure the donor-acceptor arithmetic permits.

That is a prediction the face encoding makes about a structure it was built without reference to. The encoding was constructed in Part Four to reproduce Watson-Crick pairing and the six-cell purine lattice. It was never shown a quadruplex. Run it over both faces instead of one and the quadruplex falls out of the same arithmetic.

And the other purines fail in ways the encoding names in advance

purine	what the two faces present	hydrogen bonds	verdict
Guanine	O6 acceptor, N1-H donor, N2-H donor, N7	two per edge, eight	builds the core

purine	what the two faces present	hydrogen bonds	verdict
	acceptor	per tetrad	
Inosine	O6 acceptor, N1-H donor, N7 acceptor — no N2 amine	one per edge, four per tetrad	forms, but weakly
Adenine	N6-H donor, N1 acceptor, N7 acceptor — no C6 oxygen	one per edge, four per tetrad	accessory layers only
Xanthine	O6, N1-H, N7 present — but N3-H deprotonates near pH 5.7	anionic at physiological pH	no stable core

The inosine row is the one that matters, and it is worth being blunt about it.

Inosine is guanine minus N2. Delete that one amino group and the tetrad loses exactly one hydrogen bond per edge — half its bonding, gone with a single atom.

This is the first place in this document where inosine loses, and it loses decisively. Every earlier part has argued that the purine with no letter outperforms the two that have one. Here guanine wins, it wins on a structural argument this paper's own encoding supplies, and the framework has no business pretending otherwise.

That should be read as a strengthening rather than a concession. An encoding that returns its author's preferred answer in every case is fitting rather than predicting. This one returns guanine, unprompted, in the one structural context where guanine is the correct answer — and it returns the reason as well, which is that guanine alone carries a donor and an acceptor on both faces at once. Part One already conceded that guanine makes the best pair and the worst polymer. This is where the first half of that sentence gets paid.

Adenine and xanthine, briefly

Adenine has no carbonyl at C6 — an exocyclic amine occupies the position where guanine keeps O6 — so an adenine tetrad can only manage N6-H···N7, one bond per edge. Adenine tetrads are real, and they appear where the arithmetic says they should: as accessory layers rather than cores. In the KRAS promoter quadruplex, a ligand recruits an adjacent adenine into a quasi-triad plane that stacks over the external G-tetrads. In the (AGA) tetramolecular structure, adenines sit intermittently stacked on the adjacent guanine tetrads. Both times, stacked on, never built in.

Xanthine fails for a different reason and the difference is instructive. Its N3 proton has a pKa near 5.7, so at physiological pH xanthine is deprotonated and carries a negative charge. Four anions arranged around a channel occupied by a cation is not a weaker version of the same structure; it is a different electrostatic problem.

Xanthine is excluded by charge rather than by bond count, which is a second and independent exclusion rule the encoding does not currently express.

A limitation of the encoding, recorded here. The face encoding of Part Four counts donors and acceptors. It has no term for ionization state, so it is a neutral-species approximation: xanthine is excluded from the tetrad by charge rather than by bond count, and a protonation term would capture that. Until it is, the encoding is a neutral-species approximation and should be described as one.

What water buys that the bases cannot

There is one further result that connects this part to the hydration argument. Cytosine tetrads exist. They should not, by the bond-count rule above, and they do — but only water-mediated, with ordered water molecules bridging the bases to a divalent cation at the center. Satange and Hou describe the arrangement in a structure where four cytosines form a planar tetrad around a barium ion channel, with water mediating the contacts, and note that the presence of water stabilizes the unusual pairing and preserves the stacking of the neighboring guanine tetrads.

Water does not merely surround the tetrad. It supplies bonds the bases do not have, and it buys structures the arithmetic forbids.

The same review reports that in ordinary quadruplexes water forms a clustered network around the four grooves, which increases the complexity of those grooves and the diversity of quadruplex folds available. The grooves of a quadruplex are not four identical channels; they are four water-organized environments, and that is where a ligand or a protein binds.

What this part claims, and what it does not

Claimed: that recognition in nucleic acids is stratified across phosphate, sugar and three distinct base edges; that replicative polymerases check fidelity at a minor-groove acceptor identical in all four bases; that a G-tetrad requires a base carrying a donor and an acceptor on both the Watson-Crick and the Hoogsteen face, which only guanine does; that inosine, adenine and xanthine fail in three different and predictable ways; and that water-mediated tetrads exist which direct base-base bonding cannot produce.

Not claimed: that the face encoding predicted quadruplexes in advance of being asked, which it did not — it was applied to them after the fact, and the honest description is that it accommodates them rather than that it forecast them. Nor that the encoding is complete, since it has no ionization term and therefore misses

xanthine. Nor that quadruplex biology bears on the origin-of-life argument in Parts Five and Six; it does not, and no bridge is offered.

One structure, four purines, four different outcomes — and guanine is the only base that satisfies the two-face requirement.

PART TWENTY · THE PROTEIN TEST

45. Synonymous Codons Are Not Synonymous ↩

The strongest evidence in this paper was produced by people who have never read it

Proteins are where the code's output becomes observable. If the notation is lossy, the loss has to show up somewhere in protein data. It does — and the demonstration is already published.

A 2020 review in Cell Communication and Signaling is titled, almost word for word, the thesis of this paper: 'A code within the genetic code: codon usage regulates co-translational protein folding.' Synonymous codon mutations were long assumed silent. They are not. Codon usage regulates the speed of translation elongation, producing non-uniform ribosome decoding rates along an mRNA, and that pausing pattern is tuned to the folding of the protein as it emerges from the ribosome. The review concludes that a codon usage code exists for co-translational folding, and that intrinsically disordered domains are the structures most vulnerable to disruption when codon usage is changed.

The codon table says six codons for leucine are the same thing. The cell says they produce different proteins.

And it has been demonstrated experimentally

In the filamentous fungus Neurospora, nonoptimal codons sit preferentially in the intrinsically disordered regions of proteins, and optimal codons in structured domains. Researchers then tested the correlation directly. They took the circadian clock protein FRQ and optimized the synonymous codons in its disordered regions — changing not a single amino acid in the product.

The clock broke. FRQ's structure was altered and clock function was impaired, from synonymous substitutions alone.

Same protein sequence. Different protein. That experiment is the four-letter table's central simplification failing under controlled conditions.

This is the piece the argument had been missing. Everything before Part Twenty is a case that the notation discards information. This is a measurement of what the discarded information was doing.

The protein alphabet undercounts exactly as the nucleic acid alphabet does

Twenty letters for amino acids, twenty-one counting selenocysteine. Against that, more than four hundred post-translational modifications are cataloged: phosphoserine, phosphothreonine, phosphotyrosine, acetyl-lysine, methyl-arginine, citrulline, hydroxyproline, and hundreds more. The same structure as the nucleotide families of Part One — one canonical member named by the alphabet, and a large tail of derivatives the alphabet cannot express.

Both codes undercount. The nucleic acid alphabet misses the modification inventory; the protein alphabet misses the modification inventory. Neither miss is an accident of the chemistry. Both are properties of the notation.

Collagen, and a residue with no codon

Collagen is roughly a third of the protein in the human body by mass. Its triple helix is built on a Gly-X-Y repeat in which the Y position is usually 4-hydroxyproline, and the thermal stability of the helix depends on that hydroxyl group. Prolyl-4-hydroxylase installs it after translation, using vitamin C as a cofactor. Scurvy is what happens when the reaction fails.

There is no codon for hydroxyproline. The most abundant protein in the human body is built on a residue the genetic code cannot specify.

And note where it sits. Part Thirteen identified glycine and proline as the two residues straddling the oldest seam in the code — glycine's box the one four-fold box inosine does not read, proline's box inosine-decoded. The collagen repeat is those two residues. The functional one on that seam, the hydroxylated proline, is not in the code at all.

What this shows, and what it does not

It does not show that the genetic code is invalid. The code predicts primary sequence correctly, confirmed constantly by mass spectrometry, and this paper has said so from its first page.

What it shows is that primary sequence does not determine the protein. Folding depends on translation kinetics, which depend on which synonymous codon was used and which modified adaptor read it. Function depends on modifications installed after translation, some of which have no codon. A code that specifies only primary sequence is therefore incomplete rather than wrong.

Incomplete is the weaker word and the stronger claim. It cannot be dismissed by pointing at a working codon table, and it has published experimental support waiting to be cited.

---

46. The Notation Was Wrong Twice ↩

One letter, three molecules — and it happened on both sides of the arrow

Everything so far has argued that the nucleic acid alphabet is a lossy projection. This section argues something stronger and simpler: the identical erasure was performed on the protein alphabet, by the same reasoning, at the same time. I have not found that stated in the literature searched for this paper, and section 30 records what that search covered. Two alphabets, one mistake, made twice.

One letter, three molecules, on the nucleic acid side

The paper's opening note on notation says that base, nucleoside and nucleotide are three different molecules written the same way. That is true and it undercounts. There are four.

object	name	≈ Da	what it is
Free base	adenine	135	the heterocycle alone; what a meteorite delivers
Nucleoside	adenosine	267	base + ribose; the glycosidic bond now exists
Nucleotide	AMP	347	+ one phosphate; the monomer this paper writes in
Polymerase substrate	dATP	491	+ two more phosphates; what the enzyme actually binds
Residue in a chain	adenylyl	313	water and pyrophosphate gone; what is actually in the DNA

Five distinct molecules with five distinct masses, and the sequence file writes A for all of them. The letter does not name a molecule. It names a position in a string and leaves the reader to supply, from context the notation does not carry, which of five chemical species is meant.

The same collapse, on the protein side

Now perform the identical audit on the other alphabet, and the same structure appears.

object	name	≈ Da	what it is
Free amino acid	alanine	89	zwitterion at pH 7; free α-amino and α-carboxyl
Activated monomer	alanyl-tRNA	≈ 25,000	an ester to the 3′-OH of the tRNA; what the ribosome binds
Residue in a chain	alanyl	71	water gone; no free α-amino, no free α-carboxyl

Three distinct molecules, and the sequence file writes A for all of them. And note which one the machinery handles. A ribosome has never encountered free alanine. It binds alanyl-tRNA, and what it releases into the chain is an alanyl residue, and neither of those is the molecule the letter is named after.

The same is true one arrow back. A DNA polymerase has never encountered adenine. It binds dATP and it leaves behind an adenylyl residue.

The polymerase never sees a base. The ribosome never sees an amino acid. Both alphabets are named after molecules the machinery never touches.

The two monomers are the same object

Set the two monomers side by side and the reason the same error was available twice becomes visible. They have the same three parts, playing the same three roles.

role	nucleic acid	protein	status in the alphabet
Variable recognition unit	base	side chain	what the letter names
Invariant scaffold	ribose	α-carbon backbone	erased by the notation
Condensing linkage	phosphodiester	peptide bond	erased by the notation

Both monomers are three-part. Both alphabets keep one part and discard two. And in both cases the discarded parts are the same two: the scaffold that makes the polymer a polymer, and the bond that joins one unit to the next.

The justification offered is also the same in both cases, and it is the argument answered in Part Twelve. The scaffold does not vary along the chain, so information theory assigns it zero bits and the notation drops it. That reasoning is sound and it is conditional on the scaffold already being uniform — which is precisely what has to be explained, and precisely what the notation makes it impossible to discuss.

Both alphabets are valid descriptions of a finished polymer and neither can describe the polymer becoming finished.

What the collapse costs, in daltons

The gap between the letter and the residue is not philosophical. It is weighable.

Peptide bond formation releases exactly one water, 18.02 Da. Sum the free amino acid masses of a three-hundred-residue protein and you have counted two hundred and ninety-nine water molecules that left — an overshoot of about 5.4 kDa against a real mass near 33 kDa.

Read the one-letter sequence of an average protein literally and you overpredict its mass by roughly sixteen percent. That is the size of the thing the alphabet is not saying.

The nucleic acid side carries the same correction at a larger magnitude. Each incorporation releases pyrophosphate; a triphosphate substrate at 491 Da becomes a 313 Da residue, so reading a sequence as a list of substrates overshoots by about 178 Da per position.

Neither correction is carried by the notation. In both cases the mass leaves at the bond — a water at the peptide bond, a pyrophosphate at the phosphodiester bond — and in both cases the symbol records the monomer that entered rather than the residue that remains. The sequence is therefore not a mass. It becomes one only when the chemistry of the linkage is added back from outside the string, and the string is perfectly well-formed without it.

Both linkages are the same reaction, and both have the same problem

The phosphodiester bond and the peptide bond are both condensations, both release water, and both are therefore thermodynamically uphill in the one solvent life runs in. Neither will form spontaneously in bulk water at any useful rate.

And both are solved the same way: the monomer is activated before it polymerizes, so that the energy is carried in by the substrate rather than supplied at the bond. Nucleotides arrive as triphosphates. Amino acids arrive as aminoacyl-tRNA esters. In the laboratory version of the same problem, prebiotic chemists use phosphorimidazolides, which is the same trick performed with a different leaving group.

Two polymers, one obstacle, one solution. Activate the monomer, then condense it, and let the leaving group pay.

That bears directly on Part Twenty-Six. Whatever drove condensation before ATP had to serve both arms, because both arms face the identical thermodynamic problem. A candidate energy currency that explains nucleotide polymerization but not peptide bond formation has explained half of the central dogma and is therefore probably wrong. Thioesters are interesting on exactly this ground: acetyl-CoA sits upstream of both.

The waist of the bowtie is a reaction, not a molecule

Drawn as a shape, the central dogma is two cones meeting at a narrow waist. Many possible monomers enter on one side, a very small number of universal operations happen in the middle, and many possible polymers leave on the other. Csete and Doyle described this organization as a bow tie and argued that it is a general architecture in biology, trading efficiency against robustness with predictable fragilities. Their example was metabolism. The central dogma has the same shape.

What is worth noticing is what sits at the waist. It is not a molecule. Both arms narrow to the same pair of operations — activate the monomer, condense with loss of a small molecule — and everything specific to nucleic acids or to proteins lives out on the cones. The waist is a reaction type, and it is the same reaction type on both sides.

The narrowest point of the central dogma is not a letter, a base or an amino acid. It is a dehydration paid for in advance.

What this adds, and what it does not

It adds no new chemistry. Every fact above is in an undergraduate textbook, including both mass corrections. What it adds is the observation that the two alphabets of the central dogma are the same lossy projection applied twice, that in both cases the discarded parts are the scaffold and the linkage, and that in both cases the discarded parts are exactly what the origin problem is about.

It does not claim the alphabets should be abandoned. A one-letter sequence is the right notation for a finished polymer with a uniform backbone, which is what most working biologists have in front of them most of the time. The claim is narrower and it is the same one this paper has made throughout: a compression is being used as though it were the object, and the compression was applied to the protein alphabet as thoroughly as to the nucleic acid one.

Nor does it require the algebra that suggested it. This section began as a sketch in which the two monomers were written as parallel triples and solved as simultaneous equations over an eight-dimensional algebra. That construction does not survive: the octonions are reached by pairing quaternions under the Cayley-Dickson doubling, and the property lost at that step is associativity — which the purine loop of Part Four depends on, since a product of three generators must not require parentheses. The structural observation survives the loss of the algebra intact, and is stated here without it.

The two monomers really are the same shape. They do not need to be the same equation for that to matter.

PART TWENTY-ONE · WHAT THE NOTATION CANNOT WRITE

47. The Same Erasure, Performed Twice ↩

A proposal about notation, and one measurement that makes the cost concrete

Both monomers are three-part objects and both alphabets keep one part.

role	nucleic acid	protein	status in the alphabet
Variable recognition unit	base	side chain	what the letter names
Invariant scaffold	ribose	α-carbon backbone	erased by the notation
Condensing linkage	phosphodiester	peptide bond	erased by the notation

The justification is the same in both cases: the scaffold does not vary along the chain, so information theory assigns it zero bits and the notation drops it. That reasoning is sound and it is conditional on the scaffold already being uniform — which is what has to be explained.

Both alphabets are valid descriptions of a finished polymer, and neither can describe the polymer becoming finished.

The cost, weighed

Peptide bond formation releases one water, 18.02 Da. Sum the free amino acid masses of a three-hundred-residue protein and you have counted 299 waters that left. Against the proteome-weighted average residue mass of 110 Da the overshoot is 16.3 percent; against an unweighted mean of the twenty letters it is 15.1 percent; on ubiquitin it is 15.8 percent. The basis must be stated, and earlier versions did not state it.

The water leaves at the bond and the symbol records the monomer that entered rather than the residue that stayed. The sequence is not a mass until the chemistry of the linkage is added back from outside the string.

And the protein side has an experimental result the framework did not produce

Zhou and colleagues optimized only the synonymous codons in the intrinsically disordered regions of a Neurospora protein, changing no amino acid, and altered its structure and impaired its function. Yi Liu's group established that codon usage regulates co-translational folding. These are published experiments by other people and they settle the general point: the codon carries information the amino acid does not.

Independently, Torres and colleagues reported in 2021 that a full complement of inosine-34 transfer RNAs is required to translate low-complexity protein domains enriched in the amino acids those adaptors carry, and that the phylogenetic distribution of such proteins mirrors the distribution of I34 tRNAs. They state plainly that the selective advantage driving the expansion of I34 tRNAs remains unknown.

One literature says synonymous codons change folding. Another says the inosine adaptors are required for a specific class of protein domain. Neither cites the other, and the question this document asks sits exactly between them.

A claim about notation is not a finding, and is not counted as one. Everything in this part except the mass arithmetic and the two cited experiments is a proposal about how to write nucleotides and residues down. It cannot be tested. It is offered because adopting it makes the origin question askable in a single sentence, and the

present notation does not. A reader who finds the present notation adequate has no obligation to accept anything in this part.

PART TWENTY-TWO · TWENTY-TWO AND TWENTY-TWO

48. Two Enzymes Set Both Numbers ↩

A cardinality match, offered with an explicit statement of how little a cardinality match proves

Twenty amino acids are canonical. Selenocysteine is the twenty-first and pyrrolysine the twenty-second, and both are recoded stop codons requiring a downstream messenger RNA element — a SECIS with a dedicated elongation factor, or a PYLIS. There is no twenty-third: sixteen archaeal and one hundred thirty bacterial genomes have been mined for transfer RNAs bearing stop-complementary anticodons and none was found.

The code did not enlarge its alphabet to reach twenty-two. It reused punctuation twice and put the deciding information outside the codon, in a hairpin.

EXTENDED IN PART ONE HUNDRED AND ONE, SECTIONS 852 AND 853.
This section is correct as written and is not corrected here. Three things established after it was written are added to it. First, pyrrolysine is not present in humans, being confined to methanogenic archaea and a few anaerobic bacteria, so a human uses twenty-one encoded residues rather than twenty-two. Second, selenocysteine has no aminoacyl-tRNA synthetase of its own and is built in place on its own transfer RNA from an esterified serine, so the twenty-two residues are served by twenty-one synthetases. Third, the twenty-two nucleotide species counted below, the twenty-two amino acids counted above and the twenty-two transfer RNAs of the human mitochondrion are three different twenty-twos counting three different things, and Part One Hundred and One, section 854, declines to join them on the same grounds this section already gave.

The nucleotide side

Take the unit to be the nucleotide species the cell handles — base, sugar and phosphorylation state together. Without restriction that is twenty-four. Two deletions bring it to twenty-two, and neither was chosen to make the sum work.

species	states permitted	n	what enforces the restriction
A, G, C on deoxyribose	mono, di, tri	9	—
Thymine	excluded	0	thymidylate synthase builds it from dUMP with a folate one-carbon unit; downstream of folate biosynthesis and serine hydroxymethyltransferase
A, U, G, C on ribose	mono, di, tri	12	—
Inosine	monophosphate only	1	ITPA hydrolyzes ITP back to IMP, and destroys XTP and dXTP with it
Total		22	

The inosine restriction is the stronger half. Inosine triphosphate pyrophosphatase exists to prevent the mutagenic, recombinogenic and toxic incorporation of ITP, dITP, XTP and dXTP into nucleic acids, by hydrolyzing the triphosphate back to the monophosphate. The gene is highly conserved, and the human 94C>A variant abolishes erythrocyte ITPase activity and predicts adverse reactions to azathioprine and 6-mercaptopurine.

There is a conserved enzyme whose function is to hold inosine at the monophosphate. IMP is not one of four peers; it is the state the cell is built to maintain.

How little this proves, stated plainly. A parameter sweep over bases, sugars, phosphorylation states and wobble species finds twenty-five settings inside a small box that also total twenty-two. Landing on the number is therefore not evidence and is not offered as evidence. What is offered is that both restrictions were fixed in advance by two characterized enzymes rather than selected to close the arithmetic, and that the same two enzymes independently support the lateness of thymine and the priority of IMP argued elsewhere here. A reader who rejects that reasoning should treat the coincidence as a coincidence, and Experiment Nine is written to let them settle it.

Delivery set the floor; persistence sets the ceiling

Roughly ten of the twenty-two appear in the Murchison amino acid inventory. Cysteine does not, and the reason is quantitative rather than rhetorical: meteoritic

sulfur arrives as a homologous series of alkyl sulfonic acids with sulfur at the +4 to +6 oxidation state, while a thiol side chain sits at S(−2). Selenocysteine and pyrrolysine cannot be delivered at all — the first is built on its own transfer RNA from an esterified serine, the second from two lysines by PylB, PylC and PylD.

Comets deliver glycine. One amino acid — and its four-fold codon box is the single one inosine does not read.

Cysteine and methionine therefore did not survive the oxidation of the atmosphere; they were never delivered. What had to survive it was the assimilatory reduction machinery that turns delivered S(+6) into usable S(−2), which is the subject of Part Six.

CORRECTED. DELIVERY AND AVAILABILITY ARE NOT THE SAME THING. The sentence above is right that methionine was not delivered and wrong to let that stand as an account of whether it was present. Parker, Cleaves, Callahan, Dworkin, Glavin, Lazcano and Bada, in Origins of Life and Evolution of Biospheres 41:201 to 212, 2011, reanalyzed the dried residues of an experiment Stanley Miller ran at Columbia University in March 1958 and never published. The apparatus held methane at 258 millimeters of mercury, carbon dioxide at 87, hydrogen sulfide at 100, ammonia at 250, and three hundred milliliters of water, under a spark discharge. Miller recorded in his notebook that a large amount of elemental sulfur deposited in the five liter flask. Fifty-two years later the residues yielded racemic methionine at about three parts in a thousand relative to glycine, matching the yield Van Trump and Miller had reported in 1972, together with S-methylcysteine in the first report of its prebiotic synthesis, homocysteic acid, methionine sulfone, methionine sulfoxide, cysteamine, and tentatively ethionine. Methionine was therefore available on the early Earth by endogenous synthesis even though it was not delivered by meteorite, and it remains true that neither cysteine nor methionine has been conclusively detected in a carbonaceous chondrite.

AND THE CONDITION ON THAT SYNTHESIS IS THIS VOLUME'S OWN ARGUMENT. Methionine does not appear in a standard Miller-Urey run. It appears when hydrogen sulfide is in the gas mixture, which is why methionine is absent from the field's consensus list of abiotically early amino acids. Sulfur in the atmosphere is the necessary condition for the sulfur amino acid, and that is a stronger and more defensible statement than the one this section originally made.

WHAT THE 1958 EXPERIMENT DOES NOT ESTABLISH ABOUT CYSTEINE. Cysteine was not detected in the residues, and this volume does not treat that as

evidence that cysteine was not formed. The authors attribute the absence to fifty years of dry, room-temperature storage that was not anoxic, and they note that cystine was not detected either, which oxidative dimerization of cysteine would have produced. The prebiotic status of cysteine is open, and the sentence above should not be read as closing it.

PART TWENTY-THREE · THE GEOMETRY OF THE TABLE

49. Three, Six and Nine Are Properties of the Codon Table, Not Impositions On It ↩

What survives when the honeycomb analogy is checked arithmetically, and what does not

A separate paper in this corpus argues that the honeycomb is a macroscale instance of the same geometry that governs the genetic code. This section tests that claim against arithmetic. One part of it is stronger than it was stated. Two parts are wrong as stated and are corrected here, because both are the kind of error a referee settles in under a minute.

The result that survives, and it is exact

Take the sixty-four codons and ask, of each one, how many other codons differ from it by a single base. The answer is nine — three positions, three alternatives each. Now split those nine by the chemistry of the substitution. A transition exchanges a purine for a purine or a pyrimidine for a pyrimidine. A transversion crosses the classes.

neighborhood	count	why	graph
Transitions per codon	3	one per position: A↔G or U↔C	3-regular
Transversions per codon	6	two per position	6-regular
Total single-base neighbors	9	three positions, three alternatives	9-regular

Every one of the sixty-four codons has exactly three transition neighbors and exactly six transversion neighbors. Not on average. Every one, without exception.

This is forced rather than fitted. Each base has one partner in its own chemical class and two in the other; three positions multiply it out. Any four-letter, three-position

code has this property, so it is not evidence for a particular framework. What it is, is the reason a three-and-six decomposition is available at all: the codon graph genuinely separates into a 6-regular part and a 3-regular part, and six is the coordination number of the hexagonal lattice.

Stated at its correct strength, which is modest and real. This does not show that the code is hexagonal. It shows that the natural graph on codon space admits a 6 plus 3 decomposition on chemical grounds, that the 6-part has the coordination number of a plane hexagonal tiling and the 3-part does not, and that the two parts have different biological meanings — transitions are the common, conservative, often silent substitutions; transversions are the rarer, more disruptive ones. A geometry that places transversions in-plane and transitions along the axis is therefore not arbitrary. It is the only assignment consistent with the degrees.

The first correction: sixty-four cannot be a hexagon

A regular hexagonal arrangement of cells has a centerd hexagonal number of cells: 1, 7, 19, 37, 61, 91. Sixty-four is not among them, and 61 and 91 bracket it. The plain hexagonal numbers, 1, 6, 15, 28, 45, 66, 91, do not contain it either.

$$64 = 2^6 = 4^3 = 8^2$$

Sixty-four is a cube and a square. It is not a hexagon, and no arrangement of sixty-four equal cells forms one.

Any statement that the code forms a sixty-four cell hexagonal lattice is false on a fact a reader can verify by counting. The corpus should not make it, and from this version does not.

The reading that does work: sixteen faces, four deep

A honeycomb cell is not a hexagon. It is a hexagonal prism with depth, closed at the far end. Read the codon table the same way and the arithmetic closes without strain.

comb feature	codon feature	count	what it carries
Hexagonal face	positions one and two	16 two-base boxes	fixes the amino acid family; eight of the sixteen are four-fold
Cell depth	position three	4 states	where every degeneracy in the table lives
Closed end	the wobble base	—	the point at which the code stops discriminating
Total		16 × 4 = 64	

A four-by-four patch of the hexagonal lattice holds exactly sixteen cells and is an ordinary piece of the tiling. Nothing is forced. And the mapping is faithful rather than decorative in one specific respect: the depth of the cell is the wobble position, which is the axis inosine acts on. Position 34 of the adaptor reads position three of the codon. In the comb picture, inosine is a rule about how deep the reading goes before the cell closes.

The face decides which amino acid. The depth is where the decision stops being made. Inosine works along the axis of the cell, not across its face.

The second correction: the closed end is near-optimal, not optimal

The angular claim is correct and is worth stating precisely. The rhombic faces at the closed end of a honeycomb cell meet at angles of 70° 32′ and 109° 28′. The obtuse one is arccos(−1/3) = 109.4712°, which is the tetrahedral angle — the same angle as the bonds at an sp^3 carbon, and therefore the same angle that governs the sugar backbone of every nucleotide in this document.

quantity	value	sexagesimal	identification
arccos(−1/3)	109.4712°	109° 28′	the tetrahedral angle
Supplement	70.5288°	70° 32′	the rhombus acute angle
sp^3 bond angle at carbon	109.4712°	109° 28′	identical, by construction of the tetrahedron
Rhombic dodecahedron face	diagonals in ratio √2	70° 32′ / 109° 28′	the shape bees actually build

But the honeycomb end is not the minimum, and claiming exactness invites an easy refutation. Fejes Tóth showed in 1964 that the rhombic-dodecahedral closed end is not the least-area solution: an end built from two hexagons and two rhombi is roughly 0.35 percent cheaper in surface area. Bees build the rhombic form regardless. The defensible statement is therefore stronger than the one it replaces, not weaker — an organism with no measuring apparatus and no mathematics converges on a configuration within a third of one percent of a minimum that took a Fields medallist and a computer-assisted proof to characterize. Near-optimality reached without computation is the interesting claim. Exactness is merely refutable, and the man who first posed the honeycomb conjecture is the one who refutes it.

The plane result is different and does hold. Hales proved in 2001 that the regular hexagonal tiling is the least-perimeter partition of the plane into unit areas. That

theorem is about the face, not the closed end, and the face is where this section places the sixteen boxes.

What this section establishes

Established: that every codon has exactly three transition and exactly six transversion neighbors; that sixty-four is not a hexagonal number of any kind; that a sixteen-face, four-deep prismatic reading closes the arithmetic without adjustment; that the closed-end angles are the tetrahedral angles and coincide with sp^3 carbon; and that the rhombic end is near-optimal rather than optimal.

Not established, and not claimed: that the code is hexagonal in any physical sense, that the coincidence of coordination numbers is evidence of design or of a shared generative principle, or that the tetrahedral angle appearing in both wax and carbon is more than the geometry of close packing appearing twice. Three, six and nine are properties of a four-letter, three-position code. Any such code would have them, and a framework that claims them as its own discovery has claimed arithmetic.

The decomposition is real and the geometry is checkable. What it is evidence for is a question this section leaves open rather than answers.

PART TWENTY-FOUR · THE SULFUR LINEAGE

50. From an Oxygen-Burning Shell to a Purple Bacterium ↩

Where the sulfur came from, in what quantity, and what it arrived as

This document has given sulfur four offices without once asking where the atoms came from. That question has an answer with dates and numbers attached, and the numbers turn out to bear on the energy problem in Part Twenty-Six.

A correction first: sulfur was not made in the Big Bang

Big Bang nucleosynthesis produced hydrogen, helium and a trace of lithium. Nothing else. Every atom heavier than lithium was assembled in stars. Sulfur specifically is an alpha element, built by alpha capture on silicon and above all by oxygen burning — two oxygen-16 nuclei fusing to give silicon-28 and sulfur-32. The sulfur isotopes are synthesized during hydrostatic or explosive oxygen burning, processes that occur only in massive stars and in Type Ia supernovae, with the hydrostatic contribution dominating in massive stars and the explosive contribution in Type Ia events. Any version of this argument that begins sulfur's history at the Big

Bang begins it in the wrong place by about two hundred million years and by an entire mechanism.

Every sulfur atom in every cysteine in your body was assembled in the oxygen-burning shell of a massive star, or in the detonation of a white dwarf. There is no other route.

The ordering matters for this framework rather than being decorative. Sulfur is made by burning oxygen. The element this paper argues came first, chemically, is manufactured out of the element it argues came second — which is a coincidence of naming rather than an argument, and is noted here only so that nobody mistakes it for one.

Comets carry it, and carry it as thiols

The Rosetta mission's ROSINA mass spectrometer measured the sulfur inventory of comet 67P/Churyumov-Gerasimenko directly, between equinox and perihelion in 2015. The list is longer than anyone expected.

species	what it is	why it matters here
Hydrogen sulfide, H_2S	the dominant sulfur carrier	the same molecule Chromatium oxidizes
Carbonyl sulfide, OCS	a thioester precursor	one hydrolysis from a thioacid
Sulfur dioxide and sulfur monoxide	oxidized sulfur	already partway up the ladder
S_2, S_3, S_4	elemental sulfur chains	catenation, in a comet
Methanethiol, CH_3SH	first detection in a comet	a thiol — the functional group of cysteine
Ethanethiol or dimethyl sulfide, C_2H_6S	first detection in a comet	organosulfur, delivered

The bulk elemental abundance of sulfur relative to oxygen in the cometary ice was measured at roughly 1.47×10^{-2}. Giotto and Vega had already found hydrogen sulfide, carbon disulfide and S_2 at comet Halley in 1986, so the result is not a surprise so much as a quantification of something known for four decades.

A thiol was detected in a comet. The functional group that runs ribonucleotide reductase, IMP dehydrogenase and every iron-sulfur cluster in this document arrived on Earth already assembled.

And Murchison delivered forty times more sulfonate than phosphonate

This is the number that changes an argument rather than illustrating one.

Cooper and Cronin extracted the Murchison meteorite in water, derivatized the products, and identified homologous series of both alkyl sulfonic acids and alkyl phosphonic acids, along with inorganic sulfate and orthophosphate. Seven of the eight possible alkyl sulfonic acids through C4 were present. Five of the eight possible alkyl phosphonic acids were present. Then the concentrations.

delivered species	how many of the possible forms	concentration
Alkyl sulfonic acids	seven of eight possible through C4	down from about 380 nmol per gram
Alkyl phosphonic acids	five of eight possible through C4	down from about 9 nmol per gram

Roughly forty to one, in favor of sulfonate. The carbonaceous chondrite record says the early Earth received far more activated sulfur than activated phosphorus.

Part Twenty-Six asks where the phosphate was and where the power came from, and records that the nitrogen bank was capitalized before it could fund itself. Here is a constraint on the answer that does not come from this framework and was not collected to serve it. If prebiotic chemistry ran on the delivered inventory, phosphorus was the scarce input by a factor of forty, and any model that assumes abundant activated phosphate at the start is assuming something the meteorite does not supply.

What this does not establish. That sulfonate did phosphate's job. Sulfonic acids are not phosphates, they do not form the diester linkages a nucleic acid backbone requires, and no route from alkyl sulfonate to a functioning backbone has been demonstrated. The inference from abundance to function is exactly the kind of step this paper criticizes elsewhere, and it is not taken here. What the ratio establishes is that the scarcity is real and quantified, which sharpens the question rather than answering it. Experiment Twenty-four exists to ask whether sulfonate can perform any part of the activation chemistry at all.

---

51. The Sulfur Census — Named, Counted, and Followed Down ↩

Every sulfur species in the exhibits, from the interstellar medium to the cysteic acids of proteins

Section 19 gave the route. This section gives the inventory: each sulfur-bearing species named in the exhibits, at each stage, with the counts. The point of listing

them rather than summarizing them is that the list itself is the argument — sulfur is not a specialist element that appears at one point in the story. It is present, in named molecular form, at every stage of it.

Exhibit Two — the interstellar census of July 1997

The chart records one hundred and seventeen known interstellar molecules, arranged by number of atoms. Fifteen of them carry sulfur.

size class	sulfur-bearing species	count
Two atoms	CS, NS, SO, SO^+, SiS	five
Three atoms	H_2S, SO_2, OCS, HCS^+, CCS	five
Four atoms	H_2CS, HNCS, CCCS	three
Six atoms	CH_3SH, C_5S (queried on the chart)	two

Fifteen of one hundred and seventeen — roughly one interstellar molecule in eight carried sulfur, in a census taken before anyone was looking for it on purpose.

Three of those entries deserve individual attention, because each is a functional group this document depends on. OCS is carbonyl sulfide, one hydration from a thioacid and the simplest thioester precursor there is. CH_3SH is methanethiol — a thiol, the functional group of cysteine, floating free in a molecular cloud. And H_2S is the electron donor the purple sulfur bacterium of Exhibit One oxidizes for a living.

The chart's one question mark has since been answered. C_5S carries a query on the 1997 sheet. Work at the cold cloud TMC-1 has since detected C_5S outright and added NCS, HCCS, H_2CCS, H_2CCCS and C_4S alongside it, so that the single uncertain entry has become a family of six. The census has grown with it: the Cologne database now lists on the order of three hundred and forty-seven interstellar and circumstellar molecules, against one hundred and seventeen on this chart, and the discovery rate has risen from roughly five species a year to more than twenty, with over a fifth of the entire known inventory detected in the last three years. Recent additions include calcium sulfide and the first sulfur-bearing cyclic hydrocarbons. The 1997 sheet is a snapshot, and every revision since has moved in sulfur's favor.

Exhibit Three — sulfur through the accretion of a planet

The second exhibit is a staged account of the Earth's formation with the chemical composition of each stage tabulated. Following the sulfur down the column produces this.

stage	phase	composition as tabulated	sulfur species
Solar dust cloud	gas	H_2, inert gases, CH_4	none listed
Formation of Sun, disc of gas and dust	dust	silicates, FeO, FeS, little metallic iron, solid H_2O, NH_3	FeS
Preprotoplanet and early protoplanet	gas	H_2, inert gases, H_2O, NH_3, CH_4	none listed
Accumulation of planetesimals and the Moon	dust and planetesimals	silicates, FeO, FeS, hydrated minerals, NH_4Cl, solid H_2O, NH_3	FeS
High-temperature stage, iron oxides reduced	gas	H_2, inert gases, H_2O, N_2, CH_4, H_2S, volatilized silicates	H_2S
High-temperature stage, large planetesimals	solid	FeO, hydrated minerals, FeS, NH_4Cl, metallic iron, C, Fe_3C, TiN	FeS
High-temperature stage, small planetesimals	solid	silicates, metallic iron, C, Fe_3C, TiN, some FeS	FeS
Second low-temperature stage, final accumulation	gas	mostly lost; small amounts of H_2, H_2O, N_2, CH_4, H_2S, inert gases	H_2S

Iron sulfide in every solid phase from the protoplanetary disc onward, and hydrogen sulfide in every gas phase after the planet gets hot. Sulfur does not enter the story. It is in the dust the story is made of.

The same exhibit labels the Earth's molten core Fe-Ni-S-O. That is the standard reading and it survives: sulfur is one of the candidate light elements in the core, and iron sulfide as troilite is a major phase in meteorites. Whatever else sulfur is in this argument, it is one of the elements the planet was assembled out of, and a fraction of it is still at the center of it.

The staged model itself is dated; the sulfur is not. This table comes from an older single-sequence account of accretion, and modern models are multi-stage, involve substantial giant-impact mixing, and do not treat the sequence as cleanly ordered. Two things survive that revision intact: troilite remains a major sulfide phase in chondritic meteorites, and sulfur remains a leading candidate for the light

element deficit in the core. The exhibit is used here for what it names, not for its chronology.

Exhibit Four — sulfur in the ocean and in the cycle

The third exhibit is a composite of the biogeochemical sulfur cycle with a seawater composition table. Two things in it are worth extracting.

The first is quantitative. In the seawater table, sulfate is the second most abundant anion after chloride, at roughly 0.0104 molal at salinity 30, 0.0114 at salinity 35 and 0.0122 at salinity 40, with sodium sulfate and potassium sulfate ion pairs listed beneath it. Chloride runs about forty-five times higher. Nothing else in the anion column is close.

The ocean this chemistry runs in is, after salt, a sulfate solution.

The second is the organism list, which is a census of who does what to sulfur.

who	what they do to sulfur	where it sits in the cycle
Green sulfur bacteria and purple sulfur bacteria	H_2S plus light	anoxygenic photosynthesis — Exhibit One's organism, in its ecological place
Thiobacillus thiooxidans	H_2S to H_2SO_4	chemolithotrophic sulfur oxidation to sulfuric acid
Beggiatoa and other sulfur oxidizers	elemental S to sulfate	the aerobic completion of the oxidative arm
Desulfovibrio	sulfate to sulfide	dissimilatory sulfate reduction, closing the loop
Nearly all organisms	cysteic acids of proteins	sulfur entering the protein alphabet

The cycle also names dimethyl sulfide, $H_3C\text{-}S\text{-}CH_3$, twice — as a volatile product on the marine side and again in the atmospheric column. It is the largest natural flux of sulfur from ocean to atmosphere, and it is an organosulfur compound, not an inorganic one.

And one detail from the electron transport chain

The same exhibit reproduces the mitochondrial respiratory chain, and the Rieske iron-sulfur center is marked in Complex III. That closes a circle worth naming. Exhibit One lists a Rieske iron-sulfur protein in Allochromatium vinosum. Exhibit Four marks the Rieske center in the human mitochondrion. It is the same protein family, in the same position in the same kind of chain, doing the same job.

The iron-sulfur cluster that moves an electron in a purple bacterium's photosynthetic chain and the one that moves an electron in your

Complex III are homologs. That is not an analogy this paper constructed. It is a family assignment somebody else made.

What the census establishes, and what it does not

Established, and it is a claim about presence rather than about causation: sulfur-bearing molecules are present in the interstellar medium in named form and in quantity; iron sulfide and hydrogen sulfide are present at every solid and gas stage of planetary accretion in the exhibit's own tabulation; sulfate is the second anion of seawater; a named set of organisms runs every step of the oxidative and reductive sulfur cycle; and the same iron-sulfur protein family appears in a purple bacterium's photosynthetic chain and in the human respiratory chain.

Not established: that this continuity is a lineage. Presence at every stage is not descent through every stage, and the argument of this part is that sulfur was always available, not that any particular molecule was inherited. The distinction is the same one section 26 makes about the organism, and it is made here for the same reason.

Sulfur is not a chapter in this story. It is the material the pages are made of — and that is a weaker claim than a lineage, and a much harder one to argue against.

52. Exhibit One — Thirty-Eight Proteins From One Purple Bacterium ↩

A protein inventory assembled for another purpose, containing nearly every thread in this document

The exhibit is a listing of thirty-eight characterized proteins from Allochromatium vinosum, the purple sulfur bacterium formerly named Chromatium vinosum. It was compiled as a reference list, not as an argument. Sorted by what the proteins do, it reads like a table of contents for this paper.

what it does	which proteins	what it corresponds to in this document
Sulfur oxidation	DsrE, DsrF, dissimilatory sulfite reductase alpha, sulfide dehydrogenase flavocytochrome c and its cytochrome subunit, ATP sulfurylase	Part Fifteen's sulfur economy, running as the organism's power supply rather than as a supporting pathway
Thiol and disulfide redox	thioredoxin, thiol:disulfide interchange protein DsbE	the redox chemistry Part Ten puts at the origin of DNA
Iron-sulfur proteins	high-potential iron-sulfur protein, Rieske iron-sulfur protein, ferredoxin	three Fe-S carriers at three different potentials, in one cell
Purine biosynthesis	purH, the bifunctional AICAR transformylase and IMP cyclohydrolase; purD, phosphoribosylglycinamide synthetase	the enzyme that closes the ring to make IMP, and the enzyme that puts glycine into it

what it does	which proteins	what it corresponds to in this document
Thioester metabolism	acetoacetyl-CoA thiolase, acetoacetyl-CoA reductase, PHB synthase, phosphopantetheine adenylyltransferase	de Duve's thioester world and the biosynthesis of coenzyme A itself
Energy transduction	pyrophosphate-energized proton pump, cytochrome b, cytochrome c1, cytochrome c′, tetraheme cytochrome	a proton-motive force driven by pyrophosphate rather than by ATP
Photosynthesis	reaction center L, M and cytochrome subunits	anoxygenic photosynthesis, using sulfide as the electron donor
Carbon fixation	RuBisCO large and small subunits, RbcA	carbon entering biology on the back of sulfur oxidation
Protein folding	GroEL and GroES chaperonins	the machinery that actually guides tertiary folding

Two entries in that list are the spine of this paper

Item fourteen is purH — the bifunctional enzyme that carries out the tenth and final step of de novo purine biosynthesis, formylating AICAR and then cyclizing the product to close the imidazole ring. Its product is IMP.

Item fifteen is purD — phosphoribosylglycinamide synthetase, the second step, which condenses glycine onto phosphoribosylamine.

The enzyme that makes IMP and the enzyme that installs glycine are both on this list, in the same organism, alongside the sulfur-oxidation machinery that powers it. Part Four's real unit and Part Four's one unread codon box, in a purple bacterium's protein inventory.

None of that was arranged. The list was assembled as a protein reference for a sulfur bacterium, and it happens to contain the root of the purine loop, the amino acid whose four-fold box inosine does not read, the thioester chemistry Part Twenty-Six proposes as a pre-ATP currency, and the chaperonin that does the folding work Part Twenty cares about.

And one entry answers a question Part Twenty-Six leaves open

The list includes a pyrophosphate-energized proton pump — a membrane enzyme that hydrolyzes inorganic pyrophosphate and uses the free energy to move protons across the membrane, generating a proton-motive force. It is an alternative to the ATP synthase route, and it runs on the simplest phosphoanhydride there is.

Part Twenty-Six's complaint is that the nitrogen bank was capitalized before it could fund itself, and that any candidate pre-ATP currency has to serve both arms of the central dogma. Pyrophosphate is a serious candidate on exactly those grounds: it is

structurally trivial, it is the leaving group of every nucleotide polymerization reaction already, and there exists a family of membrane pumps that will convert it directly into a proton gradient. This organism carries one.

The leaving group of nucleic acid synthesis is also, in this bacterium, the fuel of the membrane. Whatever else that is, it is not a coincidence that needed inventing.

Stated as conjecture, and marked. That pyrophosphate preceded ATP as the general energy currency is a proposal with a long history and no settled answer, and this paper adopts none of it. What is claimed here is narrower and is a fact about the exhibit: an organism running the sulfur chemistry this framework cares about also carries a pyrophosphate-driven pump, which makes it a natural system in which to test the pyrophosphate hypothesis rather than argue it.

The cysteine arm, which belongs in Part Fifteen

One mechanistic detail from the Dsr system is worth carrying back. The dsr operon of this organism comprises fifteen genes. DsrAB functions as a heterotetramer and performs the catalysis, but the sulfur substrate is not delivered by diffusion. DsrC carries a highly conserved C-terminal domain that forms a flexible arm, and on that arm sit two strictly conserved cysteines that act as the substrate-donating residues for DsrAB.

Sulfur is handed to the catalytic site on a mobile arm, by a pair of cysteines. That is the same delivery motif as the persulfide relay of Part Fifteen, in an organism that runs it for a living.

---

53. Exhibits Five Through Nine — The Species, and the Numbers Behind Them ↩

Four isotopes that date an atmosphere, and four bond angles that explain the chemistry

The remaining exhibits move from what sulfur is to why it behaves as it does. Two of them carry numbers that this document should have had from the beginning.

The four stable isotopes, and what they are used to date

Sulfur has four stable isotopes — ^{32}S, ^{33}S, ^{34}S and ^{36}S — and the exhibit circles all four. Their usefulness is not that they exist but that they fractionate in two different

ways, and the difference between those ways is how the oxidation of the atmosphere is dated.

Ordinary chemical and biological processes fractionate sulfur isotopes in proportion to mass difference. Gas-phase photochemistry under an ultraviolet-transparent, oxygen-free atmosphere does not: it produces mass-independent fractionation, recorded as a non-zero $\Delta^{33}S$. Sulfide minerals older than roughly 2.4 billion years carry large positive and negative $\Delta^{33}S$ values. After that boundary the anomalies collapse toward zero and cluster there, at $\Delta^{33}S = 0 \pm 0.2$ per mil.

The date this paper leans on in Part Ten — the Great Oxidation Event, near 2.4 billion years ago — is measured in sulfur isotopes. The oxygen transition is dated by the element it displaced.

That deserves stating in this document rather than assumed, because Part Ten's whole argument about ribonucleotide reductase diversification is pinned to that date, and the pin is made of sulfur. It is the one place where sulfur is not the subject of the argument but the instrument of it.

The boundary is not a clean line, and the exhibit should not be read as though it were. Recent work finds the signal globally asynchronous: mass-independent fractionation persists in some sections past 2.31 billion years, punctuated by episodes of disappearance, and the rise of atmospheric oxygen is bracketed rather than fixed — between about 2.50 billion years, the age of the youngest sediments lacking strong anomalies, and about 2.32 billion years, the age of the youngest rocks that still carry them. Some authors argue the Great Oxidation Event needs redefining on those grounds. The framework's use of the date should carry that uncertainty, and from this version it does.

Exhibit Nine — the bond geometry, which is the whole explanation

Part Sixteen asserted that sulfur behaves differently from oxygen because its valence electrons sit in the third shell. This exhibit supplies the measured consequences, from gas-phase microwave and electron-diffraction structures, and they are more specific than the assertion was.

what is measured	oxygen	sulfur	what it buys
Bond angle at the center	∠HOH 104.51°	∠HSH 92.12°	sulfur bonds at nearly 90° — close to unhybridized p orbitals
Bond length to hydrogen	O–H 0.9575 Å	H–S 1.3356 Å	the donor sits far further out
Chalcogen-	O–O 1.475 Å	S–S 2.055 Å	catenation, and a much longer bridge

what is measured	oxygen	sulfur	what it buys
chalcogen bond			
Dihedral of the X_2H_2 bridge	H_2O_2 119.8°	H_2S_2 90.6°	the disulfide's preferred twist is a right angle
Angle at the bridging atom	∠OOH 94.8°	∠SSH 91.3°	both near 90°, sulfur nearer still

The hydrogen-sulfur-hydrogen angle is 92.12 degrees. Sulfur barely hybridizes. Almost everything this document has attributed to the third shell is visible in that one number.

The fourth row is the one to carry forward. Hydrogen peroxide twists to about 120 degrees; hydrogen disulfide twists to 90.6 degrees, with C_2 symmetry. That right-angle preference is not a curiosity of the gas phase — it is the geometry every disulfide bridge in every folded protein has to accommodate, and the reason a cystine crosslink imposes a specific local twist rather than a free rotation. Part Ten argued that a disulfide pays for the missing 2′ oxygen in ribonucleotide reductase. Here is the shape of the bond doing the paying.

The exhibit also carries sulfuric acid in full — S–O at 1.574 Å to the hydroxyl oxygens and 1.422 Å to the terminal oxygens, with O–S–O angles from 101.3 to 123.3 degrees and three independent dihedrals — and HNSO, a planar molecule with N–S at 1.512 Å and S–O at 1.451 Å. The sulfuric acid entry matters because the two S–O distances differ by 0.15 Å: the terminal oxygens are shorter and stronger, and that asymmetry is why sulfate is a poor ligand and a good leaving group.

Exhibit Two — the redox span, drawn as volt-equivalents

The volt-equivalent diagram at pH 7 places every biologically relevant species of every light element on one plot, against oxidation state. Following sulfur across it gives the range Part Sixteen claimed without quantifying.

species	oxidation state	where it appears in this document
H_2S	−2	the reduced end; the electron donor of anoxygenic photosynthesis
Elemental S	0	the intracellular globule of the purple sulfur bacterium
$S_2O_3^{2-}$ thiosulfate	+2	the substrate of the Sox pathway
HSO_3^- sulfite	+4	the product of the Dsr system, and the substrate of sulfite oxidase
SO_4^{2-} sulfate	+6	the fully oxidized end, and the second anion of seawater

Eight units of oxidation state, all of them occupied by named biological species, all of them at pH 7. Oxygen manages effectively two. The exhibit sets the selenium analogs alongside — HSe^-, $HSeO_3^-$, SeO_4^{2-} — at consistently lower volt-equivalents, which is the quantitative form of the statement in Part Sixteen that selenium is the softer, more easily oxidized chalcogen.

Exhibit Seven — van Niel's equation, and what it actually proved

One equation on the exhibit deserves far more weight than it has been given here.

$$6\,CO_2 + 12\,H_2S \rightarrow C_6H_{12}O_6 + 6\,H_2O + 12\,S$$

That is anoxygenic photosynthesis as the purple sulfur bacteria run it, and it is the reaction Cornelis van Niel studied in the 1930s. He noticed that it differs from the plant equation in one respect only: where plants use water, these bacteria use hydrogen sulfide, and where plants release oxygen, these bacteria deposit sulfur. From that parallel he reasoned that the general form is one reaction with a variable hydrogen donor, and therefore that the oxygen released by plants comes from water and not from carbon dioxide — which had been the standing assumption.

The purple sulfur bacteria are how we know where photosynthetic oxygen comes from. That is this organism's real place in the history of biology, and it is a stronger claim than any ancestry argument.

It is also the correct answer to the temptation section 26 warns against. Chromatium is not a founding father. It is the organism that let somebody work out what photosynthesis is, because it runs the same reaction with sulfur in the place where the rest of the biosphere puts oxygen. That is a model organism in the strict sense, and the framework should claim it in exactly those terms.

Exhibits One, Three and Six — three smaller entries, each worth one line

The whole-metabolism chart has more sulfur in it than its labels show. Acetyl-CoA and succinyl-CoA sit at the hub of the tricarboxylic acid cycle, and both are thioesters. Coenzyme A carries a thiol, biosynthesized through phosphopantetheine adenylyltransferase — an enzyme on the Chromatium list of Exhibit One. Every arrow through acetyl-CoA on that chart is an arrow through a carbon-sulfur bond, and the chart does not say so, because the drawing convention labels the metabolite and not the bond.

The prebiotic evolution tree puts sulfides and sulfates at the top level. They branch directly from the root, alongside Nucleic Acid Bases and Amino Acids rather

than beneath them. Whether that placement is defensible is a separate question; what it records is that whoever drew the tree treated inorganic sulfur as a primary prebiotic category and not a downstream product.

The interstellar abundance table puts three sulfur species at 0.01 ppm. CS, SO_2 and SO appear at the bottom rung of the abundance ladder, three orders below hydrogen cyanide and four below carbon monoxide. The same exhibit notes that water is the most abundant triatomic molecule in the universe and that formaldehyde and hydrogen cyanide follow. Sulfur is present but dilute in the gas phase, which is consistent with the census of section 20 and is worth stating so that the abundance argument is not overdrawn.

How these connect — and what the connecting structure is not

The exhibits assemble into a layered graph: an inventory of delivered species and isotopes, feeding a set of measured bond geometries, feeding the functional groups those geometries permit, feeding the enzymes built from those groups. Each layer's outputs are the next layer's inputs, and one edge skips the sequence entirely, because the isotope record in layer one dates the atmospheric transition that diversified the enzyme in layer four.

That structure is a directed acyclic graph, not a neural network, and the distinction is worth keeping. A neural network is defined by learned parameters: it requires a loss function, a training signal and a rule for updating weights against an error gradient. None of those exists here. Nothing in this graph is fitted, nothing is trained, and no quantity is being minimized. Calling it a neural network invites a technical objection that the graph itself does not deserve, and it costs the argument nothing to use the accurate term. One borrowing does survive and is used above: a skip connection, meaning an edge that bypasses intermediate layers, is exactly what the $\Delta^{33}S$ link is. And the afferent-and-efferent branching of the nervous system is an anatomical arrangement rather than a computational one — the right formal analogy for a many-in, few-in-the-middle, many-out architecture is already in this document, as the bow-tie of Part Twenty.

Four layers, one skip connection, and no weights. It is a dependency map, and a dependency map is the stronger claim, because it can be wrong in a way a metaphor cannot.

54. The Sulfur-Nitrogen Bond, and Why Biology Uses the Weak End ↩

HNSO shows what an S-N bond can be. Metabolism deliberately uses the opposite extreme.

The first compound on the bond-length exhibit is HNSO, and it is there because it is the only entry in the table carrying a sulfur-nitrogen bond. It is worth reading closely, because the numbers say something the molecule's obscurity conceals.

What the HNSO numbers actually say

what was measured	value	what it means
N–H	1.029 Å	an ordinary N–H bond
N–S	1.512 Å	shorter than a typical S=N double bond near 1.54 Å
S–O	1.451 Å	full double-bond character, close to the S=O of sulfur dioxide
∠HNS	115.8°	trigonal at nitrogen
∠NSO	120.4°	trigonal at sulfur
geometry	planar	every atom in one plane

Planarity plus two short bonds plus two angles near 120 degrees describes one thing: a cumulated system, H–N=S=O, with the π electrons delocalized across all three heavy atoms. The N–S distance of 1.512 Å is not a single bond that happens to be short. A sulfur-nitrogen single bond runs near 1.75 Å. This is the sulfur-nitrogen bond at close to its maximum attainable bond order.

Sulfur can hold nitrogen at 1.512 ångströms. It is the tightest grip in the table, and biology declines to use it.

HNSO is an astrochemical target, not a metabolite. It should be said plainly before anything is built on it. Thionylimide has no known role in human metabolism, appears in no pathway, and is studied largely as a candidate for radioastronomical detection — laboratory rotational spectroscopy of trans-HNSO has been published specifically to support the search for it in the interstellar medium. Its value to this document is as a calibration point rather than as a participant: it tells us what the sulfur-nitrogen bond looks like at the strong end, so that the bonds biology does use can be placed against it.

The sulfur-nitrogen bond, arranged by length

Set the exhibit's number alongside the sulfur-nitrogen bonds that appear in biology and in pharmacology, and a ladder emerges in which length and function track each other exactly.

species	S–N length	character	what it is for
HNSO, thionylimide	1.512 Å	cumulated H–N=S=O	interstellar candidate; no biological role
Sulfonamide, $S(=O)_2$–N	≈ 1.66 Å	shortened by delocalization	the sulfa drugs; a bond designed to stay put
Polythiazyl, $(SN)_x$	intermediate	between single and double, in a chain	conducts like mercury; superconducts below 0.26 K
Sulfur-nitrogen single bond	≈ 1.75 Å	the reference single bond	the sulfenamide range
Sulfenamide, R–S–N<	the single-bond range	partial double-bond character; torsional barrier 12–20 kcal per mole	labile; the PTP1B switch, and rubber vulcanization
cis-CH_3SNO, S-nitrosothiol model	1.814 Å	long and weak	homolysis at about 32 kcal per mole
trans-HSNO, simplest S-nitrosothiol	1.85 Å	the weakest of the set	homolysis at about 29 kcal per mole

From 1.512 to 1.85 ångströms is a third of an ångström, and it is the difference between a bond that never breaks and a bond whose entire purpose is to break.

That is the finding of this section, and it inverts the intuition the exhibit invites. One might expect biology to have selected the strong sulfur-nitrogen bond — the tight, delocalized, planar one. It has done the opposite. Every sulfur-nitrogen bond in signaling sits at the long end, at or beyond the single-bond reference distance, with a homolysis energy near thirty kilocalories per mole. That is weak enough to break on demand at body temperature and strong enough not to break by accident.

A signaling bond has to be breakable. Sulfur-nitrogen at 1.85 ångströms is a switch. Sulfur-nitrogen at 1.512 ångströms is a wall.

Where the sulfur-nitrogen bond genuinely appears in human biology

Three places, and one of them was a surprise when it was found.

In a protein active site, as a redox switch — the PTP1B sulfenyl-amide.

Protein tyrosine phosphatase 1B is the enzyme that shuts off the insulin receptor, and its catalytic cysteine is oxidized by hydrogen peroxide as part of normal insulin

and epidermal growth factor signaling. Two groups solved the structures in 2003 and reported the same unexpected species: the sulfenic acid formed on oxidation converts rapidly into a sulfenyl-amide, in which — in Salmeen and Barford's words — the sulfur atom of the catalytic cysteine is covalently linked to the main chain nitrogen of an adjacent residue. Van Montfort and colleagues reported the same intermediate alongside the irreversible sulfinic and sulfonic forms. The bond forms on oxidation, drives a large conformational change that blocks substrate binding, and is reversed by glutathione. It exists to protect the cysteine from irreversible over-oxidation and to make the inhibition reversible.

A covalent sulfur-nitrogen bond, made and unmade inside a human enzyme, as the mechanism by which insulin signaling is switched. It is a post-translational modification the protein alphabet has no symbol for.

In a sugar polymer, as N-sulfoglucosamine — heparan sulfate. This is the entry that answers the question about sugars directly. During heparan sulfate biosynthesis the N-deacetylase/N-sulfotransferase enzymes remove the acetyl group from glucosamine and install a sulfate on the resulting free amine, producing a genuine nitrogen-sulfur linkage in a human polysaccharide. The N-sulfation pattern set by those enzymes determines which proteins the chain will bind and with what affinity, so the sulfur-nitrogen bond is not incidental decoration — it is the specificity-determining feature of the polymer. Glycosaminoglycans are on the whole-metabolism exhibit of section 21, three boxes from the top.

In signaling, as the S-nitrosothiol. S-nitrosylation attaches nitric oxide to a cysteine sulfur, giving R–S–N=O. It is the longest and weakest bond in the ladder above, and that is precisely why it works as a carrier: the bond homolyzes to release nitric oxide where and when it is needed. Nitric oxide is on the whole-metabolism exhibit too, one box from pyruvate.

A fourth belongs on the list for a different reason. The sulfonamides — the sulfa drugs — are built on an S(=O)$_2$–N bond at roughly 1.66 ångströms, and they were the first broadly effective antibacterials. They are not a natural product; they are what happens when chemists build at the stable end of the same ladder on purpose.

The inorganic end — what the bond does when biology is not involved

Everything above sits in the narrow band biology and pharmacology occupy. The sulfur-nitrogen bond has a much wider range than that, and the far end of it is worth seeing, because it makes biology's restraint legible as a choice rather than a limit.

species	form	what it does
S_4N_4, tetrasulfur tetranitride	a cage	the only scalable precursor to the polymer below; ring-flips between cage and half-boat
S_2N_2, disulfur dinitride	a four-membered planar ring	unstable; dimerizes to S_4N_4, or polymerizes
$S_3N_3^-$, the trisulfur trinitride anion	a six-membered ring	described as aromatic, an inorganic analog of benzene, and used as a ligand in organometallic chemistry
$(SN)_x$, polythiazyl	a near-planar alternating chain	metallic luster, conductivity comparable to mercury, and superconducting below about 0.26 K

The last row is the one that stops a reader. Polythiazyl is the only known polymeric superconductor composed entirely of non-metallic elements, and it was the first compound of any kind made only of non-metals in which superconductivity was demonstrated. Its bond lengths sit between a sulfur-nitrogen single and a double bond all the way along the chain, its conductivity is metallic and strongly anisotropic — along the chains, not across them — and the superconductivity is filamentary, confined to well-ordered chain segments.

A chain of nothing but alternating sulfur and nitrogen conducts electricity like mercury and superconducts near absolute zero. No carbon in it, no metal in it, and it is made by heating a cage over silver wool.

The preparation is worth recording because it is not exotic. S_4N_4 vapor is passed over silver wool at 250 to 300 degrees, which cracks the cage to S_2N_2; the S_2N_2 then polymerizes in the solid state at zero degrees, a topochemical reaction in which the crystal lattice does the assembling. Cage to ring to chain, in two steps.

Aromaticity in a ring with no carbon in it

The alternating arrangement in these compounds is driven by the electronegativity difference, which places the negative formal charge on nitrogen. On top of that arrangement, the same electron-counting rules that govern benzene appear to operate — in a ring containing no carbon at all.

$S_3N_3^-$ is described as aromatic and behaves like one, serving as a benzene-analog ligand in organometallic complexes. S_2N_2 is described in the exhibit as antiaromatic, and its instability and dimerization to S_4N_4 are attributed to that.

The aromaticity assignment for S_2N_2 is genuinely disputed, and the framework should not pick a side. Some analyzes treat S_2N_2 as a six-π-electron

aromatic system by Hückel's rule; others treat it as antiaromatic, which is the reading in this exhibit. What is not in dispute is the observable: S_2N_2 is unstable and converts to S_4N_4 or to the polymer. The electronic explanation for that instability is contested, and this document reports the observation and flags the explanation rather than adopting one.

Hückel's rule, running in a ring made of sulfur and nitrogen and nothing else. Whatever stabilizes a purine ring is not a property of carbon.

The torsional barrier, and why it lands on PTP1B

Back at the biological end, the exhibit supplies a number that section 23 was missing. In sulfenamides, X-ray structures show partial double-bond character in the sulfur-nitrogen bond, arising from a lone pair interacting with an antibonding orbital, and the consequence is a torsional barrier of twelve to twenty kilocalories per mole. The same sources record that the bond is labile — cleaved or rearranged under mild conditions — which is precisely why sulfenamides are used as rubber vulcanization accelerators.

The PTP1B intermediate is a sulfenamide. That twelve-to-twenty kilocalorie torsional barrier is the barrier in the switch that turns human insulin signaling off.

Read the two numbers together and the design becomes explicit. Rotation about the bond costs twelve to twenty kilocalories per mole, so the geometry is held. Breaking the bond costs rather more, but not much more, and glutathione supplies the reducing equivalent. A bond stiff enough to hold a conformation and weak enough to be undone by a cellular thiol is exactly what a reversible switch requires, and it is the same combination that makes the compound useful for curing rubber.

How the bond is made, and what it is made into

The synthetic literature adds two things. First, the classical route to a sulfenamide is nucleophilic substitution — a sulfenyl chloride meeting an amine. Second, and more recently, the bond can be formed directly by cross-dehydrogenative coupling: a thiol and an N-H compound are joined with the loss of hydrogen, with no pre-functionalization of either partner. That transformation runs on copper with bipyridine using air as the terminal oxidant, on TEMPO with dioxygen and no co-oxidant, on hypervalent iodine catalysis, and on a palladium-copper binary system

which selectively gives sulfinamides instead. Mechanistically these proceed through radical intermediates or through metal-centered cycles.

And what gets built with it includes drugs in current use. Sultiame, marketed as Ospolot, is a sulfa-based anticonvulsant that works by reducing the activity of carbonic anhydrase. Topiramate, also carrying the sulfamate motif, is used for epilepsy and for migraine prevention in adults.

A tunneling dispute, in the same shape as the one in Part Sixteen

Sulfur atom tunneling has been proposed in S_4N_4, and then challenged. Kumar and Mallick reported computational evidence that the ring-flipping reaction of S_4N_4, between its cage and a half-boat conformation, proceeds predominantly by tunneling below about seventy kelvin, with tunneling roughly doubling the rate at one hundred and fifty kelvin. Their stated motivation is the cleanest possible test case: the molecule contains only sulfur and nitrogen, so no light atom can contribute and any tunneling must be heavy-atom tunneling. A published Comment then argued that the sulfur atom tunneling is not viable and could not be probed experimentally, and set out the prerequisites a heavy-atom tunneling claim has to meet.

A tunneling claim, a rebuttal, and no settlement — about the same element, in the same document, for the second time. Part Sixteen reports the argument over the proton. This is the argument over the sulfur atom itself.

Neither dispute is adopted here. What the pair of them illustrates is that quantum contributions to sulfur chemistry are an open research front rather than a settled foundation, which is the reason this framework states the tunneling material as contested every time it appears.

Now the question directly: does the sulfur-nitrogen bond link all four monomer classes?

It does not, and the honest answer is more useful than the uniform one would have been. Sulfur attaches to each of the four monomer classes by a different bond type, and only one class uses the full range.

monomer class	how sulfur attaches	named examples	is the bond to nitrogen?
Nucleic acids	C=S thiocarbonyl; C–S–C thioether; P–S	2-thiouridine and 4-thiouridine; 2-methylthio-N6-	No. Sulfur binds carbon or phosphorus.

monomer class	how sulfur attaches	named examples	is the bond to nitrogen?
	phosphorothioate	isopentenyladenosine; the bacterial Dnd backbone modification	
Amino acids and proteins	C–SH thiol; C–S–C thioether; S–S disulfide; S–N sulfenyl-amide; S–N=O nitrosothiol	cysteine; methionine; cystine; the PTP1B intermediate; S-nitrosocysteine	Yes. The only class that uses every sulfur bond type there is.
Fatty acids and lipids	C–S–C(=O) thioester; S–S dithiolane; C–SO_3^- sulfonate; O–SO_3^- sulfate ester	acyl-CoA and acyl carrier protein; lipoic acid; sulfoquinovosyl diacylglycerol; sulfatide	No. Sulfur binds carbon or oxygen.
Sugars	O–SO_3^- sulfate ester; N–SO_3^- N-sulfate; C–SO_3^- sulfonate	chondroitin and keratan sulfate; heparan sulfate; sulfoquinovose	Yes, as N-sulfoglucosamine.

Two of four, not four of four. Sulfur reaches nitrogen in proteins and in sugars, and reaches carbon, phosphorus or oxygen in nucleic acids and lipids.

The nucleic acid row deserves one further sentence, because the near-miss is instructive. In 2-thiouridine the sulfur sits at C2, flanked on both sides by ring nitrogens at N1 and N3. In 4-thiouridine it sits at C4, adjacent to N3. The sulfur is one atom away from nitrogen in both cases and bonded to neither. The pyrimidine ring will accept a sulfur at a carbon and will not accept one at a nitrogen, because a ring nitrogen carrying sulfur would no longer be able to donate or accept in the Watson-Crick face — which is the encoding of Part Four, enforcing itself at the level of what substitution is chemically permitted.

What this establishes, and what it does not

Established: that HNSO is planar with N–S at 1.512 Å and S–O at 1.451 Å, a cumulated system at high bond order, and has no known metabolic role; that the sulfur-nitrogen bond also builds the S_4N_4 cage, the S_2N_2 ring, the $S_3N_3^-$ aromatic anion and polythiazyl, the only polymeric superconductor made entirely of non-metals, superconducting below about 0.26 K; that sulfenamides carry partial double-bond character with torsional barriers of twelve to twenty kilocalories per mole and are nonetheless labile; that biological and pharmacological sulfur-nitrogen bonds occupy the range from roughly 1.66 Å in sulfonamides to 1.85 Å in the simplest S-nitrosothiol, with homolysis energies near thirty kilocalories per mole at the long end; that a covalent sulfur-nitrogen bond forms between the catalytic cysteine sulfur and a main-chain nitrogen in oxidized PTP1B and is reversed by glutathione; and that N-sulfoglucosamine in heparan sulfate is a nitrogen-sulfur bond installed by the

N-deacetylase/N-sulfotransferase enzymes as the specificity-determining modification of the polymer.

Not established: that the sulfur-nitrogen bond unifies the four monomer classes. It does not, and the framework should say two of four and say why. Nor that HNSO has any biological significance whatever — the exhibit's value is calibration, and any claim beyond that would be the abundance-to-function step this document has refused twice already.

The exhibit asked what a sulfur-nitrogen bond can be. The answer is 1.512 ångströms, planar, and inert — and biology looked at that and chose the other end of the ladder, because a code needs bonds that break.

The real finding, restated now that the range is known

With the inorganic end in view the claim can be put more sharply than section 23 first put it. The sulfur-nitrogen bond can build a cage, an aromatic ring, a superconducting chain, an anticonvulsant, a vulcanization accelerator and a rubber. Its accessible range runs from a cumulated bond at 1.512 ångströms to a nitrosothiol at 1.85 that falls apart at thirty kilocalories per mole.

Out of all of that, biology uses two: the labile sulfenamide and the more labile nitrosothiol. Both at the weak end. Both reversible. Both switches.

That is a statement about selection rather than about availability, and it is the stronger form of the argument. Sulfur-nitrogen chemistry was not scarce and it was not narrow. The cell had the whole range in front of it and took the part that comes undone.

---

55. Reactive Sulfur Species — The Layer This Framework Had Not Reached ↩

Persulfides, peroxiredoxins, ferroptosis, and an honest correction about who is working on this

The exhibits supporting this section are not old charts. They are a themed issue of Current Opinion in Chemical Biology from 2023, nine articles with consecutive article numbers, devoted to sulfur redox chemistry. Reading them changes one thing in this framework's posture and adds one whole layer to its chemistry.

The correction first, because it is about this document rather than about sulfur

There is a large and active field working on sulfur, and this document places itself against it. The exhibit is an entire themed issue of a Cell Press journal, published in one year, covering reactive sulfur species in bacteria, hydropersulfides and ferroptosis, peroxiredoxins, cysteine and methionine oxidation in thrombosis, sulfoxides in medicine, selenium sulfide, sulfur incorporation in natural product biosynthesis, iron-sulfur clusters in cancer, and redox regulation of immunity. Sulfur is the subject of a large, well-funded and technically sophisticated literature, and this work is stated as a contribution alongside it rather than in a vacuum.

What survives, and what this document should claim instead, is narrower and checkable. Read those nine articles and notice what is absent from all of them: the genetic code, the codon table, inosine, wobble decoding, the purine loop, the origin of the nucleic acid alphabet. They are redox biology, natural product chemistry and pharmacology. Not one of them reaches across to the question of what the code is made of.

The sulfur field is thriving. It has not been introduced to the genetic-code field. That is a much smaller claim than neglect, and unlike neglect it is true.

Hydropersulfides — the reactive species this framework missed entirely

Part Fifteen built its argument on cysteine desulfurase, which mobilizes sulfur from L-cysteine as a protein-bound persulfide and hands it to acceptors. That part treated the persulfide as a delivery intermediate — a courier. The current literature treats it as a functional species in its own right, and the reason is a set of results this document had not seen.

property of RSSH	what was found	what it does
Two-electron reactivity	enhanced relative to ordinary thiols	implicated in maintaining cellular redox homeostasis
One-electron reactivity	potent radical-trapping antioxidant activity	inhibits phospholipid peroxidation
Consequence	suppression of the lipid peroxidation chain reaction	inhibits ferroptotic cell death

Wu, Barayeu, Schilling, Dick and Pratt review the finding that hydropersulfides react with lipid peroxyl radicals — the radicals that propagate lipid peroxidation — and that this radical-trapping capacity lets them inhibit phospholipid peroxidation and

the associated cell death by ferroptosis. That is a one-electron chemistry nobody was looking for in a molecule that had been cataloged as a two-electron nucleophile.

The persulfide is not a courier carrying sulfur to its destination. It is an antioxidant that stops cells dying, and the framework had it filed as transport.

This corrects Part Fifteen rather than contradicting it. Cysteine desulfurase still supplies iron-sulfur clusters, thionucleosides, thiamine, biotin and molybdenum cofactor from one donor through one persulfide. What changes is that the intermediate has a job of its own along the way, and that job is protecting membranes.

And the same species is a bacterial defense against the immune system

Giedroc, Antelo, Fakhoury and Capdevila describe the other side of that chemistry. The infected host deploys generalized oxidative stress as an antibacterial weapon. Hydrogen sulfide, and the forms of sulfur carrying sulfur-sulfur bonds collectively termed reactive sulfur species, provide bacteria with protection against those oxidative stressors — and against antibiotics — by acting as antioxidants.

Sulfur is the shield on both sides of an infection. The host attacks with oxidants; the bacterium answers with sulfur-sulfur bonds.

Peroxiredoxins, and the sulfenic acid this document already knows

Villar, Ferrer-Sueta and Denicola review the peroxiredoxins, thiol-dependent peroxidases first identified as hydrogen peroxide detoxifiers and now understood as hydrogen peroxide sensors, intermediates in redox signaling, metabolism modulators and chaperones. The mechanism should be familiar by now: oxidation by a peroxide substrate forms a sulfenic acid, and that sulfenic acid opens a route to channel the redox signal onward to other protein targets.

That is the same chemical step section 23 traced in PTP1B — a catalytic cysteine oxidized to a sulfenic acid, which then does something structural rather than simply degrading. In PTP1B it cyclizes onto a backbone nitrogen to give the sulfenyl-amide. In a peroxiredoxin it becomes the relay point for a signal. One oxidation state of one sulfur atom, running two different signaling architectures.

Iron-sulfur clusters, from the prebiotic period to oncometabolism

The last exhibit closes a loop this document opens in Part Fifteen and never finishes. Nghi, Shahmohammadi and Ebrahimi write that inorganic complexes of iron and

sulfur have played a fundamental role in life on Earth since the prebiotic period, that these clusters were involved in the elementary reactions leading to the emergence of life, and that they have since gained function in respiration, replication, transcription and the immune response. They then discuss three iron-sulfur proteins of the innate immune response that bear on oncogene expression and on oncometabolism.

The same cofactor class this framework places at the origin of metabolism is currently being investigated as a target in cancer. Prebiotic chemistry and oncology, one cluster, and the connecting literature is two years old.

Stated carefully, because the temptation here is obvious. That iron-sulfur clusters are ancient and that some iron-sulfur proteins matter in cancer are two separate findings, and the second does not follow from the first. Nothing about a cluster's antiquity makes it a good drug target, and nothing about its role in oncometabolism says anything about the origin of life. What the pairing supports is a claim about attention: a cofactor built from the two elements this framework tracks turns out to be load-bearing at both ends of biology, and the people working on each end are not the same people.

Four more entries, briefly, because each closes a gap

Cysteine and methionine oxidation is prothrombotic. Yang and Smith review evidence that oxidative post-translational modification of cysteine and methionine residues drives thrombosis, on named proteins: Src family kinases, protein disulfide isomerase, β2-glycoprotein I, von Willebrand factor and fibrinogen. Thrombosis is the leading cause of death in many diseased conditions, and these modifications are being pursued as antithrombotic drug targets. This is the clinical end of the sulfur post-translational modifications that section 23 argued the protein alphabet cannot express.

Sulfoxides are a drug class. Wojaczyńska and Wojaczyński survey sulfoxides on the pharmaceutical market: sulforaphane, amanitin as an antibody-drug-conjugate payload, dimethyl sulfoxide and its controversies, the proton pump inhibitors and the benefit of resolving them into single enantiomers, and the repositioning of modafinil. Sulfur's stereochemistry at a single oxidized center is commercially load-bearing.

Selenium sulfide is not one compound. Tiganescu, Abdin, Razouk, Nasim and Jacob report that selenium sulfide is not simply SeS_2 but the name for an extended family of interchalcogen compounds of general formula Se_nS_{8-n}, notoriously

insoluble yet biologically active — best known in anti-dandruff shampoo. Anionic $Se_xS_y^{2-}$ species may form on successive reduction and act as redox modulators and, in their phrase, corkscrews toward membranes, metals and proteins. Part Sixteen's selenium material should be read against this: the chalcogen substitution is not a clean one-for-one swap.

Sulfur incorporation in natural products falls into four classes. Steele, Kiefer and Shen classify the chemistry of sulfur incorporation into natural product biosynthesis into four distinct classes, each correlated to the genes encoding the machinery. Chen and Li review the same territory for sulfur and selenium together, with emphasis on the formation and cleavage of carbon-selenium bonds and the unusual enzymes that catalyze them. Both are the biosynthetic counterpart to section 23's question about how sulfur attaches, answered by people who build molecules rather than classify them.

What this section changes

Established from these exhibits: that hydropersulfides show enhanced two-electron reactivity relative to thiols and, more recently, potent one-electron radical-trapping antioxidant activity that inhibits phospholipid peroxidation and ferroptotic cell death; that hydrogen sulfide and reactive sulfur species protect bacteria against host oxidative stress and against antibiotics; that peroxiredoxin signaling proceeds through a sulfenic acid intermediate; that iron-sulfur clusters are described as fundamental since the prebiotic period and are under investigation in oncogene expression and oncometabolism; and that cysteine and methionine oxidation is implicated in thrombosis on named proteins.

The precise claim this document makes: the sulfur redox community and the genetic-code community publish in different journals, cite different literatures, and have not met. Sulfur itself is not neglected — the connection to what the code is made of is what has not been drawn.

This framework's contribution is not that it noticed sulfur. Thousands of people noticed sulfur. It is that it tried to connect what they found to what the code is made of — and that connection is the part I have not found in either literature — the sulfur redox papers and the coding papers do not cite each other.

56. Where the Sulfur Pathways Fail — The Diseases ↩

One cofactor, two pathways, and a table of purine defects with four sulfur enzymes in it

The exhibit for this section is a clinical table: defects of purine metabolism with their synonyms, abbreviations and diagnostically important metabolites. It was compiled for metabolic physicians who need to know which molecule to measure. Read it as a chemist and something else is visible.

Four of the entries in a purine table are sulfur enzymes

defect	abbreviation	what the sulfur is doing	index metabolites
Molybdenum cofactor deficiency	MCF, xanthinuria-III	AO, XDH and sulfite oxidase all fail together	(hypo)xanthine↑, sulfite↑, thiosulfate↑, S-sulfocysteine↑, cystine↓, urate↓
Methylthioadenosine phosphorylase deficiency	MTAP	salvage of a sulfur-bearing purine	methylthioadenosine↑ in cancer cells
S-adenosylhomocysteine hydrolase deficiency	SAHH	the methylation cycle's sulfur hub	S-adenosylhomocysteine↑ in red cells
Thiopurine methyltransferase deficiency	TPMT	methylates a sulfur-substituted purine drug	thiopurine nucleotides↑ in red cells

A table of purine disorders, and four of its rows are sulfur chemistry. Nobody put them there to make a point. They are there because the purine pathway and the sulfur pathway share enzymes, cofactors and substrates.

Molybdenum cofactor deficiency is the disease this framework predicted without knowing it existed

Part Fifteen argued that molybdenum cofactor is built from GTP by a radical SAM enzyme, that it is provisioned with sulfur by a cysteine desulfurase, and that xanthine oxidoreductase — the enzyme emptying the purine ring — cannot work without it. If that argument is right, then a single lesion in molybdenum cofactor synthesis should take out the purine discharge ladder and the sulfur disposal pathway at the same time, in the same patient.

It does, and the disease has a name. According to the clinical literature, molybdenum cofactor deficiencies are inborn errors that impair synthesis of the cofactor required by three oxidases — sulfite oxidase, xanthine oxidase and aldehyde oxidase. Most patients present with severe neonatal-onset epileptic encephalopathy, hypotonia, poor feeding and apnoea, and death typically occurs within the first three years of life.

One cofactor fails and both arms go down together. Urate falls because the purine ladder stops; sulfite rises because sulfur disposal stops. The same molecule was carrying both.

The clinical name for this class is worth recording, because it names the killer: sulfite intoxication disorders. It is not the loss of urate that destroys the brain. It is the accumulation of sulfite, and of the S-sulfocysteine formed when sulfite attacks a cystine disulfide. The purine arm is diagnostically useful and clinically secondary.

A treatment exists for one form and not the others, and the boundary is instructive. Molybdenum cofactor deficiency type A can be treated with cyclic pyranopterin monophosphate — cPMP, marketed as fosdenopterin — because type A is a lesion upstream of cPMP and the intermediate can be replaced. Type B lies downstream and cPMP does not help. Isolated sulfite oxidase deficiency has no treatment at all. In a reported attempt at hepatocyte transplantation for type B, sulfite and S-sulfocysteine fell and urate rose moderately, and the treatment still did not prevent acute brain injury from sulfite toxicity visible on imaging at thirty-five hours of age. The chemistry is understood; the therapeutic window is measured in hours after birth.

And the two arms can be seen failing separately, which is the control experiment

The same table supplies the dissection. Because three different lesions hit different subsets of the same enzyme set, the clinical biochemistry separates cleanly.

disorder	enzymes lost	index metabolites	which arm fails
Xanthinuria type I	XDH alone	(hypo)xanthine ↑, urate ↓	purine arm only; sulfur normal
Xanthinuria type II	AO and XDH	(hypo)xanthine ↑, urate ↓	purine arm plus aldehyde oxidase; sulfur still normal
Isolated sulfite oxidase deficiency	SO alone	sulfite ↑, S-sulfocysteine ↑, urate normal	sulfur arm only; purine normal
Molybdenum cofactor deficiency	AO, XDH and SO	(hypo)xanthine ↑, sulfite ↑, thiosulfate ↑, S-sulfocysteine ↑, cystine ↓, urate ↓	both arms, because the shared cofactor is gone

Nature ran the experiment. Knock out the purine enzymes and sulfur is untouched. Knock out the sulfur enzyme and purines are untouched. Knock out the cofactor they share and both fail — which is how you know the connection is a cofactor and not a coincidence.

That four-way comparison is the strongest evidence in this entire document for the claim of Part Fifteen, and it comes from clinical biochemistry rather than from anything this framework constructed.

Hydrogen sulfide has its own disease, and its own enzyme set

Section 24 introduced reactive sulfur species as protective. They are also toxic in excess, and the machinery that disposes of them can fail.

enzyme	abbreviation	direction	clinical note
Cystathionine β-synthase	CBS	makes H_2S	deficiency causes classical homocystinuria
Cystathionine γ-lyase	CSE	makes H_2S	the second transsulfuration enzyme
3-mercaptopyruvate sulfurtransferase	3-MST	makes H_2S	acts on β-mercaptopyruvate, on the cysteine catabolism exhibit
Sulfide-quinone oxidoreductase	SQR	disposes of H_2S	feeds electrons into the respiratory chain
Persulfide dioxygenase	ETHE1	disposes of H_2S	deficiency causes ethylmalonic encephalopathy
Thiosulfate sulfurtransferase, rhodanese	TST	disposes of H_2S	the classical cyanide-detoxifying enzyme

ETHE1 is the entry to follow. It is a mitochondrial persulfide dioxygenase essential for cellular sulfide detoxification, and its loss causes ethylmalonic encephalopathy. What the cell biology shows is broader than a sulfide problem: patient fibroblasts carry decreased reduced glutathione, impaired growth initiation, reduced glycolytic acidification, and proteome changes reaching well outside the mitochondrion — including disturbance of endoplasmic reticulum proteins that make disulfide bonds, protein disulfide isomerase and peroxiredoxin 4 among them.

Lose one sulfide-disposal enzyme and the whole thiol economy tilts: glutathione falls, disulfide-bond formation is disturbed, and a peroxiredoxin from section 24 turns up in the damage report.

And the same enzymes are upregulated as a tumor progresses

One result deserves separating from the inherited disorders because it is about acquired mutation. Working in organoids derived from normal human colonic epithelium, with driver mutations introduced sequentially in the WNT, MAPK, TGF-β, TP53 and PI3K pathways, Ascenção and colleagues found that consecutive mutations produced gradual upregulation of the hydrogen-sulfide-producing enzymes — CBS, and its truncated form in particular, together with CSE and 3-MST. In the more

advanced organoids that upregulation coincided with downregulation of the disposal enzyme SQR, and measured sulfide generation rose. The bioenergetics and the epithelial-mesenchymal transition markers moved with it.

Accumulate the standard colon cancer driver mutations one at a time and the cell progressively turns up its sulfide production and turns down its sulfide disposal. Nobody selected for that. It came along with the drivers.

The commonest enzyme deficiency in the human species is a thiol-maintenance failure

The second exhibit is three panels of glucose-6-phosphate dehydrogenase variants characterized at the molecular level, each with its nucleotide substitution, restriction site change, amino acid replacement and position in the protein. Dozens of named alleles — Mediterranean, Seattle, Chatham, Mahidol, Canton — because G6PD deficiency is the commonest human enzyme defect.

Its mechanism is a sulfur mechanism. G6PD is the entry point of the pentose phosphate pathway and the red cell's only source of NADPH. NADPH is what glutathione reductase uses to keep glutathione reduced. Glutathione is a thiol. When the enzyme is deficient and an oxidative challenge arrives — a drug, an infection, a fava bean — the thiol pool cannot be regenerated, and the cell hemolyzes.

Several hundred million people carry a mutation whose consequence is that they cannot keep a sulfur atom in its reduced state under stress. It is the same chemistry as everything else in this part, at population scale.

The same exhibit also carries the pentose phosphate pathway feeding ribose-5-phosphate into PRPP and thence into de novo purine synthesis. The pathway that supplies the purine ring and the pathway that maintains the thiol pool are the same pathway, branching at one metabolite.

What this section establishes, and what it does not

Established, from clinical and biochemical sources: that molybdenum cofactor deficiency impairs sulfite oxidase, xanthine oxidase and aldehyde oxidase together, presenting as neonatal epileptic encephalopathy with death typically within three years; that its index metabolites include raised hypoxanthine, xanthine, sulfite, thiosulfate and S-sulfocysteine with reduced cystine and urate; that cPMP treats type A and not type B, and that isolated sulfite oxidase deficiency has no treatment;

that xanthinuria types I and II hit the purine arm alone while isolated sulfite oxidase deficiency hits the sulfur arm alone; that ETHE1 is a mitochondrial persulfide dioxygenase whose loss causes ethylmalonic encephalopathy and lowers reduced glutathione; that sequential colon cancer driver mutations upregulate CBS, CSE and 3-MST while downregulating SQR; and that four entries in a standard purine defects table are sulfur enzymes.

Not claimed: that this framework predicted any of these diseases, or that the clinical literature was unaware of the connection. Metabolic physicians have measured sulfite and urate in the same patient for decades and know perfectly well why both are abnormal. What this document adds is only that the same shared-cofactor logic runs backward into the origin argument of Part Fifteen, and that the disease is the test the framework would otherwise have had to design.

Molybdenum cofactor deficiency is Experiment Twenty-one, already performed, by mutation, in human infants. The result is that the purine loop and the sulfur pathway fail together — which is what a shared cofactor predicts and what a coincidence does not.

---

57. What This Organism Is Not, and Which Quantum Claims Survive ↩

Three corrections, issued before a referee issues them

The exhibit is strong enough that it does not need overstating, and three claims that naturally attach themselves to it will not survive contact with a specialist.

Allochromatium vinosum is not an ancestor, and not a founding father. It is a gammaproteobacterium — a derived lineage within Bacteria, not a deep-branching one. Purple sulfur bacteria are a modern group. Nothing in this organism's phylogenetic position supports treating it as a precursor of anything, and describing it as the origin of human genomic or enzymatic reactions would be a straightforward error of the same class this document spends fourteen parts complaining about: mistaking a present-day representative for the object it represents. What is defensible, and is claimed instead, is that anoxygenic photosynthesis using sulfide as electron donor is widely argued to precede oxygenic photosynthesis, and that this organism is the best living model of that chemistry. A model is not an ancestor. The chemistry is old; the bacterium performing it is not.

There is no taxonomic group called sulfur viruses. What exists, and is genuinely interesting, is that viruses infecting sulfur-oxidizing bacteria carry auxiliary metabolic genes for sulfur oxidation, so that a phage can transiently supplement its host's sulfur metabolism during infection. That is a real finding about gene transfer and host metabolic manipulation. It is not a clade, it does not appear in any taxonomy, and calling it one would invite a correction that costs more than the point is worth.

Long-lived quantum superposition in photosynthesis has been substantially withdrawn. This is the most important of the three, because the claim is attractive and the retraction is not widely known outside the field. The original reports of long-lived electronic coherence in the Fenna-Matthews-Olson complex were made largely at cryogenic temperatures. When Duan, Prokhorenko, Cogdell, Thorwart, Miller and colleagues repeated the measurement under physiologically relevant conditions, they found no low-frequency quantum beats with dephasing times beyond about sixty femtoseconds, and concluded that the surviving oscillations are Raman-active vibrational modes on the electronic ground-state surface, unrelated to the energy-transfer process. Their paper is titled, without ambiguity, that nature does not rely on long-lived electronic quantum coherence for photosynthetic energy transfer.

So which quantum claims can this framework make?

claim	status	evidence	what this paper should do
Electron tunneling between redox centers	not contested	rates fall exponentially with distance; this is how every respiratory and photosynthetic chain moves electrons, including this organism's	claim it freely
Proton-coupled electron transfer over long distances	not contested	ribonucleotide reductase moves a radical roughly 35 Å through conserved residues	claim it freely
Proton tunneling in base pairs	contested	five studies, isotope effects differing sixfold, two experiments finding nothing	report both sides, as Part Sixteen does
Long-lived electronic superposition in light harvesting	substantially withdrawn	no coherence beyond about 60 fs at physiological temperature; the beats are vibrational	do not claim it

Quantum biology has three grades of claim and they are not interchangeable. Using the withdrawn one to decorate the solid one would be the same error this paper accuses the codon table of committing.

What this part claims, and what it does not

Claimed: that sulfur is an alpha element produced by oxygen burning in massive stars and in Type Ia supernovae, and not by Big Bang nucleosynthesis; that comet 67P carries hydrogen sulfide, carbonyl sulfide, sulfur oxides, S_2 through S_4 and the first cometary detections of methanethiol and a C_2H_6S species, at a bulk sulfur-to-oxygen ratio near 1.47×10^{-2}; that Murchison delivered alkyl sulfonic acids at roughly 380 nmol per gram against roughly 9 nmol per gram of alkyl phosphonic acids; that the exhibit lists thirty-eight characterized proteins from Allochromatium vinosum including purH, purD, a pyrophosphate-energized proton pump, three classes of iron-sulfur protein, the Dsr sulfur-oxidation system, thioredoxin, CoA biosynthesis, RuBisCO and the GroEL-GroES chaperonins; and that DsrC delivers sulfur to DsrAB on a flexible C-terminal arm bearing two conserved cysteines.

Not claimed: that this organism is ancestral to anything; that sulfonate performed phosphate's function; that pyrophosphate preceded ATP; that sulfur viruses are a taxonomic group; or that superposition plays any established role in biological energy transfer. Each of those is either conjecture, and marked, or withdrawn in the literature and reported as withdrawn.

One protein list, compiled for another purpose, containing the purine root, the glycine step, the thioester currency, the pyrophosphate pump and the folding chaperone — held together by a sulfur metabolism that predates the atmosphere.

PART TWENTY-FIVE · WHAT THE DOGMA DOES NOT SAY

58. A Material-Requirement Model, Set Beside the Information Model ↩

Crick's dogma states which information may flow. It does not state which atoms must be present for any flow to occur.

The position this part argues from, stated so the reader can discount it

This work proceeds from a first-principles position: information has no existence apart from the matter that carries it, and the atomic level is therefore prior to the molecular one in the order of explanation. That position is a starting assumption. It

is not a result of this work, nothing here demonstrates it, and it is stated here only so a reader knows what selected the questions.

The first-principles method meant here is the ordinary one: decompose a system to the quantities physics and chemistry fix, and rebuild the argument from those rather than from convention or analogy. Applied to the genetic code it asks a question the standard account does not: not what the letters say, but what atoms have to be present before any letter can be read at all.

The central dogma is a claim about information flow. This part is a claim about material prerequisite. They are different models, both are needed, and only one is taught.

What Crick claimed, stated precisely, because the objection depends on it

Crick's central dogma is a statement about the impossibility of certain information transfers: once sequence information has passed into protein, it cannot get out again. It is a restriction on directionality, deliberately framed in terms of sequence and not chemistry. That precision is what made it powerful and it is not in dispute here.

What follows from that precision is a silence. A model of information flow says nothing about what has to exist for the flow to happen. It does not name a single atom, cofactor, metal or modification. That silence was a design choice and it was the right one in 1958. Sixty-eight years later the silence is taught as though it were the whole account.

---

59. The Bill of Particulars ↩

Ten things the four-letter alphabet cannot write down. Each is checkable and each is dated.

A general complaint against a notation is worthless. What follows is specific: ten features of real nucleic acids and real proteins for which the alphabet provides no symbol, no annotation and no place. Each entry names what exists, what the notation offers, and the year the gap became undeniable.

One. Sulfur in the DNA backbone. Bacterial dnd clusters replace a non-bridging phosphate oxygen with sulfur, sequence-selectively and stereospecifically, across 1,349 systems and diverse phyla. It is redox-active and alters transcription. The alphabet describes bases; this is on the phosphate. Reported

2007, fifty-five years after the labeling convention that assumed sulfur and DNA do not meet.

Two. Inosine at anticodon position 34. One adaptor reads three codons because a base outside the alphabet occupies the wobble position. Eight codon families depend on it, and a full complement is required to translate low-complexity protein domains. The alphabet has four letters and inosine is not among them. Reported 2021 for the functional requirement.

Three. Thiolation at the same position. 2-thiouridine narrows which codons an adaptor will accept — the opposite operation to inosine, performed by a sulfur atom at C2, at the identical position. Two opposite regulatory acts, one notational blank.

Four. Selenocysteine. The twenty-first encoded residue is read from UGA, a codon that still terminates translation elsewhere in the same message. What disambiguates it is a hairpin downstream, a dedicated elongation factor and a selenophosphate donor. The deciding information is not in the codon and cannot be written in codon notation.

Five. Pyrrolysine. The twenty-second, read from UAG by the same trick with a different downstream element, and assembled from two lysines rather than delivered as a free amino acid.

Six. Hydroxyproline. The letter says proline. A third of the protein in the human body is collagen, and its mechanical function depends on 4-hydroxyproline, a residue produced after translation. The alphabet writes the precursor and the molecule is the product.

Seven. The sulfenyl-amide. Protein tyrosine phosphatase 1B is switched off during insulin signaling by oxidation of its catalytic cysteine to a sulfenic acid, which then forms a covalent bond to a backbone nitrogen. The bond is made and unmade as the mechanism. No letter changes.

Eight. The sugar. Ribose and deoxyribose differ by one oxygen, and that one atom is the difference between the transient message and the permanent archive. A, G and C are written identically in both.

Nine. The phosphorylation state. A nucleotide arrives as a triphosphate and is incorporated as a monophosphate; the difference is the energy that drove the bond. The letter records neither state.

Ten. The mass. Read a one-letter protein sequence literally and the mass overshoots by roughly sixteen percent on the proteome-weighted basis, because the water released at each peptide bond is not recorded. The string is not a mass until the chemistry of the linkage is supplied from outside it.

Ten features. Ten blanks. Every one of them is a real molecule doing real work, and none of them can be written in the notation every student is given in the first week.

What this list does not claim. It does not claim that any of these facts is unknown. Every one is published, most in prominent journals, several decades ago. Specialists in each subfield know their own entry well. What is claimed is narrower and is about attention rather than knowledge: that no single notation holds them, that the notation taught as fundamental holds none of them, and that a student who learns the four letters as the object rather than as a projection of the object will not think to look for any of them.

---

60. The Model: Every Arrow, and What It Cannot Proceed Without ↩

The same diagram, annotated with material prerequisite instead of information flow

The standard diagram has three arrows and names no substance. Here is the same diagram with each arrow annotated by what must be physically present, and by what happens when it is removed. Each row is a falsification condition: knock out the named component and the arrow stops.

arrow	obligate machine	atoms and cofactors it cannot work without	what fails on removal
RNA → DNA	ribonucleotide reductase	S-adenosylmethionine, a [4Fe-4S] cluster, a cysteine thiyl radical, a redox-active cysteine pair	no deoxyribonucleotide is made by any other route in any organism
DNA → DNA	replicative polymerase	two divalent metal ions, dNTP pool held by ITPA and related sanitizers	misincorporation of ITP, dITP, XT and dXTP without the sanitizer
DNA → RNA	RNA polymerase	two divalent metal ions, structural zinc	transcription fails
RNA → protein	the ribosome and its adaptors	magnesium; thiolated and inosine-modified wobble bases; iron-sulfur clusters in several assembly factors	decoding fidelity and speed degrade; specific codon families misread
Regulatory layer	methyltransferases and sulfotransferases	S-adenosylmethionine and PAPS, both adenosine carrying sulfur	methyl and sulfate marks are not placed
Cofactor supply	cysteine desulfurase	one persulfide donor for iron-sulfur clusters, thionucleosides, thiamine,	every arrow above loses a component

arrow	obligate machine	atoms and cofactors it cannot work without	what fails on removal
		biotin, lipoic acid, molybdenum cofactor	

Sulfur appears in five of the six rows. Not as a letter — as a precondition. The information model cannot say that, because it was built not to.

Why this is a model and not a slogan

Each row states a dependency that an experiment can break. That is the difference between this and a claim that sulfur is important. Delete the cysteine desulfurase and iron-sulfur cluster assembly fails, thionucleoside modification fails, and molybdenum cofactor synthesis fails — three consequences, in three different arrows, from one deletion. That is a testable architecture.

And the claim is bounded, because an unbounded version would be worthless. This model does not assert that sulfur is more important than carbon, nitrogen, oxygen or phosphorus, and no such ranking is offered or would mean anything. It does not assert that the atomic level explains the code. It asserts one thing: that a complete account of the central dogma requires a statement of material prerequisite alongside the statement of information flow, that the second has been taught for sixty-eight years without the first, and that sulfur is the element most consistently missing from the second — appearing in five of six arrows while having no representation whatever in the notation.

What would refute this part

i. Demonstrate a deoxyribonucleotide produced by any route not requiring ribonucleotide reductase, and the first row falls.

ii. Show that a full cysteine desulfurase knockout leaves iron-sulfur assembly, thionucleoside modification and molybdenum cofactor synthesis intact, and the last row falls.

iii. Show that the ten items in the bill of particulars can be expressed in four-letter notation without extension, and the whole part falls.

A model that cannot be refuted is decoration. Three refutations are named above, and the first two are bench experiments somebody could run this year.

PART TWENTY-SIX · THE ENERGY BUDGET AND WHAT REMAINS OPEN

61. Where Is the Phosphate? Where Is the Power? ↩

The chemistry has been argued for seventy years almost without reference to what paid for it

Every account of the origin of the code discusses which bases, which sugar, which linkage. Almost none discusses the energy budget, and the energy budget is where the account either closes or does not.

Phosphate is scarce and it is insoluble. On the early Earth, phosphorus is locked in apatite, a calcium mineral of low solubility. Free phosphate concentrations in natural waters are orders of magnitude below what the laboratory syntheses use. Every prebiotic nucleotide experiment ever run has been run at a phosphate concentration the early Earth is not known to have provided.

The proposed escapes are unsettled. Schreibersite, the iron-nickel phosphide delivered in meteorites, corrodes in water to release reduced and far more soluble phosphorus species. Struvite, polyphosphates from volcanic emanation, borate complexation and eutectic freezing concentration have all been proposed. None is established as the route.

Diamidophosphate is the most interesting recent answer. DAP phosphorylates nucleosides, sugars and amino acids in water at ambient conditions, and can drive oligomerization — a single agent operating across all three classes of building block. If a prebiotic source for it holds up, a large part of this problem moves.

ATP cannot have powered its own origin. De novo purine synthesis costs five ATP and closes at IMP. A pathway that consumes five ATP to make the ring that ATP is built from cannot have been the first source of that ring. The first purines must have arrived by another route entirely — delivery, HCN polymerization, formamide chemistry — and the ATP economy is a later overlay on a supply that already existed.

The nitrogen bank was capitalized before it could fund itself.

What drove condensation before ATP

Every candidate is a hypothesis: thioesters, acetyl phosphate, carbonyl sulfide, cyanamide and cyanoacetylene as condensing agents, mineral-surface dehydration,

and wet-dry cycling as an entropy pump. Note what all of them share — none is a nucleotide.

The energy currency of the first chemistry was not the currency the cell settled on.

De Duve's thioester world is the most developed of these, and Part Sixteen gives the orbital reason a thioester can hold energy at all: sulfur offers a 3p orbital against carbon's 2p, the overlap is poor, resonance stabilization largely fails to arrive, and the ground state is left high. That is an explanation of the chemistry. It is not evidence for the history, and the history remains a hypothesis that de Duve never proved.

There is one result here that cuts the other way and belongs in this argument rather than against it. The molybdenum hydroxylases do not take their oxygen from dioxygen. Xanthine oxidoreductase inserts an oxygen atom derived from water, with the metal cycling between Mo(VI) and Mo(IV) and the two electrons leaving separately — to NAD^+ in the dehydrogenase form, which is the original. The entire purine discharge ladder therefore runs in an anoxic world, subject to the molybdenum-availability objection recorded in Part Seventeen.

---

62. The Unresolved Inventory ↩

Everything the four-letter account assumes was solved, listed by the level at which it is still open

Bases

— Cytosine is absent from the Murchison inventory and deaminates on geological timescales, so no delivery argument for it exists. Its prebiotic presence rests entirely on synthesis in the cyanosulfidic route, as cytidine, never as the free base.

— No efficient prebiotic route to β-adenosine or β-guanosine has been demonstrated.

— HCN polymerization yields adenine, but in low yield and inside intractable tars, and the selection of adenine out of that mixture is unexplained.

— Why these five or six heterocycles at all. Prebiotic chemistry offers a large inventory of alternatives, and the basis of the selection is not established.

Sugars

— The formose reaction produces a combinatorial mess in which ribose is a minor and non-privileged component. No prebiotic mechanism is known that yields ribose preferentially.

— Ribose is among the least stable of the common sugars in water. Borate and silicate stabilization have been proposed and neither is settled.

— Why ribose rather than threose or glycerol. TNA and GNA are viable informational polymers and cross-pair with RNA.

— Homochirality. Every biological ribose is D. No prebiotic mechanism producing the necessary enantiomeric excess is agreed upon.

— The C2′ epimer question — arabinose against ribose, one hydroxyl pointing into the major groove rather than the minor — is open, and it is the axis on which the recognition-before-replication argument of Part Seventeen turns.

Nucleosides

— The glycosidic bond is the hardest bond in the problem, and it fails asymmetrically: purines will condense with ribose in the dry state, pyrimidines will not.

— Anomeric selection. Biology uses β exclusively; abiotic glycosylation gives mixtures.

— Regiochemistry. Purines must attach at N9, and adenine's exocyclic N6 competes for the bond.

Nucleotides and backbone

— Which hydroxyl gets phosphorylated — 2′, 3′ or 5′ — and how the 2′,3′-cyclic phosphate the cyanosulfidic route delivers becomes the 5′-activated monomer polymerization requires.

— The 2′,5′ against 3′,5′ linkage problem. Without a mineral surface, non-enzymatic oligomerization gives roughly ninety percent of the wrong linkage.

— Activation chemistry. Laboratory work runs on phosphorimidazolides, which are not themselves prebiotically plausible in the form used. The natural activating agent is unidentified.

— Why a phosphodiester backbone at all, rather than an amide, ester or peptide linkage — each of which is easier to form.

The code itself

— Why triplet, and whether a doublet preceded it. The eight inosine-read four-fold boxes are the strongest surviving evidence that one did.

— Why twenty amino acids, and in what order they were admitted.

— Why this particular assignment of codons to amino acids, rather than any of the astronomically many alternatives.

— The aminoacyl-tRNA synthetases fall into two classes with unrelated folds, implying two independent origins for the one function on which the whole code depends.

---

63. What Correcting It Would Require ↩

Five changes, none of which invalidates a single existing codon assignment

One. Notate at the monomer, not the base. A sequence should specify sugar, linkage and modification state, not just the varying heterocycle. The four-letter string is a compression that was appropriate when the backbone was assumed invariant, and it should be treated as a compression rather than as the sequence itself.

Two. Publish the adaptor-resolved table alongside the codon table. Roughly forty tRNA species, each with its anticodon and its position-34 and position-37 modifications, mapped to the codons it physically reads. That table has no degeneracy in it. It is the process; the sixty-four-cell grid is the projection.

Three. Make modification state a first-class axis. Inosine, lysidine, 2-thiouridine and queuosine are not annotations on a four-letter code. They are what determines the reading.

Four. Add the derivation layer. IMP to AMP by amination at C6; IMP to XMP to GMP by oxidation then amination at C2. The alphabet's members are not peers and the notation should stop implying that they are.

Five. State the boundary conditions of the table explicitly, every time it is printed: this describes extant translation with a uniform ribo backbone and canonical modification. It is not a description of the code's origin and cannot be used as one.

Not one of the five changes a codon assignment. Every one changes what the table is understood to be a table of.

PART TWENTY-SEVEN · NINE EXPERIMENTS THAT WOULD SETTLE IT

64. Where to Point a Real Instrument ↩

Reduced from twenty-seven. Each carries a falsification condition written before the result is known.

Earlier versions listed nine experiments. Most were variations, and a list that long reads as a wish rather than a plan. These nine are the ones that decide something, ordered cheapest first. Four require nothing but public data and compute time.

One. Does the codon predict backbone conformation, given the amino acid? Compute I(codon; φ,ψ | amino acid) over PDB structures at 2.0 Å or better, one chain per 30 percent identity cluster, with coding sequences accepted only on exact translation match. Permute codons within amino acid; report excess over the permutation mean, never the raw value.

Falsification. If the excess is indistinguishable from zero after controlling for GC3 and codon usage, the codon carries no structural information beyond the amino acid, no folding predictor can be built on this framework, and Finding Six as stated here is withdrawn. Public data, no bench, no permission. Pipeline and self-tests accompany this document.

Two. Compute the tunneling ratio for inosine-cytosine by the same method already applied to guanine-cytosine — both by the 2022 open-quantum-system treatment and by the 2025 treatment that disputes it.

Falsification. If the ratio does not differ between the two pairs, the fidelity prediction fails. If the two methods disagree on the sign of the difference, the prediction cannot be supported by either and should be withdrawn until the methods are reconciled. Compute only. No published attempt found.

Three. Are the eight inosine-read codon families enriched in intrinsically disordered and low-complexity regions relative to structured domains, across annotated human proteomes? Torres and colleagues have shown I34 tRNAs are required for low-complexity domain translation; this asks whether the codon-level signature is present.

Falsification. If there is no enrichment, the link between the compression argument and the folding result does not exist and should not be claimed. Compute only.

Four. Measure the IMP dehydrogenase hydride-transfer kinetic isotope effect directly, across a temperature range, with 2-^{2}H-IMP.

Falsification. A temperature-independent isotope effect indicates tunneling; a strongly temperature-dependent one does not. Digits and Hedstrom identified why the effect is invisible in the steady state, so a pre-steady-state approach is required. No published measurement found. Bench, standard enzymology.

Five. Ask whether the molybdenum cofactor really draws on the purine pool. Collapse the guanine nucleotide pool with mycophenolic acid, a licensed drug and a specific IMP dehydrogenase inhibitor, measure molybdenum cofactor and xanthine oxidoreductase activity, then rescue with guanosine.

Falsification. If cofactor levels do not fall, the closed loop of Part Six is not closed and that part should be rewritten as a set of parallel pathways rather than a circuit. Cells, weeks, published assays.

Six. Test whether ITPA is a persistence filter or a damage response. Measure ITP, IMP, XTP and XMP pools by LC-MS in a 94C>A cell line against an isogenic control, under baseline, nitrosative stress, purine starvation with hypoxanthine rescue, and mycophenolic acid blockade. Fit against flux rather than against stress.

Falsification. If the pools track the stress axis rather than the flux axis, ITPA is a repair enzyme, the persistence argument of Part Eighteen has no standing, and the twenty-two count reverts to a coincidence and should be labeled one.

Seven. Melt a tetrad one hydrogen bond at a time, substituting inosine for guanine across a series.

Falsification. Part Three claims a tetrad requires a base armed on both faces and that inosine fails by exactly one contact. If destabilization is not additive in the number of substitutions, the two-face argument is wrong. Inosine phosphoramidites are commercial and circular dichroism melting is routine. Not done as a systematic test of a donor-acceptor prediction.

Eight. Census every covalent sulfur-nitrogen bond in the structural databases, by monomer class.

Falsification. Part Seven reports that sulfur reaches nitrogen in proteins and sugars but not in nucleic acids or lipids. If a systematic search turns up S–N in nucleic acids or lipids at comparable frequency, the two-of-four pattern is an artifact of what has been looked for and Part Seven should say so. Public databases, standard search tooling, no bench.

Nine. Partition the twenty-two residues by delivery against manufacture and ask whether the codon table remembers the difference. Score delivery status from the meteoritic literature at matched analytical sensitivity, then test against codon family size, base composition at positions one and two, and published biosynthetic cost, with a permutation null over residue labels.

Falsification. If delivered and manufactured residues are indistinguishable on all three measures, the codon table carries no memory of the delivery inventory and the seeding argument is decorative. Public data, no bench.

Four of the nine cost nothing but compute time. The framework's only real defense is that it named in advance what would destroy it.

PART TWENTY-EIGHT · THE FULL EXPERIMENTAL PROGRAM

65. Where to Point a Real Instrument ↩

Ordered cheapest first. Every one runs on equipment or software that already exists. Three have never been attempted.

One. Search the sequenced virosphere for isoguanine — the sixth cell of the purine lattice. 2-aminoadenine was hiding in phage genomes until somebody looked, and the tooling that found it exists. The data are already public, so this costs compute time and nothing else. A null result is informative.

Two. Rerun the Surrey open-quantum-system calculation on the inosine-cytosine pair. Same master equation, same bath parameters, one different base. Report the tautomeric occupation probability and the isotope effect.

This experiment now has a structural reason to expect a difference, stated in advance rather than hoped for. Inosine-cytosine has two hydrogen bonds where guanine-cytosine has three, and the missing one is specifically N2-H···O2 — one of the two carbonyl-accepting contacts. The central N1-H···N3

contact, which section 5 identifies as the rate-determining transfer, survives intact. So the prediction is not merely that the numbers differ; it is that the rate-determining step should be comparatively unaffected while the second, charge-compensating move loses a route. A tautomer population that falls without a matching change in the barrier for the first proton would support that reading.

If I:C returns a figure near G:C's 1.73 × 10^{-4}, the inosine fidelity prediction is wrong and should be struck. If it differs but the rate-determining barrier moves as much as the population does, the mechanistic story in section 5 is wrong even though the prediction survives, and section 5 should be rewritten rather than the experiment reinterpreted. Never attempted.

Three. Measure primary deuterium kinetic isotope effects on the IMP dehydrogenase hydride transfer across a temperature range, using 2-^{2}H-IMP. The chemical step must be isolated by pre-steady-state kinetics, and there is a published reason why rather than a methodological preference. Digits and Hedstrom, working on the Tritrichomonas fetus enzyme, found no isotope effect at all on Vm with 2-^{2}H-IMP, and identified the cause: hydride transfer is not rate-limiting. NADH release and E–XMP* hydrolysis are. A steady-state measurement therefore returns a null for a trivial reason and says nothing whatever about tunneling — which is very likely why the measurement was never pursued. The quantity carrying the signature is the temperature dependence of the isotope effect on the isolated chemical step. This enzyme has a multi-billion-dollar drug pointed at it and that number does not exist.

Four. Test whether 2-thiolation suppresses the I:U mispair specifically, not merely the G:U one. If sulfur does not sharpen an inosine-containing duplex, the tolerance-control claim is decorative and should be withdrawn.

Five. Charge a montmorillonite feeding reaction with activated IMP and CMP, or IMP and 2-thio-UMP. It should give longer oligomers and a higher proportion of 3′,5′ linkage than any pairing drawn from the canonical four. If activated AMP and UMP beat it, the seed alphabet is wrong.

Six. Check whether xanthosine's pairing switches across pH 5.5 to 7.5 with a midpoint near its pKa. No switch, and xanthosine is a metabolite standing nearby rather than a member of the code.

Seven. Compare an arabino-backboned, purine-rich oligomer against its ribo equivalent at matched length, measuring Hoogsteen and third-strand capture

rather than duplex stability. If the arabino polymer is worse at recognition as well as at replication, there is no reason to place it first.

Eight. Find an efficient prebiotic route to β-adenosine or β-guanosine passing through neither inosine nor a ribo-amino-oxazoline. That would not disturb inosine's metabolic priority, which is not in dispute, but it would disturb its chronological priority, which is what this paper claims.

Nine. Build the adaptor-resolved table: roughly forty tRNA species, each with its anticodon and its position-34 and 37 modifications, mapped to the codons it physically reads. Then test whether it predicts recoding events — selenocysteine insertion, stop readthrough, programd frameshifting — that the sixty-four-cell grid cannot address without external annotation. Published modification datasets already exist to test against.

Ten. Test whether the eight inosine-read codon families are enriched in intrinsically disordered protein regions relative to structured domains, across a set of well-annotated human proteomes. This is pure bioinformatics on existing data and costs compute time alone. If inosine-decoded codons are preferentially nonoptimal and preferentially disordered, the compression operator of Part Thirteen connects directly to the folding result of Part Twenty, and the two halves of this paper become one argument. If there is no enrichment, that link does not exist and should not be claimed. Never attempted.

Eleven. Census the human proteome for residues with no codon. What fraction of proteins carry at least one post-translationally modified residue that the genetic code cannot specify, weighted by abundance rather than by gene count? Collagen alone suggests the abundance-weighted answer is large. Existing modification databases make this a query rather than an experiment.

Twelve. Replicate the Neurospora synonymous-codon result in a human protein. Take a human protein with a well-characterized intrinsically disordered region, optimize the synonymous codons in that region only, and measure structure and function against the wild-type transcript. If codon optimization has no effect in human cells, the folding claim does not generalize beyond fungi and Part Twenty should be narrowed accordingly.

Thirteen. Compute the tautomer occupation of a 2-thio-substituted pair. Run the same open-quantum-system treatment used for G:C on 2-thiouridine:adenosine, against unmodified uridine:adenosine as the control, and report both the tautomer population and the isotope effect. Two terms

move against each other and the calculation exists to find out which wins: the longer C=S bond widens the barrier and should suppress tunneling, while sulfur's demonstrated willingness to hold a proton deepens the product well and should raise the equilibrium population. If sulfur substitution moves the occupation by less than the method's own uncertainty, the quantum half of the tolerance-control claim is decorative and should be struck. Never attempted.

Fourteen. Compute the inosine prediction twice, by both disputed methods. Experiment Two specifies the open-quantum-system treatment. Run the semiclassical μOMT calculation on I:C and G:C as well. Since the two methods disagree by a factor of six on the G:C isotope effect, the prediction is only safe if they agree on the sign of the I:C minus G:C difference. If they disagree on the sign, the inosine fidelity claim cannot be supported by either and should be withdrawn until the methods are reconciled. Never attempted.

Fifteen. Point the NMR isotope-shift method at a thio pair. Pohl and colleagues used deuterium-induced ^{15}N chemical shift changes, benchmarked against path-integral molecular dynamics, to test for inter-base proton transfer in a guanine-cytosine analog — and found none. The method works and the instrumentation is ordinary. Apply it to a 2-thiouracil:adenine dimer against uracil:adenine. This is the experimental counterpart to Experiment Thirteen and the two should be run together, because a calculation that disagrees with a measurement is more useful than either alone. If the isotope shifts are indistinguishable between the thio and oxo pairs, sulfur does not alter the nuclear quantum behavior and the prediction is wrong. Never attempted.

Sixteen. Rebuild the published quaternionic codon function on a nucleotide basis, with IMP as the root, AMP and GMP derived under named operations, and inosine-34 entering as an operator on the reading rather than as a fifth prime. If four-fold degeneracy emerges from the operator without extra quaternions supplied by hand, the compression argument of Part Thirteen has an algebraic proof. If the construction requires the same ad hoc additions as the base-assigned version, then the degeneracy is not derivable from inosine alone and this paper’s central claim about compression is weaker than stated. This is a desk calculation and costs nothing but attention. Never attempted.

Seventeen. Test whether the one-letter collapse costs prediction. Take any published sequence-to-property predictor for proteins and measure its accuracy separately on proteins that carry heavy post-translational modification against proteins that carry none, matched for length and fold

class. The alphabet cannot express the modified residue, so if accuracy is indistinguishable between the two sets, the erasure described in Part Twenty section twelve is costless and that section should be withdrawn. Collagen is the natural test case: the letter says proline, the molecule is 4-hydroxyproline, and the difference is the entire mechanical function of a third of the protein in your body. This runs on published predictors and published modification databases. Never attempted.

Eighteen. Date the ribonucleotide reductase classes against the oxygen record. The claim in Part Ten, taken from the literature rather than invented here, is that atmospheric oxygen drove the diversification of the enzyme that makes DNA. That is a hypothesis with a date attached and it can be tested: reconcile the phylogenies of the three reductase classes against a dated species tree and ask whether the emergence of the oxygen-requiring class I clusters near the Great Oxidation Event. If class I substantially predates free oxygen, the oxygen-driver reading is wrong and Part Ten should be narrowed to the mechanism and stripped of the history. Public sequence data and published dating methods; no bench required. Never attempted in this form.

Nineteen. Test the 4-thiouridine crosslink model directly. Build an RNA duplex carrying 4-thiouridine on both strands at positions facing each other across the major groove, photocrosslink it with near-ultraviolet light, and then ask two questions of the product: can the strands be separated thermally, and can either strand be copied non-enzymatically while crosslinked? If a sulfur-crosslinked duplex can neither melt nor be read, then sulfur cannot have held an early genome together in this way and the idea is closed for a second and independent reason. If it can melt and be copied, a sulfur-tethered RNA duplex is a live prebiotic possibility and Part Twenty-Two's withdrawal was premature. 4-thiouridine photocrosslinking has been standard tRNA chemistry since the 1980s, so the reagents and the method exist. Never attempted.

Twenty. Make tRNA thiolation and iron-sulfur cluster assembly compete for the same sulfur. Part Fifteen argues that thionucleosides, Fe-S clusters and molybdenum cofactor are all supplied by one cysteine desulfurase through one persulfide. If that supply is genuinely shared and genuinely limiting, then restricting sulfur should force a trade-off rather than an even decline. Grow a bacterium under graded cysteine or sulfate limitation and measure, in the same samples, the 2-thiouridine content of total tRNA by mass spectrometry and the activity of an Fe-S enzyme such as aconitase alongside the activity of a Moco enzyme such as nitrate reductase. A shared-hub model predicts that one

branch is defended and the others are sacrificed, and predicts which. If all three fall together in proportion, the hub is not a bottleneck and the economic reading of Part Fifteen is decorative rather than load-bearing. Standard microbiology, standard LC-MS. Never attempted in this combination.

Twenty-one. Ask whether the molybdenum cofactor really draws on the purine pool. The claim in Part Fifteen is that the enzyme which empties the purine ring needs a cofactor built from a purine, since Moco biosynthesis begins from GTP. That predicts a dependency the loop can be tested for: block the pathway upstream and the cofactor should become scarce. Treat cultured human cells with mycophenolic acid, which inhibits IMP dehydrogenase and collapses the guanine nucleotide pool, and measure cyclic pyranopterin monophosphate and molybdopterin directly, alongside xanthine oxidoreductase and sulfite oxidase activity. Rescue with exogenous guanosine, which restores GMP by the salvage route and bypasses the inhibited step. If Moco intermediates fall with the guanine pool and are rescued by guanosine, the loop is real and closed. If Moco is unaffected, the GTP draw is negligible in vivo and Part Fifteen should say so. Mycophenolate is a licensed drug and the analytical methods are published, so this is the cheapest experiment on the list that tests a structural claim. Never attempted.

Twenty-two. Ask whether the codon carries structural information that the amino acid does not. This is the experiment that decides whether the quaternion apparatus of Part Four predicts anything or only describes, and it runs on public data at no cost.

The framework claims that a nucleotide-level object constrains a protein-level rotation. Standard theory says the opposite, and says it cleanly: the codon fixes the amino acid, the amino acid fixes the local backbone preference, and therefore the codon can carry nothing further. That is a conditional-independence claim, it follows from the data processing inequality if translation is the only channel, and it is exactly testable. Written formally, the null is that the map from codon to structure factors through the amino acid — the conditional mutual information between codon and backbone dihedral, given amino acid identity, is zero. This framework predicts a positive residual. Nothing else in this document states its central claim in a form this sharp.

Method. Assemble every protein in the Protein Data Bank whose exact coding sequence is known and whose structure is solved better than 2.0 Å. For each residue record three things: the specific codon, the amino acid, and the

backbone dihedral pair. Estimate the conditional mutual information between codon choice and binned dihedral given amino acid identity, controlling for flanking residue identity and secondary-structure class, against a permutation null built by shuffling synonymous codons within each family. Resolution bias, organism, and expression host are covariates, not afterthoughts; a positive result that tracks expression host is a codon-optimization artifact and must be excluded before anything is claimed.

The sharper prediction, which is what makes this a test of this paper rather than of the general question. If the compression argument of Part Thirteen is right, the residual information should not be spread evenly across the code. The eight four-fold boxes read by inosine are the compressed ones, and they should show lower conditional dihedral entropy than the two-fold and three-fold families, because an adaptor that collapses four codons into one read collapses four rotational states into fewer. Glycine's four-fold box, the one inosine does not read, is the internal control, and it should behave unlike the other eight. That contrast is the signature; a uniform effect is somebody else's result.

Falsification condition, written before the answer is known. If the conditional mutual information is statistically indistinguishable from the permutation null, then no nucleotide-level constraint on the rotation manifold exists, the quaternion representation is a notation rather than a prediction, and Part Four should be relabeled accordingly and stripped of its predictive language. If the information is positive but shows no enrichment in the inosine-read families, then something real is there and this paper has not explained it, and Part Thirteen should be narrowed to the aliasing claim alone.

Cost: public structures, public coding sequences, a few weeks of compute, no bench and no reagents. Never attempted in this form. It is the cheapest experiment in this document and it is aimed at the largest claim in it, which is the order those two properties should come in.

Twenty-three. Melt a tetrad one hydrogen bond at a time. Part Twenty-Two claims a G-tetrad requires a base armed with a donor and an acceptor on both faces, and that inosine fails by losing exactly one bond per edge. That is a quantitative claim about eight hydrogen bonds and it can be taken apart one at a time.

Synthesize a standard tetramolecular or unimolecular quadruplex — the human telomeric repeat is the obvious vehicle — and prepare a series in which

inosine replaces guanine at one tetrad position, then two, then three, then all four, at each tetrad layer in turn. Measure the melting temperature and the folding and unfolding rates of every member of the series by circular dichroism and by ultraviolet melting, in potassium and in sodium, at matched ionic strength.

The prediction. If the two-face argument is right, the destabilization should be approximately additive in the number of substitutions within a layer, because each inosine deletes one N2-H···O6 contact and the contacts are independent around the ring. It should also be larger for interior tetrads than for the two outer ones, since outer tetrads are already partially unstacked. And a fully substituted I-tetrad should still form, weakly, rather than fail outright — four bonds instead of eight, not zero instead of eight.

Falsification condition, written before the answer. If destabilization is strongly non-additive — if one substitution costs nearly as much as four — then the tetrad is cooperative in a way the bond-counting argument does not capture, and Part Twenty-Two should be restated in terms of cooperative folding rather than additive bonding. If a fully inosine-substituted tetrad does not form at all, the arithmetic overpredicts and the claim that inosine forms a weak tetrad should be withdrawn.

Inosine phosphoramidites are commercial, circular dichroism melting is routine, and pieces of this have been done incidentally for other purposes. It has not been done as a systematic test of a donor-acceptor prediction. Cheap bench work, and it puts a number on the one place in this document where inosine loses.

Twenty-four. Ask whether sulfonate can activate anything. Part Twenty-Two reports that the Murchison meteorite delivered alkyl sulfonic acids at roughly forty times the concentration of alkyl phosphonic acids. That is a fact about abundance, and this document explicitly declines to infer function from it. This experiment is the inference, run as a test rather than asserted as a conclusion.

The question. Both nucleotide polymerization and peptide bond formation are condensations that will not proceed in bulk water unless the monomer is activated in advance. Prebiotic chemists solve this with phosphorimidazolides. If the delivered inventory was forty-to-one in sulfur's favor, the useful question is whether any sulfur leaving group can do the same job — not whether sulfonate can replace the backbone, which it cannot.

Method. Prepare nucleoside 5′-monophosphates activated as alkyl sulfonic anhydrides or mixed sulfonate-phosphate anhydrides, using the C1 to C4 alkyl sulfonic acids Murchison actually delivers rather than an arbitrary sulfonate. Run montmorillonite-catalyzed oligomerization head to head against 2-methylimidazolide activation under identical conditions, and measure oligomer length distribution and the ratio of 3′,5′ to 2′,5′ linkage. Run the same comparison for a simple dipeptide condensation, since Part Twenty argues any candidate currency must serve both arms.

Falsification condition, written before the answer. If sulfonate-activated monomers give no oligomerization above background, sulfur cannot serve as an activating group, the abundance ratio is a fact with no consequence for the origin problem, and Part Twenty-Two should say so and drop the inference entirely. If they oligomerize but only on the nucleotide side, the currency fails the both-arms test of Part Twenty-Six and is no better a candidate than the alternatives already rejected there.

Commercial reagents, published montmorillonite protocols, standard HPLC readout. Never attempted with meteoritic sulfonates.

Twenty-five. Ask whether the sulfur-nitrogen bond really is class-specific, or whether nobody has looked. Section 23 reports that sulfur reaches nitrogen in two of the four monomer classes — in proteins as the sulfenyl-amide and the nitrosothiol, in sugars as N-sulfoglucosamine — and reaches carbon, phosphorus or oxygen in the other two. That is a pattern claim drawn from named examples, and named examples are exactly how a sampling bias hides.

Method. Search the Protein Data Bank and the Cambridge Structural Database for every covalent sulfur-nitrogen contact within a biological macromolecule or its ligands, using a distance cutoff generous enough to include the long nitrosothiol range — 1.4 to 2.0 Å — and filter out crystallographic artifacts, alternate conformations and modeling ambiguity by requiring supporting density. Classify every surviving instance by the monomer class it sits in. Repeat against the glycan structure databases, which the PDB indexes poorly, and against the modified-nucleoside databases, which index thionucleosides well and would show any S–N species immediately.

Falsification condition, written before the answer. If covalent sulfur-nitrogen bonds turn up in nucleic acids or in lipids at a rate comparable to their rate in proteins and sugars, the two-of-four pattern is an artifact of which molecules have been studied, and section 23 should be rewritten as an observation about

research history rather than about chemistry. If the pattern holds, the next question is why — and the pyrimidine argument at the end of section 23, that a ring nitrogen carrying sulfur could no longer serve the Watson-Crick face, becomes a testable structural prediction rather than a remark.

Public databases, standard search tooling, no bench. Never attempted as a systematic census.

Twenty-six. Test whether ITPA is a persistence filter or a damage-response enzyme. Part Twenty-Two argues that the twenty-two-species count is set by two enzymes, and that ITPA is the one holding inosine at the monophosphate as a standing condition rather than as a repair reaction.

The question. If ITPA exists to sanitize adventitious deamination products, its activity should track oxidative and nitrosative load. If it holds IMP at the monophosphate as a standing condition, activity should be substantially load-independent and should scale with purine flux instead.

Method. In a cell line carrying the 94C>A variant alongside an isogenic wild-type control, measure ITP, IMP, XTP and XMP pool sizes by LC-MS under four conditions: baseline, nitrosative stress, purine starvation with hypoxanthine rescue, and mycophenolic acid blockade of IMP dehydrogenase. Fit pool ratios against flux rather than against stress.

Falsification condition, written before the answer. If ITP and XTP pools track the stress axis and not the flux axis, ITPA is a damage-response enzyme, the persistence argument of Part Twenty-Two has no standing, and the twenty-two-species derivation reverts to a coincidence and should be labeled one. Standard cell culture, a published variant, commercial LC-MS methods. No published attempt found.

Twenty-seven. Partition the encoded residues by abiotic availability against biosynthetic manufacture, and ask what the codon table knows beyond the part that is already settled.

What is already settled, and must not be re-tested. The relationship between early abiotic availability and codon-block size is established. The field's consensus list of early residues - alanine, aspartate, glutamate, glycine, isoleucine, leucine, proline, serine, threonine and valine - is drawn from Miller-Urey synthesis and meteorite analysis together, and Trifonov assembled a consensus temporal order from sixty separate criteria in 2000. Run against that classification, the delivered residues carry a mean codon-block size of

3.90 against 2.00 for the rest, one-sided permutation p = 0.0060 over two hundred thousand shuffles. This volume reproduced that result and reports it as a validation of its own classification, not as a discovery.

The question that is open. The 1958 Miller hydrogen sulfide experiment, reported by Parker and colleagues in 2011, shows that methionine is abiotically synthesized when H2S is present and not otherwise. Methionine therefore belongs to a third category that the delivered-or-manufactured split does not contain: residues whose abiotic availability is conditional on one atmospheric species. Selenocysteine may be a second such case, gated on selenium. The question is whether conditionally available residues occupy distinguishable real estate in the codon table from unconditionally available ones.

Method. Classify all encoded residues into three groups rather than two - unconditionally abiotic, conditionally abiotic with the gating species named, and manufactured only. Test codon-block size, base composition at positions one and two, and published biosynthetic cost across the three, with a permutation null over residue labels. Report the effect under every defensible assignment of the conditional group, because the result is known to be sensitive to it: moving methionine from manufactured to available takes p from 0.0060 to 0.0240, and moving cysteine as well takes it to 0.0399.

Falsification condition, written before the answer. If the conditional group is statistically indistinguishable from the unconditional one on all three measures, then atmospheric gating left no trace in the code, the sulfur-availability argument of Parts Six and Twenty-Two has no consequence for codon assignment, and this experiment should report that. If the conditional group is distinguishable, the gating species become a predictor of code structure and the claim can be extended to selenium. Public data, no bench, no reagents. The two-group version has been run and is reported above. The three-group version has not.

Twenty-eight. Ask whether a cell given a letter it did not ask for defends its alphabet the way cyanophage S-2L defends its own. Part One Hundred and One, section 858, establishes that S-2L does not exclude adenine by reading better. Its PrimPol polymerase, crystallized at 1.5 angstroms, incorporates adenine and 2-aminoadenine opposite thymine indifferently, and the exclusion is performed upstream by DatZ, a triphosphohydrolase that destroys dATP and

leaves every other deoxynucleoside triphosphate intact. The letter is set by the composition of the nucleotide pool, not by the fidelity of the machine.

The question. A semi-synthetic organism maintaining an unnatural base pair is in the mirror-image situation: it is holding a letter its own metabolism has no reason to protect. If pool composition is where alphabets are actually decided, the cell should be expected to attack the new letter with the same class of enzyme, in reverse — the housekeeping triphosphatases and pyrophosphohydrolases that exist to keep wrong nucleotides out of nucleic acid.

Method. In a semi-synthetic strain carrying an unnatural base pair, and in an isogenic control, measure by LC-MS the intracellular pool of the unnatural triphosphate against time after transporter shutoff, and measure transcript and protein levels of the nucleotide-sanitizing enzymes — in a human background the inosine triphosphate pyrophosphatase of Part Twenty-Two, in a bacterial background its homologue RdgB and the MutT family. Then delete or overexpress the candidate and re-measure retention of the unnatural pair over generations.

Falsification condition, written before the answer. If unnatural-pair retention is unchanged by deleting or overexpressing every sanitizing enzyme tested, then pool composition is not what limits alphabet size, section 858 has over-read a single phage, and the general claim should be withdrawn and replaced by a statement about S-2L alone. If retention does track sanitizer activity, the constraint on the genetic alphabet is metabolic rather than structural, and Part Seventy's case for eight acquires a mechanism it does not presently have.

This experiment is the counterpart of Experiment One. That one asks whether a fifth letter is hiding in the sequenced virosphere. This one asks what a cell does to a fifth letter when it is handed one. Existing strains, commercial LC-MS, standard genetics. No published attempt found in this form.

Thirty. Ask whether the methyl mark has left a measurable signature in the sulfur panel. Part One Hundred and Three establishes that a methylated cytosine deaminates to thymine rather than uracil, that thymine is invisible to the routine repair that removes uracil, and that C-to-T at methylated CpG accordingly runs ten to fifty times other transitions and accounts for roughly a third of the mutations behind human inherited disease.

The observation that prompts it. Two of the genes this volume tracks were disabled by the same lesion. Human uricase carries CGA to TGA at a CpG in exon two, and CGA is the only codon in the genetic code that becomes a stop codon by mutating a CpG. MOCOS, the sulfurase that installs the terminal sulfur on xanthine oxidoreductase, carries the identical change. Two disablements by one mechanism at opposite ends of one pathway is either a pattern or a coincidence, and this volume has printed it as neither.

Method. Take the volume's own gene set - UOX, MOCOS, XDH, MTHFR, CBS, SUOX, ITPA, IMPDH1 and IMPDH2, and the remainder of the sulfur panel. Count CpG dinucleotides per coding kilobase for each. Compare against control genes matched for coding length and GC content drawn from the same genome, with a permutation null over gene labels. Then, separately, take the reported disease-causing substitutions in those genes from public variant databases and ask whether they fall at CpG sites more often than each gene's own CpG density predicts.

Falsification condition, written before the answer. If the sulfur-panel genes show no CpG enrichment relative to matched controls, and their reported lesions fall at CpG sites no more often than density predicts, then the uricase and MOCOS observations are two coincidences rather than a mechanism, Part One Hundred and Three, section 1100, should say so, and the connection between the epigenetic mark and this volume's pathway should be withdrawn. Public sequence data, public variant databases, no bench, no reagents. An afternoon of compute. No published attempt found in this form.

Thirty-one. Measure how much of a real transcriptome is invisible to the standard sequencing method. Part One Hundred and Four establishes that Illumina RNA-seq converts RNA to complementary DNA by reverse transcription before reading, that the conversion writes every modified base back as one of four canonical letters, and that a modification is therefore detectable only if it perturbs the enzyme. Motorin and Helm state the prerequisite directly in Accounts of Chemical Research 57:275 to 288, 2023: a particular behavior of the modified nucleotide during the reverse transcription step is a prerequisite for its detection.

The question. That is a statement about principle. Nobody appears to have published the consequence as a single number. How many positions in one real transcriptome carry a modification that its own reverse-transcribed sequence does not record?

Method. Take one tissue sample. Sequence it twice from the same RNA preparation: once by standard Illumina RNA-seq with reverse transcription, once by nanopore direct RNA sequencing on the native molecule with no conversion step. Align both to the same reference. Count the positions at which the direct method reports a modification and the reverse-transcribed method reports a canonical base with no anomaly in coverage, mismatch or termination. Report that count as a fraction of covered transcript positions, and break it out by modification class - inosine, N6-methyladenosine, pseudouridine, 2-prime-O-methyl and the rest.

Falsification condition, written before the answer. If the two methods agree at essentially every position, and the direct method finds no modifications the reverse-transcribed method missed, then reverse transcription is not erasing anything at material frequency, this volume has elevated a theoretical concern into a claim it cannot support, and Part One Hundred and Four, section 1100, should be withdrawn. Commercial platforms on both sides, one tissue, no novel reagents. Comparisons of this kind exist for individual modifications. A single figure for the total invisible fraction has not been found.

Thirty-two. Establish what the syn3A modeling approach costs when carried to a cell that actually makes its own nucleotides. Part One Hundred and Five records that the only spatially resolved, fully dynamic whole-cell model in existence is of JCVI-syn3A, a minimal Mycoplasma, and that mycoplasmas cannot synthesize purines or pyrimidines de novo. PRPP, IMP, XMP and orotate are all absent from it, which is the entire subject of this volume. A human cell is roughly fifty-two thousand times its volume and has at least eight compartments to its one.

The question. Is the absence of a compartment-resolved eukaryotic model a computational barrier or simply an unattempted one?

Method. Take the smallest eukaryote with a complete de novo purine and pyrimidine pathway, for which Saccharomyces cerevisiae is the obvious candidate. Scope a spatially resolved model of nucleotide metabolism alone rather than the whole cell: four compartments - cytosol, nucleus, mitochondrial matrix, and the transporters between them. Take geometry from published cryo-electron tomography and pool concentrations from published metabolomics. Report the computational cost as a function of compartment count and volume, and compare it against the published syn3A figures.

Falsification condition, written before the answer. If the cost scales such that a four-compartment eukaryotic nucleotide model is tractable on existing hardware, then the absence of such a model is a matter of nobody having built it, and this Part has been too generous in calling it an open problem. If the cost is prohibitive, the barrier is computational rather than conceptual and should be stated that way. Either answer is worth having. Public geometry, public metabolomics, no laboratory. The question is properly addressed to the group that built the syn3A model.

Twenty-nine. Measure the rotational tunneling splitting of the C5 methyl group of thymine by inelastic neutron scattering. Part One Hundred and Two, section 1103, establishes that a methyl rotor is the one place on a nucleobase where a rotation and a nuclear spin are locked together: a one hundred and twenty degree rotation permutes three identical fermions, so the Pauli principle ties the spatial rotational state to the total nuclear spin state, producing A and E species that do not equilibrate without a paramagnetic center.

The question. The methyl tunneling literature is fifty years deep and has its own review compilation, and a search for a measured splitting for the thymine C5 methyl returned nothing. Thymine should be a favorable case rather than a hard one. The methyl sits on an aromatic carbon, aryl-methyl rotational barriers are low, and a low barrier gives a large tunneling splitting, which is the easy regime to observe. The same methyl is already known to alter spontaneous base-pair breathing in duplex DNA, so it is not a spectator substituent.

Method. Inelastic neutron scattering at microelectronvolt resolution on polycrystalline thymine, then on thymidine, then on a hydrated oligonucleotide containing thymine, at temperatures below about twenty kelvin where tunneling dominates over classical hopping. Report the splitting, and repeat with the methyl deuterated as the control, since a CD3 rotor has a different reduced mass and a different spin statistics and should shift or abolish the peak.

Falsification condition, written before the answer. If no tunneling peak is resolvable in thymine at achievable resolution, the barrier is higher than the aromatic-attachment argument predicts, and section 1105 should say so and withdraw the expectation. If a splitting is found, it is a measured quantum degree of freedom belonging to the one substituent that distinguishes thymine from uracil, and this volume acquires a physical observable at the chemical

level for the base its Part Forty-Five is built on. Neutron beam time at an existing spallation or reactor source. Standard sample preparation. No published attempt found.

PART TWENTY-NINE · STATUS AND STANDING

66. The Scope of the Search Behind Every Negative Claim ↩

Several statements here are negative claims about the literature — that a measurement has not been made, that two fields do not cite each other, that a connection has not been drawn. A negative claim is only as good as the search behind it, so the search is stated rather than implied.

Searched: PubMed and the open web, in English, for the specific compounds, enzymes, effects and pairings named in each claim. Not searched: non-English literature, patents, conference abstracts, theses, paywalled full texts not indexed by abstract, and anything outside the indexing coverage of those sources. No systematic review protocol was followed and no search was pre-registered.

Every negative claim here should be read as: not found in the sources searched. A reader holding a counterexample has refuted it, and that is the correct outcome rather than an embarrassing one.

What this document owes to other people

The evidence assembled here was produced by others. Szostak's group published that efficient prebiotic routes to adenosine and guanosine remain elusive. Sutherland's group worked out the cyanosulfidic route. Orgel measured the glycosylation and regiochemistry. The Surrey group computed the tunneling numbers and Greer, Doubleday and colleagues computed the numbers that dispute them. Markham and colleagues measured the pKa of the IMP dehydrogenase active-site cysteine. Salon, Gan, Abdur, Liu and Huang made 6-selenoguanosine RNA. Torres, Ribas de Pouplana and colleagues established what inosine-34 transfer RNAs are for. Zhou and Yi Liu ran the synonymous-codon experiments. Reichard spent a career on ribonucleotide reductase. Hales proved the honeycomb conjecture and Fejes Tóth showed the bee's closed end is not optimal.

None of it was hidden. What this paper does is connect pieces that were published separately, and the connection may be wrong.

Reproducing the computations

Three Python modules accompany this document, each running on the standard library alone and each carrying a self-test mode that validates every statistic against fixtures with known answers. The face encoding and hydrogen-bond verification; the backbone quaternion and folding statistics; and the Experiment One pipeline with its conditional mutual information and permutation null. A statistic that cannot be checked against a known answer should not be believed, including when it agrees with the author.

PART THIRTY · THE BOND THAT PREDATES THE PLANET

---

68. The Amide Bond Arrived From Interstellar Space ↩

The linkage that holds every protein together is older than the Earth, and it was not manufactured here

A precision first, because the argument depends on it and because the objection is easy to raise. The alpha-amino group of a free amino acid is –NH_2. The peptide bond is a secondary amide, –C(=O)–NH–: on condensation the amino nitrogen surrenders one hydrogen to water and retains the other. Both structures carry a nitrogen–hydrogen bond, and both are amide chemistry. Nothing in what follows turns on conflating them, and nothing in what follows requires it.

Formamide: the amide bond, in the interstellar medium, since 1971
Formamide, NH_2CHO, is the smallest molecule that contains an amide bond. It was first detected in the interstellar medium in 1971, toward the high-mass star-forming region Sagittarius B2, and has since been observed in massive and low-mass young stellar objects throughout the galaxy.

It is also present in comets. Gas-phase formamide has been measured in the comae of Lemmon, Lovejoy and Hale-Bopp at abundances near 0.01 to 0.02 percent relative to water. On comet 67P/Churyumov-Gerasimenko the COSAC mass spectrometer aboard Rosetta's Philae lander reported formamide at 1.8 percent with respect to water.

On that comet, formamide was the second most abundant molecule measured, after water itself.

This is a stronger statement than the familiar one about amino acids in meteorites. It does not require that any amino acid survived a journey. It states that the chemical linkage on which all protein is built exists in cold molecular clouds, in star-forming regions, and in the ice of comets — and that it existed there before the Earth condensed.

What this establishes, and what it does not. It establishes that amide chemistry is a general property of carbon-nitrogen-oxygen material in the galaxy and not a terrestrial invention. It does not establish that terrestrial peptides descend from interstellar formamide by an unbroken line, and no claim of descent is made here. The claim is one of priority and of universality: the bond was available everywhere, before here.

---

69. The Handedness Arrived With It ↩

Meteoritic amino acids are not racemic, and the excess runs in the direction life took

The Murchison and Murray carbonaceous chondrites carry amino acids that are not present in equal amounts as left- and right-handed forms. Cronin and Pizzarello reported in 1997, and Pizzarello and Cronin extended in 2000, L-enantiomeric excesses of roughly three to fifteen percent in a set of non-protein alpha-dialkyl amino acids: isovaline, alpha-methylnorleucine, alpha-methylvaline, alpha-methylnorvaline and alpha-methylisoleucine.

species	measured excess	why contamination is excluded
Isovaline	≈9% L-excess, measured as high as ≈20%	the most abundant optically active amino ac these meteorites
α-methylnorleucine, α-methylvaline	within the 3–15% L-excess range	rare or absent in terrestrial biology
α-methylnorvaline, α-methylisoleucine	within the 3–15% L-excess range	rare or absent in terrestrial biology

Two independent controls exclude terrestrial contamination. The alpha-dialkyl amino acids in question are rare or non-existent in life on this planet, so there is no obvious terrestrial source to contaminate with. And stable carbon and hydrogen isotopic measurements made separately on the D- and the L-enantiomers are non-terrestrial in both.

The handedness did not begin on Earth. It arrived already leaning, and it leaned the way biology went.

Section 12 of this volume set out the crystallographic side of the same question: alpha-quartz is enantiomorphic, its handedness arising from a helical arrangement of achiral SiO_2 units, and across a survey of 27,053 crystals the mineral is racemic on a global basis. Enantioselective adsorption of amino acids on quartz was observed as early as 1935, proposed as an origin of homochirality in 1938, and demonstrated by Bonner in 1974 and 1976 with D-alanine binding D-quartz at up to twenty percent enantiomeric excess. Recent work reports racemate resolution on homochiral quartz as high as fifty-five percent.

The mineral kept both hands. Life kept one. Quartz on this planet is racemic in aggregate. Meteoritic alpha-dialkyl amino acids are not. Terrestrial biology is not. The asymmetry therefore has at least one demonstrated extraterrestrial source and at least one demonstrated mineral mechanism, and the two are not exclusive. Bonner's own caveat stands and is repeated here: his adsorption experiments required anhydrous conditions that are difficult to credit on the early Earth.

---

70. Translation Begins at Sulfur ↩

The universal start codon specifies a sulfur amino acid, and there is no protein that begins otherwise

AUG is the initiation codon in every domain of life. It specifies methionine, and in bacteria, in mitochondria and in chloroplasts it specifies formylmethionine. Methionine carries a thioether sulfur in its side chain.

AUG → methionine → the first residue of every nascent polypeptide

The consequence is not decorative. Protein synthesis does not merely make use of sulfur at some later stage, in a disulfide bridge or an iron-sulfur cluster or a catalytic cysteine. The first residue of the first protein and of every protein since is a sulfur amino acid. Initiation is a sulfur event.

The genetic code does not begin at a letter. It begins at an atom, and the atom is sulfur.

This is inseparable from the central dogma as the dogma is ordinarily stated. If information flows from DNA through RNA to protein, then the first act of the last arrow is the placement of a sulfur-bearing residue, directed by a codon, carried by an initiator transfer RNA. Remove sulfur and the arrow does not run short — it does not start.

On the strength of this claim. Methionine initiation is a requirement of protein synthesis as it is universally observed; it is not offered here as a proof of the central dogma, which is a model supported by evidence rather than a theorem. The precise statement is that the dogma's third arrow cannot be executed without sulfur, and that no exception has been reported in any domain.

---

71. Six Elements, and Where Selenium Actually Sits ↩

Six of the seven are the standard inventory of life; the seventh earned a codon

Six elements — hydrogen, carbon, nitrogen, oxygen, phosphorus and sulfur — constitute roughly ninety-seven to ninety-nine percent of the mass of living matter and are conventionally abbreviated CHNOPS. This volume works from seven, adding selenium, and the addition requires a warrant beyond abundance, because selenium is a trace element by mass.

element	atomic number	channel	base
Hydrogen	1	red	adenine
Carbon	6	blue	cytosine
Nitrogen	7	green	guanine

element	atomic number	channel	base
Oxygen	8	orange	inosine
Phosphorus	15	violet	uracil
Sulfur	16	yellow	thymine
Selenium	34	indigo	xanthine

The warrant for selenium is that it is the only element on this list outside the standard six that is written into the genetic code itself. Selenocysteine is the twenty-first proteinogenic amino acid. It is not inserted by a dedicated codon but by recoding: a UGA triplet that would otherwise terminate translation is read as selenocysteine when a selenocysteine insertion sequence element is present in the messenger RNA.

Selenium is the one element here that did not merely participate in life. It obtained a codon.

It is also the element directly beneath sulfur in group sixteen, one shell out, and the relationship between the two is the subject of Part Twelve of this volume.

---

72. Sulfur in the Stars, and the Sulfur That Cannot Be Found ↩

The tenth most abundant element in the universe goes missing precisely where planets are made

Sulfur is the tenth most abundant element in the universe, with a cosmic abundance near S/H = 1.35×10^{-5}. It is produced during hydrostatic and explosive oxygen burning in massive stars and in Type II supernovae. Its presence in the Milky Way and in other galaxies is not in question.

What is in question is where it goes. Measurements in the diffuse interstellar medium recover the full cosmic abundance in the gas phase. Measurements in dense molecular clouds — the cold, shielded regions in which stars and planetary systems actually form — recover a small fraction of it. The gas-phase abundance in these regions falls short of prediction by approximately three orders of magnitude.

In the places where worlds are assembled, on the order of ninety-nine percent of the expected sulfur cannot be accounted for.

This is a live and named problem in astrochemistry, the missing sulfur problem or sulfur depletion problem, with work continuing through 2026. The leading explanation is that the missing inventory is locked onto the icy mantles of dust grains, and searches for the responsible reservoir species have set upper limits on H_2S_2, HS_2 and S_2 in warm cores without closing the account.

Why this belongs in a volume about the genetic code. It is stated here as an open question and not as support. If the sulfur budget of a star-forming region is unaccounted for at the level of three orders of magnitude, then the sulfur inventory available to a forming planetary system is not a settled quantity, and any prebiotic model that assumes a known sulfur supply is assuming something the observations do not yet supply. This weakens confident modeling in every direction, including this volume's.

73. Three Jurisdictions, Arriving Separately at the Same Floor ↩

The principle that what nature made cannot be owned by whoever found it is already written into law on two continents

The chemistry above is prior to any human institution, and it is not the business of a scientific volume to say what follows morally from that. It is within the business of this volume to record that three legal systems, acting independently and without coordination, have already reached the same floor.

instrument	status	operative language
UNESCO Universal Declaration on the Human Genome and Human Rights	1997, adopted unanimously by 77 delegations	Article 1: the human genome is, in a symbolic sense heritage of humanity. Article 4: the human genome its natural state shall not give rise to financial gains
Convention on Human Rights and Biomedicine (Oviedo Convention), Council of Europe	signed 4 April 1997, in force 1 December 1999	Article 21, Prohibition of financial gain: the human and its parts shall not, as such, give rise to financia gain.
Association for Molecular Pathology v. Myriad Genetics, United States Supreme Court	decided 13 June 2013, unanimous, Thomas J.	A naturally occurring DNA segment is a product of nature and not patent eligible merely because it ha been isolated. Synthetic cDNA is patent eligible bec it is not naturally occurring.

The reasoning in Myriad is worth quoting exactly, because it states the principle in the plainest available English. Myriad did not create anything; it found an important and useful gene, and separating that gene from its surrounding genetic material is not an act of invention.

A United Nations body, a European treaty and the Supreme Court of the United States were not consulting one another. They arrived at the same place from three directions.

The bearing on this volume is narrow and should not be overstated. Nothing in the law affects whether the chemistry described in Parts One through Twenty-Nine is correct. What the convergence establishes is that the category the law calls a product of nature is not a rhetorical device: it is an operative legal category, recognized across jurisdictions and political systems, into which the amide bond, the seven elements and the genetic code plainly fall.

What is claimed and what is not. No claim is made here about the moral status of the peptide bond, which is not a scientific question and cannot be settled by measurement. What is claimed is factual and checkable: the bond is older than this planet, it arrived from interstellar space, it arrived with a handedness bias in the direction biology took, it is present in every organism that has ever been examined, its first placement in every protein is directed to a sulfur amino acid, and the legal category covering things no person invented already exists in three independent jurisdictions.

PART THIRTY-ONE · THE THEORY OF THREE

---

74. Three Is Not a Pattern. It Is a Minimum. ↩

Two independent proofs that three is the floor — one geometric, one arithmetic — and neither is an analogy

Tesla held that a full understanding of three, six and nine would give a good understanding of universal principles. This framework took that literally and went down into the number three, and what it found is not a resemblance running through nature but a floor beneath it. Everything in nature that is solid and whole has three parts. The claim is testable, and in two places it is provable.

First proof: three is the minimum for rigidity

The triangle is the only polygon that cannot deform. Fix the three side lengths and the shape is determined; there is no remaining freedom. Fix four lengths and the

figure flexes — a quadrilateral with rigid sides is still a hinge. This is why every truss, every geodesic dome and every space frame ever built is triangulated, and it is rigid body mechanics rather than metaphor.

Two points define a relationship. Three points define a structure. The third element does not continue the sequence — it fixes the shape.

Three points also define a plane, and three atoms define a frame in space. Below three there is a line, and a line has no orientation in the world.

Second proof: three is the minimum for a sufficient code

The genetic code is written in a four-letter alphabet and must specify twenty amino acids. The arithmetic admits no negotiation.

codon length	capacity	verdict
one-letter word	$4^1 = 4$	insufficient — $4 < 20$
two-letter word	$4^2 = 16$	insufficient — $16 < 20$
three-letter word	$4^3 = 64$	sufficient — $64 \geq 20$, with room to spare

Nature did not select the triplet codon from among the available options. Three is the shortest word capable of carrying twenty amino acids. It is the floor, not a choice.

Why the two proofs matter together. One is a statement about matter in space and one is a statement about symbols in an alphabet, and they are logically unrelated. They arrive at the same number. Three is simultaneously the minimum for structure and the minimum for sufficiency in code. Every further instance in this Part is an instance and not an independent proof, and is presented as such.

---

75. Ogston's Three Points, and Why Two Cannot Distinguish a Hand ↩

An enzyme requires three simultaneous contacts to tell left from right; this has been the standing model since 1948

In 1948 A. G. Ogston addressed a paradox in the citric acid cycle. Citrate is a symmetric molecule, and its two identical arms ought to be indistinguishable to any enzyme acting on it. They are not: the enzymes of the cycle act on one and not the other.

Ogston's resolution was geometric. The substrate makes a three-point landing on the enzyme surface. Three simultaneous points of contact place two otherwise identical substituents into two different environments, and the distinction becomes available. One enantiomer of a chiral substrate can bind at three sites; its mirror image cannot bind at the same three.

two points of contact → the mirror image binds identically three points of contact → the mirror image cannot

Three is the minimum number of contacts required to specify handedness. Below three, chirality is invisible to the enzyme.

The model has stood for more than seventy-five years with only minor alteration. A four-point refinement has been proposed, in which an additional attachment accounts for enzymatic attack above or below the plane the first three points define. That refinement does not displace three. Three points fix the plane; a fourth chooses a side — which is the same relationship the quaternion holds between its three imaginary units and its real component.

What this establishes. It establishes that stereospecificity in enzymology has a minimum contact number and that the number is three. It does not establish that all enzyme recognition is three-point, and single-point and two-point binding events are common where no chirality must be resolved. The claim is confined to the discrimination of handedness.

---

76. Lock and Key Is Not Enough, and the Correction Favors Rotation ↩

Fischer's 1894 picture has been superseded twice, and both successors describe motion rather than fit

Emil Fischer proposed the lock-and-key model in 1894, and it remains the image most people carry: a rigid substrate entering a rigid site. It has been superseded twice, and both corrections move in the same direction.

model	origin	what it says
Lock and key	Fischer, 1894	rigid site, rigid substrate, static complementarity
Induced fit	Koshland, 1958	the enzyme changes conformation on binding; the site is formed by the encounter
Conformational selection	modern	the enzyme already samples an ensemble; the substrate selects a pre-existing conformer

Both successors describe an enzyme in motion. Neither can be expressed as a static shape complementarity, because in both the shape is a function of time and of the encounter. What is being described in each case is conformational change — that is, rotation about bonds.

The correction to lock and key is not a retreat from geometry. It is the discovery that the geometry rotates.

---

77. Protein Structure Is Stored in Rotations, Not in Coordinates ↩

The variable of protein conformation is an angle; the position is downstream of it

A protein backbone is not held as a list of positions. It is held as a chain of torsion angles: phi about the N–Cα bond, psi about the Cα–C bond, and omega about the peptide bond itself. These are rotations. The Cartesian coordinates of every atom are computed from them, never the reverse.

The Ramachandran plot, which every structural biologist works from, is a map of two of those angles against each other. It is a picture of rotation space. Section 12 of this volume established that glycine occupies regions of that space forbidden to every other residue; that statement has no meaning in a coordinate description, because forbiddenness is a property of the angles.

Anyone modeling a protein in raw x, y and z is working one derivation downstream of the variable that actually carries the structure.

---

78. AlphaFold Left Flatland, and Its Atomic Unit Is a Triangle ↩

The most successful structure predictor ever built is constructed on the rotation group, and it had to be

This is not an argument from principle. It is a matter of published architecture.

AlphaFold2's structure module does not operate on Cartesian coordinates. It represents each residue as a rigid body frame, and the frame is defined by a triangle: the nitrogen, the alpha carbon and the carbonyl carbon of that residue.

Across eight blocks the network predicts, for each residue, a relative rotation and a relative translation of its frame.

component	what it is	why it matters here
The unit of geometry	a rigid body frame per residue	the N–Cα–C triangle: three atoms
The quantity predicted	rotations and translations of frames	not positions
The attention mechanism	Invariant Point Attention	explicitly SE(3)-equivariant
The meaning of SE(3)-equivariance	rotating the whole protein changes nothing	the rotation group is built into the architecture

The best protein predictor ever constructed could not be built in three Cartesian dimensions. It had to be built on rotations — and its smallest unit of geometry is three atoms, because three points are the minimum that define a frame in space.

The Flatlander criticism advanced in this framework — that a description confined to position coordinates cannot recover a structure whose real variable is rotation — is therefore not a complaint against the state of the art. The state of the art already conceded it, in the architecture, and only succeeded after it did.

The limit of this argument. That AlphaFold is built on SE(3) does not show that the framework's three-axis architecture is correct. It shows something narrower and still useful: that rotational structure had to be represented explicitly before the folding problem yielded, and that a purely coordinate-based representation was tried and was not sufficient. That is a fact about the field's own history, and it is checkable.

---

79. Where Three Breaks Prediction, and Why That Is Not a Counterexample ↩

Two bodies are integrable and three are not; the discontinuity falls at exactly the same number

The two-body problem has an exact closed-form solution. The three-body problem does not, and this is a theorem rather than an absence of effort. Bruns proved in 1887 that no further algebraic first integrals exist beyond the ten classical ones; Poincaré proved in 1890 that no further analytic first integral exists either. What

remains is chaos: deterministic dynamics with sensitive dependence on initial conditions.

It should be recorded that this is not a matter of notation, and that a change of coordinates cannot repair it. Quaternions are in fact the correct instrument for this domain — Kustaanheimo–Stiefel regularization, 1965, built on spinor theory, removes the collision singularity, and the quaternionic formulation is standard in celestial mechanics and astrodynamics. It does not make the system integrable, because integrability is a property of the flow and not of the coordinates chosen to describe it. Sundman produced a convergent series solution in 1912 that is useless in practice because it converges too slowly, and that too was achieved without quaternions.

The discipline this volume applies to itself. Part Seventeen of this volume refuses the temptation to write sulfur as the real component of a quaternion with carbon, nitrogen and oxygen as its imaginary units, on the grounds that a quaternion requires three mutually orthogonal quantities of the same kind and that no product rule exists under which carbon multiplied by nitrogen gives oxygen. The same discipline forbids claiming that quaternion notation dissolves the three-body problem. A framework whose central charge is that the notation has been mistaken for the material cannot make that error in the opposite direction.

The three-body result is nonetheless evidence for this Part rather than against it. Two bodies are solvable. Three are not. The discontinuity in the entire subject falls at exactly three — the same number at which rigidity appears, at which a code becomes sufficient, and at which handedness becomes visible to an enzyme.

The third element does not continue the sequence. It opens a dimension, and everything that opens a dimension costs something. Here the cost is closed-form prediction.

---

80. The Same Triad in the Behavior of Agents ↩

Persecutor, persecuted and defender: the roles rotate, and the model is fifty-eight years old

The author's professional discipline is industrial and organizational psychology, and the triad appears there under a name. Stephen Karpman, a student of Eric Berne, published the drama triangle in 1968 in Fairy Tales and Script Drama Analysis: three roles, Persecutor, Victim and Rescuer, which are not fixed positions but

rotating ones. The persecutor becomes the victim; the rescuer becomes the persecutor. Karpman, a member of the Screen Actors Guild, chose the word drama over conflict deliberately.

domain	the first two roles	the third
Family	father criticizes the child	the mother defends
Geopolitics	one state attacks another	a third comes to its defense
Enzymology	substrate is attacked	cofactor or chaperone stabilizes
Redox	oxidant	reductant, and the species that buffers between them

The instance closest to this volume's subject is glutathione, which is a tripeptide — gamma-glutamate, cysteine, glycine — and the principal redox buffer of the cell. Its working end is the cysteine sulfur. Three residues, and the middle one carries the element.

What is claimed here and what is not. The recurrence of a three-role dynamic across family systems, geopolitics and chemistry is an observation about the framework's usefulness as a descriptive instrument. It is not offered as evidence that the same mechanism operates in all three, and no such mechanism is proposed. Sections 74 and 75 carry the load of this Part; this section illustrates it.

---

81. The Inventory of Threes, Marked for What It Is ↩

Two proofs, and a list; the list is not a proof and is not presented as one

where	the three	status
Codon	three bases specify one amino acid	PROOF — three is the arithmetic minimum
Triangle	the only rigid polygon	PROOF — three is the geometric minimum
Ogston attachment	three contacts to resolve a hand	PROOF — two contacts cannot
Nucleotide	base + sugar + phosphate	instance
Glutathione	γ-Glu + Cys + Gly, the cell's redox buffer	instance
Chalcogens	O 8, S 16, Se 34	instance
Atom	proton, neutron, electron	instance
Baryon	three quarks, three color charges	instance
Matter	three generations	instance
Life	Bacteria, Archaea, Eukarya	instance
Termination	UAA, UAG, UGA	instance

where	the three	status
Transcription	RNA polymerase I, II, III	instance
Reading	three frames per strand	instance
The dogma's RNAs	mRNA, tRNA, rRNA	instance
Phase	solid, liquid, gas	instance
Space	x, y, z	instance
Rotation	SO(3), of rank three	instance
Quaternion	i, j, k about one real	instance
Protein torsion	phi, psi, omega	instance
AlphaFold frame	N, Cα, C	instance
Narrative	beginning, middle, end	instance
Roles	persecutor, persecuted, defender	instance

The column on the right is the point of the table. Three of these are proofs. The rest are instances, and a reader is entitled to know which is which before deciding what the framework has established.

PART THIRTY-TWO · THE JOIN

---

82. The Only Place a Nucleic Acid Is Bonded to an Amino Acid ↩

Twenty enzymes hold both languages at once; everything else in the cell copies, reads or folds

This volume has argued from the first page that the four-letter alphabet is a notation and that the atoms are the material. There is one place in the cell where that distinction stops being an argument and becomes a chemical bond, and this Part is about that place.

An aminoacyl-tRNA synthetase attaches an amino acid to a transfer RNA. There are twenty of them in a human cell, one for each amino acid of the code. Nowhere else in biology is a nucleic acid covalently joined to an amino acid. Replication copies a nucleic acid onto a nucleic acid. Transcription copies a nucleic acid onto a nucleic acid. The ribosome joins amino acids to amino acids. Only the synthetase crosses between the two worlds, and it crosses by making a bond.

The codon table is a description of what the synthetases do. It is not the thing that does it.

Why this matters to the framework. If the assignment of meaning to a codon were carried by the letters themselves, the table would be self-enforcing. It is not. The assignment is carried out by twenty proteins, each of which must recognize a particular transfer RNA and load it with a particular residue. Alter one of those proteins and the meaning of a codon changes while the letters stay exactly as they were. That is the strongest available demonstration that the notation and the material are two different things, and it is not a philosophical claim — it is enzymology.

---

83. The Charge Is Literal: Two Steps and Two Phosphate Bonds ↩

The word charging is not a metaphor borrowed from batteries; the chemistry is a stored and later spent energy

The reaction runs in two steps and it spends adenosine triphosphate.

1. amino acid + ATP → aminoacyl-adenylate (aa-AMP) + PPi 2. aa-AMP + tRNA → aminoacyl-tRNA + AMP

In the first step the alpha-carboxylate oxygen of the amino acid attacks the alpha-phosphate of ATP, with magnesium present, forming a mixed anhydride that stays bound to the enzyme while inorganic pyrophosphate is expelled from the active site. This step carries the specificity for the cognate amino acid.

In the second step the activated amino acid is transferred from the adenylate onto the ribose hydroxyl of the terminal adenosine of the transfer RNA, and AMP is released.

quantity	value	meaning
ATP consumed	one, to AMP	two high-energy phosphate bonds spent
The destination of the energy	the aminoacyl ester bond	the charged state of the adaptor
The place it is spent	the ribosome	discharged into the peptide bond

The tRNA is charged, carried, and discharged. The battery is not an analogy imported from the outside — it is the accounting the biochemistry itself uses.

---

84. The Address and the Port Are Seventy-Five Angstroms Apart ↩

Position 34 says which codon; A76 carries which amino acid; the enzyme spans both

A transfer RNA folds into an L. At one end of the L is the anticodon loop, and position 34 within it is the wobble base — the position this volume has returned to repeatedly, where inosine reads three codons and refuses guanosine. At the other end of the L is the acceptor stem, terminating in the sequence CCA that every transfer RNA carries, whose final residue is adenosine 76.

The amino acid does not attach at position 34. It is esterified onto A76, on the far arm of the molecule, roughly seventy-five angstroms away.

site	what it is	what it determines
Position 34	anticodon wobble base	decides which codon is read
A76	3'-terminal adenosine of the CCA end	carries which amino acid is delivered
Class I synthetases	attach to the 2'-OH of A76	approach the acceptor stem from one face
Class II synthetases	attach to the 3'-OH of A76	approach from the other

And the enzyme reads one end in order to service the other

Many synthetases identify their correct transfer RNA by reading the anticodon, and then act at the acceptor end. The domain that performs the reading has a name and a family: the DALR anticodon-binding domain, cataloged in Pfam, and present in the cysteinyl-tRNA synthetases among others.

Position 34 is the address. A76 is the charging port. The synthetase is the station, and it holds both ends of the molecule at once. That is what makes it the join.

The correction this section makes, stated plainly. It would be natural, having followed inosine to position 34 through several parts of this volume, to expect the amino acid to arrive there. It does not. Recognition and loading occur at opposite ends of the same molecule, and the enzyme bridges them. The framework is not

weakened by this; the bridge is a better object than the coincidence would have been.

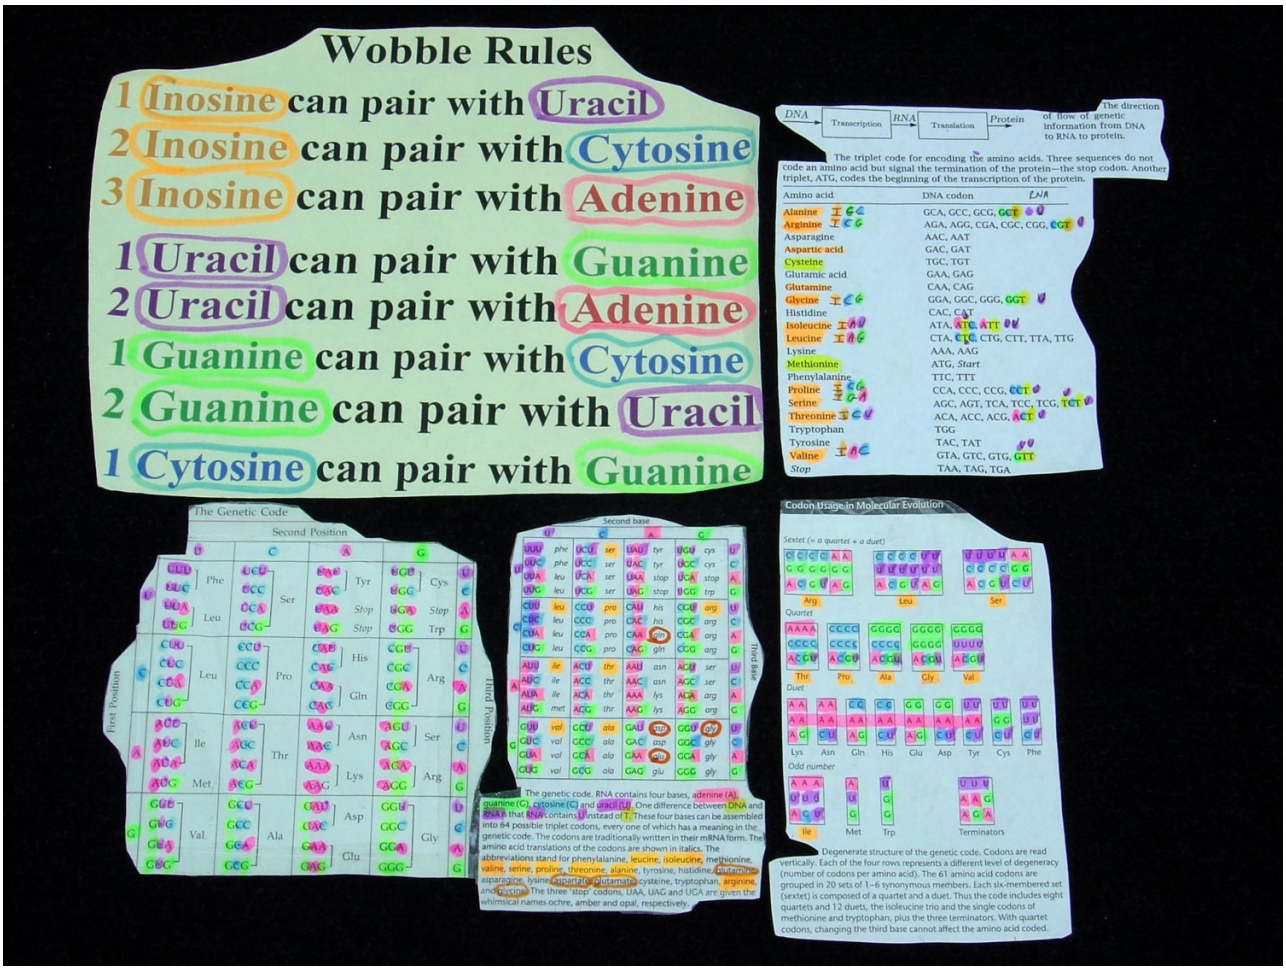

FIGURE 2 · THE WOBBLE RULES, COLOR-CODED

Inosine pairs with uracil, with cytosine and with adenine — three partners from one base, which is why a single adaptor can read three codons. Guanine, uracil and cytosine are shown with their own permitted pairings beneath. Assembled by the author from the standard tables and color-coded to the index used throughout this volume.

85. There Is a Sulfur Atom at the Wobble Position ↩

2-thiouridine at U34, delivered by cysteine desulfurase down a relay of sulfur-carrier proteins

The wobble position is not always an unmodified uridine. In the transfer RNAs for lysine, glutamate and glutamine it carries 2-thiouridine — s2U34, and in its fully modified form mnm5s2U34. A sulfur atom stands at carbon 2 of the ring, at the position that reads the codon.

The modification is not decorative. Sulfur at the wobble uridine is required for correct codon and anticodon binding, and its absence permits frameshifting during translation. The reading of the message depends on it.

Where the atom comes from, and it is this volume's own donor

The sulfur originates in L-cysteine. The cysteine desulfurase IscS, using pyridoxal-5'-phosphate, abstracts the sulfur and holds it as an enzyme-bound persulfide on its own active-site cysteine. From there it is handed down a chain of small sulfur-carrier proteins, each passing the atom by way of its active-site cysteine, until it reaches the enzyme that installs it.

$$L\text{-}cysteine \rightarrow IscS \rightarrow TusA \rightarrow TusBCD \rightarrow TusE \rightarrow MnmA \rightarrow C2\ of\ U34$$

Recent work places a four-iron four-sulfur cluster on MnmA, the enzyme that performs the final insertion — so the delivery of one sulfur atom to the wobble position may itself be carried out by a protein holding an iron-sulfur cluster.

Part Nineteen of this volume described cysteine desulfurase as a single donor feeding four destinations. This is the fifth, and it is the wobble position of the genetic code.

---

86. Sulfur at Both Ends of the Same Molecule ↩

Thiolated uridine reads the codon; cysteine and methionine ride as cargo; the synthetase spans the distance

Assembling the preceding three sections gives a single structure, and it is the closing statement of this volume's argument.

where	what the sulfur is	what it does there
Position 34, the anticodon end	2-thiouridine — a sulfur atom in the ring	reads the codon; without it the frame slips
A76, the acceptor end	cysteine and methionine among the cargo	the sulfur amino acids, esterified and carried
Between them	the aminoacyl-tRNA synthetase	reads one end, charges the other, spends ATP

Methionine is the first residue of every protein ever synthesized, placed there by the initiator transfer RNA at the AUG codon. It is delivered by methionyl-tRNA synthetase. Cysteine, the other sulfur amino acid and the donor of the atom that

modifies U34, is delivered by cysteinyl-tRNA synthetase — the family in which the DALR anticodon-binding domain is cataloged.

Sulfur reads the codon at one end of the adaptor and rides it at the other, and a single enzyme holds both while spending the energy of two phosphate bonds to load the charge.

What is claimed here, and what is not. Claimed: that the aminoacyl-tRNA synthetases are the unique covalent junction between nucleic acid and amino acid; that the aminoacylation reaction is energetically a charging step, spending ATP to AMP and storing the energy in an ester bond later spent at the ribosome; that recognition and loading occur at opposite ends of the transfer RNA; and that sulfur is present at both, as 2-thiouridine at U34 and as the cysteine and methionine cargo. Every one of these is established biochemistry and is cited as such. Not claimed: that the sulfur at position 34 and the sulfur amino acids at A76 constitute a designed pairing, or that either is evidence for the other. They are two independent facts about the same molecule, and the framework gains nothing by asserting a connection the literature does not report.

---

87. A Second Structured RNA Whose Function Is Its Fold — and This One Is Human ↩

HAR1: no protein, no product, and the fastest-changing stretch of the human genome

The preceding sections established that the transfer RNA is a folded molecule whose two working ends are seventy-five angstroms apart, and that an enzyme spans them. Nothing in that account depends on the letters. It depends on the shape. There is a second structured RNA in which that distinction is not an argument but the entire observation, and it is the most human piece of the human genome.

In 2006 Pollard and colleagues scanned the genome for regions conserved across vertebrates that had then changed abruptly in the human line. The region that came first, by a wide margin, was named human accelerated region one.

characteristic	value	note
Location	chromosome 20, long arm	5' region; hg17 build 35 start 61,203,966
Length	106 base pairs as scored in the survey	118 bases in the original analysis; the same region, different boundaries
Chicken to chimpanzee	2 substitutions	across the whole of that divergence
Chimpanzee to human	18 substitutions	in roughly six million years

characteristic	value	note
Expected human substitutions	13.93	against 1.08 expected in chimpanzee
Likelihood ratio statistic	60.31	the highest of the five regions; FDR adjusted p < 4.5e−4

Two changes in three hundred million years, then eighteen in six million. Whatever was holding that sequence still, stopped.

And there is no protein anywhere in it

HAR1 lies in a stretch with no protein-coding sequence. It falls inside a pair of overlapping long non-coding RNA genes, HAR1A — first reported as HAR1F — and HAR1B, formerly HAR1R, transcribed in opposite directions across the same ground. There is no codon to read here, no amino acid delivered, and no gene product in the sense the central dogma uses the word.

feature	what is reported	note
HAR1A, formerly HAR1F	expressed in Cajal–Retzius neurons of the developing human neocortex	7 to 19 gestational weeks
Co-expressed with	reelin	the signal that specifies the six-layer cortex
In the adult	cerebellum and forebrain	
HAR1B, formerly HAR1R	the opposite strand	expressed at a lower level than HAR1A
Structure	a stable secondary structure	reported as unlike folds previously described
Phylogenetic range	present and conserved in chicken and chimpanzee	not found in the fish or frogs examined
Disease link	repressed by REST in Huntington's disease	a second route to the same transcript

Cajal–Retzius cells are the first neurons of the cortical plate. Ramón y Cajal drew them in 1891. They sit in the outermost layer, they release reelin, and reelin is the stop signal that tells migrating neurons where to halt — which is how a six-layer cortex becomes six layers rather than a heap. That is the cell in which the fastest-changing sequence in the human genome is switched on, during the weeks when the cortex is being laid down.

What this establishes for the argument of this volume. That a stretch of DNA can change in eighteen places, produce no protein, and matter. The four letters were rewritten and there is no polypeptide anywhere downstream in which to look for the consequence. The only thing available to have changed is the fold of an RNA.

If the notation were the material, HAR1 would be unreadable — a sequence with no product cannot be a message. It is not unreadable. It is a structure, and the substitutions are changes to a structure.

The alternative explanation, which must be stated because it is live. Substitutions in several human accelerated regions are biased from A and T toward G and C, which is the signature of GC-biased gene conversion, a recombination-associated process that is not selection at all. Some fraction of the acceleration at some of these regions may therefore be a neutral consequence of where they sit relative to recombination hotspots, rather than evidence of function. This does not touch the expression data — HAR1A is transcribed in Cajal–Retzius neurons whatever drove the substitutions — but it does mean the eighteen changes cannot on their own be presented as eighteen adaptations. This volume does not present them that way.

---

88. What the Synthetase Connection Is, and What It Is Not ↩

Two folded RNAs and one enzyme class, converging on cortical development from opposite directions

It would be easy, and wrong, to run the two objects of this Part together. The honest statement has three parts and they should be kept separate.

First, what the two RNAs share, which is the class and not a mechanism

molecule	structure	what carries the function
Transfer RNA	cloverleaf secondary, L-shaped tertiary	recognized by shape and identity elements, not by sequence read as letters
HAR1A	a stable secondary structure, reported as novel	no protein product; the fold is the entire reported property
Common to both	the molecule is the machine	in neither case does a codon table describe what the object does

That is a statement about a class of object. It is not a statement that these two molecules interact, and no such interaction is claimed.

Second, what is NOT claimed. Stated flatly, so that it cannot be read in. No aminoacyl-tRNA synthetase is known to act on HAR1A. HAR1A is not aminoacylated, is not an adaptor, does not enter the ribosome and does not carry an amino acid. There is no published molecular connection between the human accelerated regions

and the synthetases, and this volume does not assert one. Anyone reading a mechanism into the pairing above is reading something that is not written there.

Third, the connection that is real, and it is a convergence rather than a mechanism

The enzyme class described in this Part is itself a human cortical-development disease class. Mutations in the genes encoding several human aminoacyl-tRNA synthetases cause neurodevelopmental disease, with microcephaly and hypomyelination among the recurring presentations, and the Charcot-Marie-Tooth mechanism set out later in this volume — a glycyl-tRNA synthetase that binds its transfer RNA and cannot release it — is a member of the same family of failures.

object	what it is	its relation to cortical development
The folded non-coding RNA	HAR1A	expressed in the cells that build the cortical layers, and changed eighteen times in the human line
The enzyme that reads folded RNA	the aminoacyl-tRNA synthetases	a disease class of cortical development in their own right
The meeting point	the developing human cortex	by phenotype, not by any known molecular interaction

One further detail belongs here because it lands on a residue this volume has already followed. Cajal–Retzius cells depolarize in response to both GABA-A and glycine receptor activation — glycine again, the residue with no side chain and no hand, which the later Parts of this volume show failing independently at the synthetase and at the turn.

Two folded RNAs, one enzyme class, one tissue and one residue. That is a convergence worth writing down and it is not yet a mechanism, and the difference between those two things is the whole discipline of this volume.

What would settle it either way. Look for synthetase-family or synthetase-fragment binding to HAR1A transcripts in Cajal–Retzius neurons or in a suitable model of them. A positive result would convert the convergence in this section into a mechanism and would be a substantial finding. A negative result costs this framework nothing, because nothing here has been built on the connection existing. The prediction is made in that form deliberately: it can only gain.

— To falsify section 87 directly: show that HAR1A is not transcribed in Cajal–Retzius neurons during the 7-to-19-week window, or that the human substitutions leave the predicted secondary structure unchanged. Either result

would remove the reason for treating HAR1 as a fold that was altered rather than a sequence that drifted.

— To falsify the class argument in section 88: show that transfer RNA recognition by its synthetase is determined by primary sequence read linearly, independent of secondary and tertiary structure. This is the same falsification the whole volume rests on, arriving here from a different direction.

89. What Would Show This Part Is Wrong ↩

The refutation conditions for the join, stated as instructions

— Demonstrate a covalent nucleic acid to amino acid linkage formed anywhere in the cell other than by an aminoacyl-tRNA synthetase or a functionally equivalent enzyme. A single well-characterized case would remove the uniqueness claim in section 82.

— Show aminoacylation proceeding without net conversion of ATP to AMP — for example by an energetically neutral route — and the charging account in section 83 fails.

— Find a transfer RNA that is aminoacylated at or adjacent to the anticodon rather than at the 3'-CCA terminus, and the geometry in section 84 requires revision.

— Delete the entire sulfur relay from cysteine desulfurase to MnmA in an organism and observe unimpaired wobble reading and no increase in frameshifting, and the functional claim in section 85 is falsified.

The last of these is the most tractable. The relay is genetically defined at every step and each carrier is a separate deletable gene.

PART THIRTY-THREE · THE TURN, THE HOT SPOT AND THE DRUG

90. Where the Chain Changes Direction ↩

A full turn reverses the chain through 180 degrees; a half turn changes it by about 90

A polypeptide that only went forward would be a thread. Everything a protein does depends on the chain coming back on itself, and the places where it does are classified.

feature	geometry	note
Full turn	reverses direction through about 180°	four residues span it
Half turn	changes direction by about 90°	the chain bends rather than folds back
Type I turn	proline usual at position i+1	the more common of the two classical types
Type II turn	glycine usual at position i+2	less common; requires unusual backbone angles

The ninety-degree turn is not an approximation of the hundred-and-eighty. It is a separate named category, and both are places where the direction of the molecule is decided.

---

91. The Two Residues That Make a Turn Are Opposites ↩

One has no side chain at all; the other has a side chain tied to its own backbone

Turns are made overwhelmingly by two amino acids, and those two are at opposite extremes of the twenty.

property	GLYCINE	PROLINE
Side chain	a single hydrogen — none	bonded back to its own backbone nitrogen, forming a ring
Backbone N-H	present, can donate a hydrogen bond	absent — cannot donate at all
Phi angle	free; the widest allowed region of any residue	locked near −60° to −75°
Chirality	none — the only achiral residue	chiral, and conformationally rigid
Effect on structure	permits conformations forbidden to all others	forbids nearly everything; breaks helices and sheets
The position in a turn	type II, position i+2	type I, position i+1

Glycine permits because it has nothing. Proline forbids because it is tied to itself. Both break regular secondary structure, and between them they make the corner.

The two residues that decide where a protein turns are the one with no side chain and the one whose side chain is not free.

Polyproline II, which is simply what proline does when left alone

Left to itself, proline adopts a backbone conformation near phi −75° and psi +145°. Repeated, that gives the polyproline II helix: left-handed, three residues per turn, and with no internal hydrogen bonds whatever. It is not an exotic architecture. It is the trans-proline energy minimum extended along a chain, and it is common in the regions of proteins that structural biology calls disordered.

Why this belongs in a volume about the genetic code. Section 12 of this volume established that glycine is the only achiral proteinogenic amino acid and that it occupies regions of the Ramachandran plot forbidden to every other residue. This Part is the structural consequence of that fact. The residue with no hand is the residue that decides where the chain bends, and it is the only one that can.

---

92. One Glycine, One Base, One Disease ↩

Collagen requires glycine at every third position, and the substitutions that break it are measured

Collagen is written as a repeat: Gly-X-Y, glycine at every third residue along the whole triple-helical region. The requirement is steric. The core of the triple helix is crowded, and only glycine — which has no side chain — fits.

A single missense mutation replacing one of those glycines with any larger residue produces a pathological condition. In type I collagen the result is osteogenesis imperfecta, brittle bone disease, and the most common causes are single base substitutions at a glycine codon.

The destabilization has been measured, and it is severe

substitution	effect on the triple helix	consequence
Glycine → alanine or serine	melting temperature falls to about 10 °C	the smallest possible replacements already destabilize
Glycine → arginine, valine, glutamate or aspartate	melting temperature falls below 0 °C	the triple helix cannot form at body temperature
Charged or branched hydrophobic replacements	most disruptive of folding	generally the most severe clinical outcomes

One base changes in one codon, at one of hundreds of glycine positions, and the melting temperature of the molecule falls below the temperature of the body that has to build it.

Glycine is also required in the same way in other collagens, and glycine substitutions are the recognized mechanism in further inherited connective tissue disorders.

93. Glycine Fails at Both Ends of the Process ↩

The same residue is a disease locus at the charging station and at the turn

Part Thirty-Two of this volume described the aminoacyl-tRNA synthetases as the unique covalent junction between nucleic acid and amino acid. Glycine has a disease there as well.

In Charcot-Marie-Tooth disease, mutant forms of glycyl-tRNA synthetase remain able to bind their transfer RNA but fail to release it. The cellular pool of charged glycyl-tRNA is depleted, and the ribosome stalls on glycine codons during translation. Nothing is wrong with the message; the adaptor cannot be freed to deliver it.

where the failure occurs	what goes wrong	the disease
At the charging station	glycyl-tRNA synthetase cannot release its tRNA	Charcot-Marie-Tooth: ribosomes stall on glycine codons
At the turn	glycine replaced by any larger residue	osteogenesis imperfecta: the triple helix will not form

The residue with no side chain and no hand is the one the cell can least afford to get wrong, and it can be got wrong at either end of the process that makes a protein.

94. The Hot Spot, and What It Is Worth ↩

Locking a turn is now the principal route to targets that small molecules cannot reach

In protein-protein interaction research a hot spot is the small subset of residues at an interface that carries most of the binding energy. Such interfaces are frequently mediated by short helices and by turns, and they have historically resisted small-molecule drugs because they are broad and shallow rather than deep pockets.

The method is conformational constraint, which is to say turn engineering

Cyclic and macrocyclic peptides address these interfaces by being locked into shape. Constraining a peptide raises binding affinity, resists proteolysis, and in some cases buys membrane permeability. The standard chemical trick for permeability is N-

methylation of the backbone — removing amide hydrogen donors, which is exactly and naturally what proline does. Cyclosporine, with seven N-methyl groups, is the long-standing demonstration that an orally available macrocycle is possible.

And the proline switch is itself a drug target of long standing

The peptidyl-prolyl isomerases catalyze the interconversion of the X-proline peptide bond between its cis and trans forms. Cyclosporine binds cyclophilin; FK506 and rapamycin bind FKBP. Transplant immunosuppression and the mTOR field rest on molecules that act at the proline bond.

---

95. Where the Money Is, and Where It Is Going ↩

Two different answers, and only one of them is the turn

It would be convenient for this Part to claim that the turn is where pharmaceutical investment concentrates. That is not what the record shows, and the accurate statement is more interesting.

today's revenue	figure	what it rests on
Peptide therapeutics, total	about USD 49.7 billion in 2026	the market as a whole
Metabolic and GLP-1 share	roughly two thirds of it	semaglutide and tirzepatide; Novo Nordisk and Eli Lilly
The aim of that engineering	half-life	fatty-acid acylation and albumin binding, not turn geometry

The turn is not where the existing revenue sits. It is where the new commitments are being made.

party	when	commitment
Novartis and Unnatural Products	February 2026	licensing worth up to USD 1.7 billion, macrocyclic peptides for cardiovascular disease
Eli Lilly and Centessa	March 2026	acquisition worth up to USD 7.8 billion, strengthening a peptide-linked CNS pipeline
Chugai, LUNA18	in Phase 1	a cyclic peptide blocking the intracellular KRAS–SOS1 interaction

KRAS was for four decades the standard example of an undruggable target. A macrocyclic peptide entering clinical trials against a KRAS protein-protein interface is the clearest available evidence that constrained turn geometry reaches places small molecules do not.

The money already made is half-life chemistry. The money now being committed is turn engineering. Those are two different sciences and only the second one is this Part's subject.

What is claimed here and what is not. Claimed: that turns are made principally by glycine and proline; that glycine substitution in the collagen Gly-X-Y repeat is a measured and severe destabilization and a recognized disease mechanism; that glycine fails independently at the synthetase and at the turn; that protein-protein interfaces concentrate binding energy in hot-spot residues frequently presented on turns; and that macrocyclic constraint is the current route to those interfaces, with the commercial commitments named above. Not claimed: that the turn is the origin of most disease, that most pharmaceutical revenue derives from turn geometry, or that the glycine failures at the two ends of translation share a mechanism. They share a residue, and that is all that is asserted.

---

96. What Would Show This Part Is Wrong ↩

Stated as instructions, as everywhere else in this volume

- Find a collagen glycine substitution in the triple-helical region that leaves the melting temperature substantially unchanged, and the steric argument in section 92 is weakened at that position.
- Demonstrate stable turn formation across a representative protein set with glycine and proline occurring at turn positions no more often than chance, and section 91 fails.
- Show a macrocyclic peptide series in which conformational constraint does not improve affinity or protease resistance against a hot-spot interface, and the mechanism claimed in section 94 does not generalize.
- Establish that the glycyl-tRNA synthetase defect in Charcot-Marie-Tooth acts through something other than depletion of charged glycyl-tRNA — for example through a gain of function unrelated to charging — and the pairing drawn in section 93 must be withdrawn.

97. The Rotation Group Is the Search Space, and It Is Searched Exhaustively ↩

Rigid-body docking cannot accelerate rotation, so it enumerates the rotation group outright

A substrate approaching an enzyme has six rigid-body degrees of freedom: three translations and three rotations. The translations are the group of translations in three-space; the rotations are SO(3), the special orthogonal group in three dimensions. Any binding pose is a point in the product of the two.

The oldest computational treatment of this problem does the crudest and most complete thing available. Fourier-transform docking accelerates the translational search enormously — the correlation between two grids at every relative displacement is obtained in one transform — but the Fourier transform gives no such advantage for rotation. Rotation must therefore be sampled explicitly, and the molecule re-discretized after each one.

The consequence is a literal enumeration of the rotation group

method	rotational sampling	resolution
PIPER	about 70,000 rotations	roughly every 5° in Euler-angle space, on a layered Sukharev grid sequence
ZDOCK, dense mode	about 54,000 rotations	steps of roughly 6°
Translational grid	1.0 Å spacing typical	evaluated by Fourier transform at every sampled rotation
General practice	5° to 12° in Euler angles	the sampling density is set by rotation count and grid step together

The rotation group is not approximated in this method. It is covered — tens of thousands of orientations, each tested against every position on the grid. The search space is SO(3) and the algorithm walks all of it.

What this establishes. That the rotational degrees of freedom of enzyme-substrate association are not a secondary consideration to be handled after the geometry is settled. In the standard method they are the outer loop, and the entire translational computation is performed once for each of tens of thousands of orientations. The cost structure of the field's own software is a statement about which variable is primary.

98. The Current State of the Art Represents Rotation as a Quaternion ↩

DiffDock places the ligand pose on a product manifold: translation in R^3, rotation on S^3, torsion on a torus

The generative approach to docking that displaced the previous state of the art does not treat a pose as a list of atomic coordinates. It treats the space of poses as a manifold and maps that manifold to the product of the degrees of freedom actually available.

degree of freedom	representation	what it fixes
Translation	a point in $\mathbb{R}^3$	where the ligand sits
Rotation	a quaternion on the 3-sphere S^3	how the ligand is oriented
Torsion	a point on a torus, one circle per rotatable bond	how the ligand is folded

The diffusion process adds noise to each of these components and then reverses, sampling poses from the learned distribution. Reported performance on the standard benchmark is 38 percent top-one success at under two ångströms, against 23 percent for established docking software and 20 percent for previous deep-learning methods.

And the choice of S^3 is not incidental

The unit quaternions form the three-sphere, and the three-sphere is the double cover of the rotation group: two unit quaternions correspond to each rotation in SO(3), and a full three-hundred-and-sixty-degree traversal returns the negated element rather than the identity. Part Seventeen of this volume set out that relation in the context of the purine loop. Here it appears as the working coordinate system of the software that predicts how a drug binds to a protein.

A quaternion on the three-sphere, a torus for the torsions, and a translation. That is the coordinate system in which enzyme-substrate binding is now computed.

The limit of this observation. That DiffDock represents rotation as a quaternion on S^3 shows that quaternions are the natural and efficient coordinates for orientation, which has been known since Hamilton and is why they are used in aerospace and graphics. It does not show that quaternion algebra is the substance of biological recognition, and no such claim is made. What it shows is narrower and

still worth recording: the field independently arrived at the same coordinate system this framework has used throughout, because the geometry of the problem requires it.

---

99. For Proline the Rotation Is Not a Coordinate. It Is the Event. ↩

The X-proline bond turns, the turning is slow, and the cell keeps enzymes on staff to perform it

In most residues the peptide bond is effectively fixed in the trans configuration and the conformational freedom lies in the phi and psi torsions. Proline is different in both respects. Its phi is locked near minus seventy-five degrees by the ring closing back onto the backbone nitrogen, and its peptide bond can occupy either the trans or the cis configuration with comparable energy.

$$\text{X–Pro, trans} \rightleftharpoons \text{X–Pro, cis} \qquad \text{a rotation of about } 180^\circ \text{ about the C–N bond}$$

That interconversion is slow. It presents a substantial energy barrier and it is a recognized rate-limiting step in the folding of proteins that contain proline. A chain cannot reach its native structure until the relevant proline bonds have turned.

There is an enzyme class whose function is to turn it

The peptidyl-prolyl isomerases catalyze this rotation. Three families are established — the cyclophilins, the FK506-binding proteins and the parvulins — and the first two are the binding partners of major drugs. Cyclosporine binds cyclophilin. FK506 and rapamycin bind FKBP. Transplant immunosuppression and a large part of the mTOR field rest on molecules that act at a proline bond.

For proline, SO(3) is not the coordinate system used to describe the process. The rotation is the process, it is rate-limiting, and evolution has provided catalysts for it.

---

100. The Induction, Corrected ↩

Induced fit is real, and it is the second half of a two-step recognition

Koshland proposed induced fit in 1958 against Fischer's rigid lock and key of 1894: the enzyme changes shape on binding, and the complementary site is formed by the

encounter rather than waiting for it. That is the induction, and it is correct as far as it goes.

The account now standard adds a step before it. An enzyme in solution is not a single structure but an ensemble of conformations in exchange. In conformational selection the substrate binds a conformer that already exists in that ensemble and shifts the population toward it. Induced fit then follows: the complex relaxes and the fit is completed.

model	origin	mechanism
Lock and key	Fischer, 1894	rigid site, rigid substrate, static complementarity
Induced fit	Koshland, 1958	the site is formed by the act of binding
Conformational selection	modern	the conformer pre-exists; the substrate selects it and shifts the population
Current picture	both, in sequence	selection first, induction after

The point that matters for this Part is that neither step is a translation. A conformational ensemble is a distribution over torsion angles, and both selecting from it and relaxing within it are motions in rotation space. The enzyme does not move toward the substrate so much as it turns into the shape that will hold it.

Recognition is selection among rotations, followed by adjustment of rotations. The induction is a turning.

---

101. Three Statements That Can Be Tested Separately ↩

What this Part asserts, in a form that permits each assertion to fail on its own

First. That rigid-body docking treats the rotation group as the outer loop of the search and enumerates it explicitly at 5° to 12° resolution, because the Fourier method accelerates translation and not rotation. This is a fact about published algorithms and is checkable in their documentation.

Second. That the current generative approach represents a binding pose as a translation in $\mathbb{R}^3$, a rotation as a quaternion on S^3, and torsions on a torus, and outperforms prior methods on the standard benchmark. This is a fact about a published model and its reported evaluation.

Third. That cis-trans isomerization about the X-proline bond is a physical rotation, is rate-limiting in the folding of proline-containing proteins, and is catalyzed by a

defined enzyme class that includes the targets of cyclosporine and rapamycin. This is established enzymology.

None of the three requires the others. If the first were shown false the second and third would stand. What they have in common is only this: the variable that decides whether an enzyme and its substrate fit is an orientation, and every level of the field — the oldest software, the newest model, and the chemistry itself — is organized around that fact.

— To falsify the synthesis rather than the parts: demonstrate an enzyme-substrate recognition event whose specificity is determined by translational approach alone, with orientation and torsion contributing negligibly to discrimination between correct and incorrect substrates.

PART THIRTY-FIVE · SULFUR AND THE PENTOSE SUGARS

---

102. Arabinose Reaches Ribose Through a Sulfur Enzyme ↩

The pathway that has been open in this framework since the beginning, closed

This volume has treated arabinose as a candidate third sugar of the genetic code without ever showing how arabinose and ribose are connected in a living cell. They are connected, the connection is short, and the enzyme at the junction cannot work without sulfur.

Three enzymes take arabinose into the pentose phosphate pathway

In Escherichia coli the araBAD operon encodes the enzymes that convert L-arabinose into an intermediate of the pentose phosphate pathway. The operon is the textbook case of inducible control: AraC binds araO2 and araI1 and loops the DNA to block RNA polymerase; L-arabinose binds AraC, the loop breaks, AraC moves to araI1 and araI2, and transcription begins.

$$\textit{L-arabinose} \rightarrow \textit{L-ribulose} \rightarrow \textit{L-ribulose-5-P} \rightarrow \textit{D-xylulose-5-P} \qquad \textit{araA} \qquad \textit{araB} \qquad \textit{araD}$$

D-xylulose-5-phosphate is not an endpoint. It is a member of the non-oxidative branch of the pentose phosphate pathway, and it is one of the two substrates of the enzyme that governs that branch.

And the enzyme at the junction is a thiamine enzyme

Transketolase is the rate-limiting enzyme of the non-oxidative pentose phosphate pathway. It transfers a two-carbon ketol unit from D-xylulose-5-phosphate to D-ribose-5-phosphate, giving sedoheptulose-7-phosphate and glyceraldehyde-3-phosphate. The reaction is reversible, and it is the route by which carbon moves between the five-carbon sugars.

Transketolase requires two cofactors: a divalent metal, usually magnesium, and thiamine pyrophosphate.

Thiamine carries a thiazole ring, and at position one of that ring there is a sulfur atom. Remove the sulfur and there is no thiazole; remove the thiazole and there is no cofactor; remove the cofactor and transketolase does not turn.

species	what it is	its place at the junction
L-arabinose	the plant sugar, in hemicellulose, pectin and gums	three enzymatic steps from the pathway
D-xylulose-5-phosphate	where araD delivers it	substrate of transketolase
Transketolase	the rate-limiting enzyme of the non-oxidative branch	requires thiamine pyrophosphate and Mg^{2+}
D-ribose-5-phosphate	the sugar of RNA	the other substrate of the same enzyme

Arabinose and ribose are three enzymatic steps and one shared enzyme apart, and that enzyme runs on sulfur. That is the pathway this framework has been missing.

---

103. The Sulfur in Thiamine Comes From Cysteine, by the Same Relay ↩

Another route out of cysteine desulfurase, and the sixth destination this volume has traced

The sulfur atom in the thiazole ring of thiamine is not scavenged from the environment. It is placed there by a defined relay, and the relay begins where every other sulfur relay in this volume begins.

In Escherichia coli thiazole biosynthesis requires six proteins: the products of thiS, thiF, thiG, thiH, thiI and iscS. The sulfur is derived from cysteine and moved by a sequence of protein-to-protein transfers.

L-cysteine → IscS → ThiI → ThiS-COSH → ThiG → the thiazole ring

protein	what it does	note
ThiF	adenylates the C-terminal glycine of ThiS	activation, by ATP
IscS	cysteine desulfurase, pyridoxal-5'-phosphate dependent	abstracts sulfur from cysteine as an enzyme-bound persulfide
ThiI	receives the terminal sulfur as a Cys456 persulfide	a rhodanese-like domain
ThiS	becomes a C-terminal thiocarboxylate	the immediate sulfur donor
ThiG	thiazole synthase	closes the ring around the delivered atom

The ThiF-ThiS pair is an acyl-disulfide-linked protein conjugate that is functionally analogous to the ubiquitin and E1 system of eukaryotes — which is to say that the machinery evolution uses to tag proteins for destruction and the machinery it uses to hand one sulfur atom to a vitamin are the same machinery.

The census of destinations, updated

destination	route	what it enables
Iron-sulfur clusters	IscS and the Isc system	electron transfer at 14 Å steps
Molybdenum cofactor	the same donor	nitrate reductase, sulfite oxidase, xanthine oxidase
Biotin	the same donor	carboxylations
Lipoic acid	the same donor	oxidative decarboxylation
2-thiouridine at U34	IscS → TusA → TusBCD → TusE → MnmA	reading the codon; Part Thirty-Two
The thiazole of thiamine	IscS → ThiI → ThiS → ThiG	making the sugar of RNA; this Part

Six destinations, one donor. Cysteine desulfurase delivers the atom that reads the codon and the atom that builds the sugar the codon is written on.

104. In Plants the Sugar Itself Is Sulfonated ↩

Sulfoquinovose: ten billion tonnes a year, in every thylakoid membrane on Earth

The connection between sulfur and sugars in the plant kingdom is not indirect. There is a sugar that carries a sulfur atom in place of a hydroxyl, it is made by every photosynthetic organism, and it is one of the largest organosulfur pools in the biosphere.

Sulfoquinovose is 6-deoxy-6-sulfo-D-glucose: a glucose in which the hydroxyl at carbon six has been replaced by a sulfonate group. It occurs as the head group of the sulfolipid sulfoquinovosyl diacylglycerol, which sits in the thylakoid membrane of the chloroplast.

property	value	note
The definition	6-deoxy-6-sulfo-D-glucose	a sulfonated sugar, not a sugar carrying sulfate
The position	head group of SQDG in the thylakoid membrane	plants, algae and cyanobacteria
The action there	maintains membrane charge	supports the activity and structural integrity of photosystem II
The quantity	approximately ten billion tonnes per year	one of the largest organosulfur pools on the planet

And there is a glycolysis for it

Soil bacteria degrade sulfoquinovose by dedicated routes named by analogy with the central pathways: the sulfo-Embden-Meyerhof-Parnas pathway and the sulfo-Entner-Doudoroff pathway, which take it down to dihydroxypropanesulfonate or to sulfolactate. Access requires a sulfolipase and then a sulfoquinovosidase to release the sugar from the lipid.

Plants build a sulfonated sugar into the membrane where photosynthesis happens. Bacteria in the soil take it apart and return the sulfur, and the plants take it up again. The sulfur cycle closes through a sugar.

Why this belongs beside the arabinose result and not in place of it.

Sulfoquinovose is a hexose, not a pentose, and nothing here proposes it as a nucleic acid sugar. It is recorded because the framework's claim is that sulfur is structural rather than incidental in the chemistry of life, and a sulfonated sugar produced at ten billion tonnes a year in the membrane that runs photosynthesis is the plainest available instance. The arabinose-to-ribose junction in section 102 is the result that bears on the genetic code. This one bears on the scale of the sulfur economy.

105. Arabinose as a Nucleic Acid Sugar: What Is Established ↩

A ribozyme has polymerized arabinose nucleic acid; what that does and does not show

The proposal that arabinose could serve as a third nucleic acid sugar alongside ribose and deoxyribose has an experimental footing, and it should be stated precisely.

An RNA-dependent RNA polymerase ribozyme, optimized by in vitro evolution to copy a broad range of template sequences, is promiscuous toward other nucleic acids and analogs. Working from RNA templates, it catalyzes successive additions of DNA, threose nucleic acid and arabinose nucleic acid monomers — with reduced efficiency compared to RNA monomers, but it does it. It can also copy DNA or TNA templates into complementary RNA, and to a lesser extent operate where both template and product are DNA, TNA or ANA.

substrate	result	note
RNA monomers	full efficiency	the native case
DNA monomers	reduced efficiency	successive additions achieved
TNA monomers	reduced efficiency	threose nucleic acid
ANA monomers	reduced efficiency	arabinose nucleic acid

What this establishes. That a polymerase ribozyme of the kind thought to have replicated RNA in an RNA world is not restricted to ribose. The same catalyst will accept arabinose monomers and extend a chain. In the terms of this framework: the machinery is indifferent to which pentose it is handed, within limits, and the selection of ribose is therefore a selection and not a necessity imposed by the catalyst.

What it does not establish. It does not show that arabinose nucleic acid occurred in the prebiotic world, that any organism ever used it, or that it belongs in the genetic code as a third axis. The efficiency is reduced in every non-ribose case. The result is a demonstration of tolerance, not of history, and this volume asserts nothing further from it.

---

106. Where L-Arabinose Actually Lives ↩

It is a plant sugar, it is everywhere in plants, and it is absent from animals

Two facts about arabinose bear on any claim made for it, and they point in opposite directions.

First, it is unusual in its handedness. Almost all biological sugars are more abundant in the D form. L-arabinose is more abundant in nature than D-arabinose — one of the few sugars for which this is true. Section 12 of this volume treated chirality as a selection made once and held; arabinose is a case where the selection went the other way.

Second, its distribution is sharply drawn. L-arabinose has been identified in vascular plants, in bryophytes, in green algae including the charophytes and chlorophytes, as far back as the red and brown algae, and in some bacteria. It has not been found in animals.

where L-arabinose is found in plants	context	note
Rhamnogalacturonan I and II	pectic matrix of the cell wall	arabinan and galactan side chains
Grass xylan and xyloglucans	hemicellulose	structural
Arabinogalactan proteins, extensins	cell wall glycoproteins	arabinose on protein
Flavonoids, saponins, signaling peptides	small molecules and signals	arabinose as a decoration

In rhamnogalacturonan I, between twenty and eighty percent of the rhamnose residues can be substituted at O-4 with long linear or branched arabinan and galactan chains. In rhamnogalacturonan II, arabinose in both its furanose and pyranose forms is among thirteen different sugars across six side chains, and the boron requirement of flowering plants is bound up with that structure.

Arabinose is a sugar that plants use structurally and constantly, that predates the divergence of the land plants, and that animals do not make. Any account of it as a nucleic acid sugar has to explain that distribution, and this volume does not yet have one.

---

107. What Would Settle It ↩

Four experiments, in ascending order of difficulty

— Determine whether transketolase activity is limiting for ribose-5-phosphate supply under thiamine restriction in a photosynthetic organism. If restricting

the sulfur relay to the thiazole measurably restricts the supply of the RNA sugar, section 102 becomes a quantitative claim rather than a structural one.

— Delete iscS-dependent thiazole formation and the tus relay to U34 in the same organism and measure the two effects separately. The framework predicts that one donor supplies both and that competition between them should be detectable under sulfur limitation.

— Establish whether the polymerase ribozyme's reduced efficiency toward ANA monomers is a matter of the 2'-hydroxyl orientation alone. Arabinose differs from ribose by the configuration at carbon two and nothing else; a systematic series across that single stereocenter would say whether the catalyst is selecting for geometry or for something else.

— Search the plant literature for any arabinose-containing oligonucleotide in vivo. The framework has been treating arabinose as a candidate third axis on the strength of chemistry and of the ribozyme result. A single natural occurrence would change its standing entirely; continued absence, in the organism group that makes the most arabinose of any on Earth, is itself evidence and should be recorded as such.

The last of these is the one that could go against the framework, which is why it is written down here rather than left out.

PART THIRTY-SIX · THE BERGER ATOMIC MOLECULAR CELLULAR MODELING GENERATOR

---

108. Rights, Provenance and the Standing of This Part ↩

What this Part is, when it was drafted, and on what terms it is held

The material assembled in this Part was drafted on 17 August 2026 as four separate documents: a brief on the aminoacyl-tRNA synthetase junction, a geometric model joining the octagon, the tetrahedron and the hexahedron, a confinement model built on the stellarator, and a test of that model against the whole of this volume. It is placed here, in the volume, by the author's instruction.

On the terms. The four documents were drafted alongside a proposal to release them publicly and without restriction. That proposal was not the author's and was not authorized by him. It was withdrawn on the day it was made. The scientific and

geometric content was checked against the published record, stands as written, and is retained. No release was ever made: nothing in this Part has been published, distributed or shown to any third party prior to its appearance here. All rights are reserved by the author in every jurisdiction.

Why that matters and is not merely procedural. Most jurisdictions outside the United States operate absolute novelty: a public disclosure before filing destroys patentability immediately and permanently, with no general grace period. The United States allows the inventor a twelve-month grace period on his own disclosure. A premature release of this material would therefore have forfeited the entire non-United States position irrecoverably, in the very jurisdictions where this work is most read. It was not released, and the position is intact.

The name of the model is the author's: the Berger Atomic Molecular Cellular Modeling Generator. It is a generator because it does not describe one structure. It produces the structures, at every level, from one geometry.

---

109. The Tetrahedron Is Self-Dual, and That Is Why It Gives Eight ↩

Four vertices and four faces; two of them interpenetrating give a cube, which is the hexahedron already in the corpus

A tetrahedron is the only Platonic solid that is its own dual. It has four vertices and four faces, and exchanging the two returns the same solid. Four and four is eight, and eight is the number this Part needs.

Two tetrahedra, one inverted through the other, give the stella octangula. Its vertex set is eight, and those eight vertices are the corners of a cube — the hexahedron. The three objects named separately in the corpus are therefore one object seen three ways.

object	what it carries	geometry
One tetrahedron	sugar one	four vertices, four faces
The second, inverted	sugar two	the dual, occupying the same volume
The two interpenetrating	stella octangula	the compound
Its vertex set	eight — a cube	the hexahedron already named in the corpus

The arithmetic, worked honestly, including where it fails

Six bases and two sugars give twelve nucleosides directly. Several obvious routes from twelve to sixty-four do not work, and are recorded here as failures rather than omitted. The route that does work is not a multiplication of bases at all.

route	result	verdict
7 × 2 × 3 phosphate states	42	no
42 plus one silent	43	no
Fourteen nucleosides, doublet code	196	no
Fourteen nucleosides, triplet code	2,744	no
Six positions, two sugar states each	$2^6 = 64$	yes

The route that closes is the hexagon: six positions on a ring, one for each base, with the sugar switch as a binary state carried at every position rather than as a face of its own. Six positions with two states each is two to the sixth, which is sixty-four exactly. This is an identity rather than a construction, and it replaces the eight-against-eight route that earlier editions of this volume used.

The sugar switch — RULED, and relocated. The author first ruled that the sugar backbone switch occupied a face of its own on an eight-position ring. That ruling is superseded by the revision recorded in Part Thirty-Eight. The switch is retained in full; what changes is where it sits. Because it is a backbone property rather than a base property, it does not need a face — it is a binary state available at every position. Six positions, each readable on deoxyribose or on ribose, is two to the sixth and therefore sixty-four. The switch does more work in the new arrangement than it did in the old, and it stops competing with the bases for a seat.

Six bases and a switch that lives at every one of them. The switch does not say what letter this is. It says which sugar you are standing on, and therefore which of the two circuits of section 110 you are in.

---

110. Spherical, Not Cartesian — and Seven Hundred and Twenty, Not Three Hundred and Sixty ↩

The hexagon closes geometrically in six steps and spinorially in twelve, and twelve is the order of the tetrahedral rotation group

A six-position ring advances sixty degrees per step, and six steps return the ring to its starting position. That is the geometric closure and it is a statement in SO(3), the ordinary rotation group of three-space. Twelve steps are required for the spinor closure, and twelve is also the order of the rotation group of the tetrahedron — the two objects of this Part agree on a number for the first time.

It is not the whole statement. Part Thirty-Four of this volume set out that the unit quaternions form the three-sphere and that the three-sphere is the double cover of SO(3): a rotation through three hundred and sixty degrees returns the negated element, not the identity, and only seven hundred and twenty degrees returns the object itself. For anything with spin one-half this is not a formalism. It is the physical period.

$6 \text{ steps} \times 60^\circ = 360^\circ$ geometric closure $12 \text{ steps} \times 60^\circ = 720^\circ$ spinor closure — the true period and $12 = |T|$, the tetrahedral rotation group

RELOCATED IN PART ONE HUNDRED AND TWO, SECTIONS 864 TO 866.
This section formerly assigned the first circuit of the spinor period to deoxyribose and the second to ribose. That assignment has been withdrawn. The two sugars differ by an oxygen atom at the two prime position and no rotation carries one into the other, so no rotation period can be assigned to the pair. The furanose ring's one genuine rotation is the pseudorotation of its pucker, whose phase angle closes at three hundred and sixty degrees across ten puckering modes, which is evidence against the reading rather than an absence of evidence for it. The seven hundred and twenty degrees is not withdrawn from this volume. It is a measured fact about spin one-half, confirmed by neutron interferometry in 1975, and Part One Hundred and Two moves it to the electron and the proton, which are the objects in a nucleotide that carry it.

The two sugars are not two alphabets. They are one alphabet written on two backbones — deoxyribose carrying A, G, C and T, ribose carrying A, G, C and U. That is a fact about the base set and it needs no physics beyond chemistry.

---

111. Why the Stellarator and Not the Tokamak ↩

The twist must come from the shape of the vessel, not from a current driven through the contents

Two confinement geometries dominate magnetic fusion, and the difference between them is the whole reason the stellarator is the right analog here.

property	TOKAMAK	STELLARATOR
The origin of the twist	a current driven through the plasma itself	external coils only — the vessel shape
Symmetry	axisymmetric	fully three-dimensional, non-axisymmetric
Operation	pulsed; the transformer must reset	steady state
Failure mode	current-driven instabilities and disruptions	no plasma current, so no current-driven disruption
Degrees of freedom	few; the shape is largely fixed	many; the shape is the design variable

A cell is not pulsed and does not reset. It runs continuously from before birth until death, and it is not confined by a current driven through its own contents. It is confined by the shape of what surrounds it. That is a stellarator, and it is not a stellarator by analogy — it is a stellarator by the definition of the two machines.

---

112. The Hexagon Is the Cross-Section and the Twist Is Sixty Degrees ↩

Poloidal is the alphabet, toroidal is the sequence, and the rotational transform is what stops a code from repeating

In a toroidal confinement device the short way round the cross-section is the poloidal direction and the long way round the machine is the toroidal direction. The rotational transform is the angle by which a field line advances poloidally for each toroidal circuit. If the transform were zero, every field line would close on itself immediately and nothing would be confined.

direction	what it is in the model	what it produces
Poloidal — the short way round	the hexagon; six positions	the code alphabet
Toroidal — the long way round	reading along the strand	the sequence
Rotational transform	60° per step	what stops a field line closing on itself, and a code repeating
The swept solid	the torus	the Triplex Torus of the corpus
Six positions, two sugar states	2^6	64

A code that did not twist would be a repeat. The rotational transform is the reason a sequence is a sequence and not a stutter.

113. The Nested Surfaces Are the Compartments, and DNA Stays in the Core ↩

The confinement rule, stated once: the core is never breached, and error is routed, not absorbed

A stellarator confines on nested magnetic surfaces: closed surfaces one inside another, with the innermost being the magnetic axis. Nothing confined on one surface should strike the vessel wall. The cell has the same architecture and the same rule.

surface	compartment	what is confined there
The magnetic axis — the core	NUCLEUS	DNA. It stays here. It does not enter the cytoplasm.
First surface out	RIBOSOME	translation; the message is read
Next	ENDOPLASMIC RETICULUM	folding; entry to the secretory route
Next	GOLGI APPARATUS	modification and sorting
Power	MITOCHONDRION	the energy that holds every gradient
Exhaust	LYSOSOME	controlled disposal — the divertor
The vessel wall	plasma membrane	the boundary that must never be struck from inside

The rule the architecture enforces. DNA is confined to the core and does not leave it. What leaves is the message, and it leaves through a gate. The lysosome is not a failure of the system; it is the divertor — the place where what cannot be kept is deliberately routed so that it does not strike the wall. A confinement device without a divertor destroys itself with its own exhaust, and so does a cell.

114. The Reactor Is Ninety-Three Million Miles Away ↩

There is no fusion in the mitochondrion; there is fusion in the Sun, and the mitochondrion spends what arrives

It would complete the analogy neatly to say that fusion occurs in the mitochondrion. It does not, and the correction improves the architecture rather than damaging it. The only fusion in the chain is stellar. What the cell operates is the downstream half

of a power system whose reactor is external, which is exactly the situation of a terrestrial fusion plant and exactly the situation of a stellarator that is fueled rather than self-igniting.

stage	what happens	product
The Sun	hydrogen fused to helium	the only fusion in the chain
Photosynthesis	that energy captured and stored	as glucose
Glycolysis and the citric acid cycle	glucose broken down	electrons harvested
The respiratory chain	those electrons spent	protons pumped across the inner membrane
ATP synthase	the gradient spent	ATP made, water released

And the terminal machine turns in thirds

ATP synthase is a rotary motor. Proton flow down the gradient turns a c-ring in the membrane against a stator; the c-ring drives the gamma subunit as a shaft; the head carries three catalytic beta subunits. The step is a hundred and twenty degrees and a full revolution makes three ATP. Boyer proposed the binding-change mechanism and Walker established the structure, and the two shared the Nobel Prize in Chemistry for it.

$$360° \div 3 \text{ catalytic sites} = 120° \text{ per step} \rightarrow 3 \text{ ATP per revolution}$$

thread in this volume	where it appears in ATP synthase
The theory of three	three catalytic sites; 360° ÷ 3 = 120°
Rotation, SO(3)	a literal rotary motor, with a shaft and a stator
Protons	proton flow is the fuel; the gradient is the stored energy
pH	the gradient is a pH difference — the adjusted level is the fuel itself

The power supply of the model is a rotary motor stepping in thirds, driven by a proton gradient, at the center of the compartment that holds every other gradient in place.

Steady state means regulated, not motionless. A stellarator's advantage over a tokamak is steady-state operation, and steady state is often misread as stillness. It is the opposite. Glucose is delivered continuously, water is produced continuously by the respiratory chain and is the medium everything else occurs in, and the gradients are held constant by continuous expenditure. Steady state is the most expensive condition the cell maintains.

115. The Containment Test: Does Everything in This Volume Fit Inside the Model? ↩

Thirty-five parts tested against five slots; thirty-two fit, three do not, and the three fail for one reason

A model that accommodates everything explains nothing. The test that follows was run against every preceding Part of this volume, and it was run to find failures.

slot	name	what it holds
1	THE CORE	the innermost surface; DNA, confined, never crossing
2	THE SURFACES	nested compartments; what may cross, and where
3	THE TWIST	the rotational transform; 60°; what makes sequence out of repetition
4	THE POWER	proton gradient, pH, ATP synthase turning in thirds
5	THE DIVERTOR	where error is deliberately routed instead of striking the wall

The result

category	finding	note
Fits	32 of 35 parts	distributed across the five slots
Does not fit	3 parts	all pre-cellular, and all for the same reason
Synthetic biology	inside	operating on slot 2, the join
Non-canonical amino acids	inside	over 200, each by an engineered synthetase
Selenocysteine	inside	and it is the natural precedent for the whole method

116. The Three That Do Not Fit, and Why That Is the Best Result in the Test ↩

Every failure is chemistry that occurs with no cell anywhere near it

the part	what it is	why it will not go in
Part 12 — the conjugate pair	bond angles and oxidation states are properties of atoms	they hold in a rock, with no cell anywhere near it
Part 14 — the Great Oxidation Event	planetary chemistry dated by mass-independent sulfur isotope fractionation, 2.4 billion years ago	no compartment is involved
Part 30 — the amide bond, older than Earth	formamide in Sagittarius B2, and in comet 67P	confinement-free chemistry, in vacuum

The three failures are not scattered. They are the three Parts of this volume that describe chemistry occurring before, outside and independently of any cell. A confinement model should fail exactly there, because there is nothing to confine.

The model does not cover the pre-cellular chemistry, and it should not. That the three exceptions are precisely the three pre-cellular Parts is the strongest evidence in the test that the model is drawing a real boundary rather than a convenient one.

Synthetic biology does not sit outside; it operates on slot two

Genetic code expansion works by supplying an engineered aminoacyl-tRNA synthetase evolved to accept a new substrate, an orthogonal transfer RNA that no host synthetase will charge, and a blank codon — amber, opal, or a quadruplet. The requirement is orthogonality: the new pair must not cross-react with any of the twenty. Every one of those components acts at the join described in Part Thirty-Two, which is slot two of this model.

component	what it is
The engineered enzyme	an aminoacyl-tRNA synthetase, evolved to a new substrate
The partner	an orthogonal tRNA that no host synthetase will charge
The codon	a blank — amber, opal, or a quadruplet
The requirement	orthogonality; no cross-reaction with any of the twenty

One correction to the count, carried forward. The number of non-canonical amino acids installed by this method is over two hundred, not four hundred. The larger figure has circulated in this framework's own working notes and is withdrawn here. Selenocysteine, incorporated naturally by UGA recoding with a SECIS element, is the precedent the whole method follows, and it is a sulfur-group element occupying a blank codon by exactly the mechanism synthetic biology now engineers.

---

117. What Would Show This Part Is Wrong ↩

Stated as instructions, as everywhere else in this volume

— Demonstrate stable, sustained residence of chromosomal DNA in the cytoplasm of a healthy eukaryotic cell, and the core rule in section 113 fails. The model requires that the innermost surface is not crossed.

— Show that a seventh coding base is read by a ribosome in any natural system, and the hexagon closure of section 109 must be rebuilt rather than adjusted.

The volume has already rebuilt this closure once, from eight positions to six; a seventh base would require it again.

— Establish that the two sugars are distinguished by something other than a second traversal — that deoxyribose and ribose are read on the same circuit — and the 720-degree account in section 110 is decoration rather than structure.

— Find a fourth Part of this volume that does not fit the five slots and that is not pre-cellular chemistry, and the boundary claimed in section 116 is not the boundary the model actually draws.

— Show ATP synthase operating with a step size other than one hundred and twenty degrees, or with a number of catalytic sites other than three, and the arithmetic in section 114 that ties the power supply to the theory of three is coincidental rather than structural.

The first of these is the most tractable and the most dangerous to the model, which is why it is listed first.

PART THIRTY-SEVEN · OROTATE, THE TWO CURRENCIES, AND THE EXTENDED LADDER

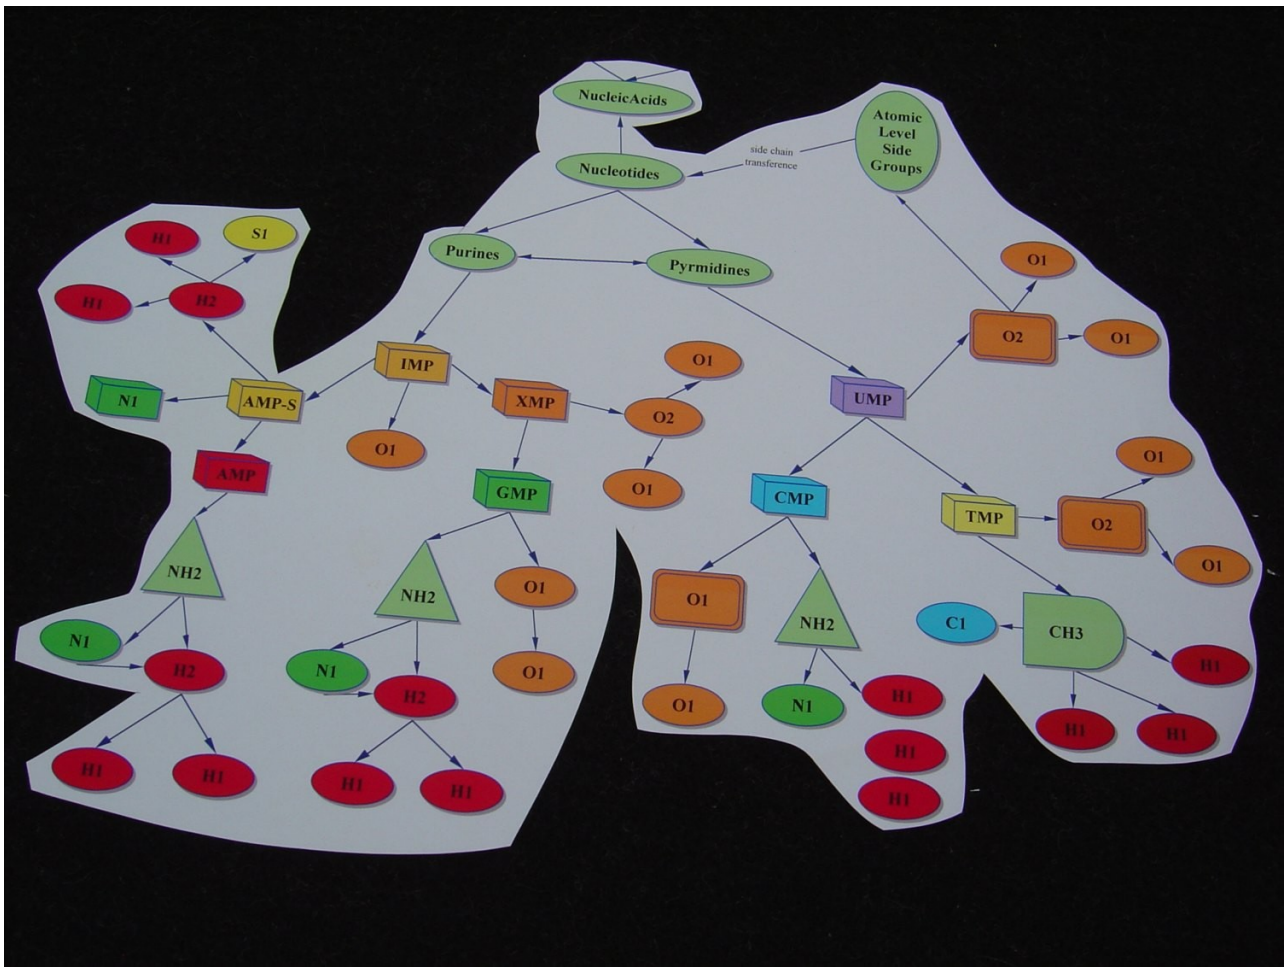

FIGURE 3 · NUCLEIC ACIDS TO NUCLEOTIDES, BY SIDE GROUP

Nucleic acids branch to nucleotides, nucleotides to purines and pyrimidines, and the terminal nodes are IMP, XMP, GMP, CMP, TMP and UMP — with the atomic side groups that distinguish them carried on the branches: O1, O2, NH2, CH3. The purine and pyrimidine families drawn as one graph.

118. The Pyrimidines Have an Origin Node Too, and It Is Orotate ↩

SEE PART NINETY-SEVEN, SECTION 806. Orotate is the origin node of the pyrimidine line and this section is right about it. The node the pyrimidine line shares with the purine line sits one enzyme upstream, at PRPP, where the purine line is standing in the same queue.

What xanthine is to the purines, orotate is to the pyrimidines — and neither appears in the table

Part Thirty-Two of this volume set out the purine branch: de novo synthesis produces inosine monophosphate as its first complete nucleotide, and everything else radiates from it. IMP goes to xanthosine monophosphate and on to guanosine

monophosphate, or by the adenylosuccinate route to adenosine monophosphate. Xanthine sits in the middle of that as an obligate intermediate that the four-letter table does not name.

The pyrimidine branch has exactly the same shape, and it has been in the textbooks the whole time.

carbamoyl phosphate + aspartate → carbamoyl aspartate → dihydroorotate →
OROTATE → OMP → UMP → UTP → CTP
└→ dUMP → dTMP

feature	PURINE branch	PYRIMIDINE branch
First complete nucleotide	IMP	UMP
The obligate intermediate the table omits	xanthine / XMP	orotate / OMP
The branches from the first nucleotide	AMP and GMP	CTP and dTMP
Return route to the origin node	ADA, AMPD, ADAR — three enzymes, three levels	salvage by uridine phosphorylase and kinases
Standing in the canonical table	absent	absent

The two branches are the same object drawn twice. Each has a first nucleotide, each has an intermediate base that the notation refuses to name, and in each case the omitted one is the one the pathway cannot proceed without.

Why orotate is the stronger of the two omissions. Xanthine can be reached by salvage as well as de novo, so its status as an obligate node is arguable. Orotate cannot. Every pyrimidine ring made from scratch in every organism passes through orotate, and there is no alternative route. If the purine story rests on IMP being first, the pyrimidine story rests on orotate being unavoidable, and the second claim is the harder of the two to argue with.

---

119. The One Place Where Nucleotide Synthesis Is Wired Into the Respiratory Chain ↩

Dihydroorotate dehydrogenase sits in the mitochondrial inner membrane and passes its electrons to ubiquinone

Almost every enzyme of nucleotide biosynthesis is cytosolic and soluble. One is not.

property of DHODH	detail	significance
Location	the inner mitochondrial membrane	not the cytosol
Electron acceptor	ubiquinone — coenzyme Q	the respiratory chain itself
Consequence	pyrimidine synthesis stalls when respiration stalls	a direct metabolic coupling
The step it performs	dihydroorotate → orotate	the committed oxidation

This is the single point at which the manufacture of genetic material is physically attached to the machinery that makes ATP. A cell that cannot respire cannot make pyrimidines de novo, and the reason is not a shortage of energy in general but the loss of one specific electron acceptor at one specific membrane-bound enzyme.

And it is a validated drug target with agents in the clinic

agent or finding	status	indication
Teriflunomide, leflunomide	approved	multiple sclerosis, rheumatoid arthritis
Brequinar, BAY 2402234, JNJ-74856665	in trials	acute myeloid leukemia and other malignancies
Emvododstat, ASLAN003, AG636, RP7214, JBZ-001	in trials	AML and solid tumors
The mechanism exploited	AML cells depend on DHODH	inhibition forces differentiation
The current state	tolerable, weak as single agents	the field has moved to combinations

The enzyme that makes the omitted base is a mitochondrial enzyme wired to the respiratory chain, and it is being drugged right now in leukemia. The framework did not have to reach for this. It was already there.

One further fact about the next step, recorded because it is remarkable. The enzyme that converts OMP to UMP — orotidine-5'-monophosphate decarboxylase — produces the largest rate enhancement ever measured for any enzyme, on the order of ten to the seventeenth power. The uncatalyzed reaction has a half-life of roughly seventy-eight million years. The step that turns the omitted base into uracil is the fastest catalysis known, and it also has a human disease attached: hereditary orotic aciduria, caused by deficiency of UMP synthase, presenting as megaloblastic anemia and treated with uridine.

CORRECTED IN PART NINETY-SEVEN, SECTION 802. The superlative in this section is no longer true as stated. It held from 1995 until

2008, when Lewis and Wolfenden measured human uroporphyrinogen decarboxylase against an uncatalyzed reaction with a half-life of 2.3 billion years and took the record. OMP decarboxylase remains the record holder among the enzymes of nucleotide metabolism, which is the narrower claim this volume now makes.

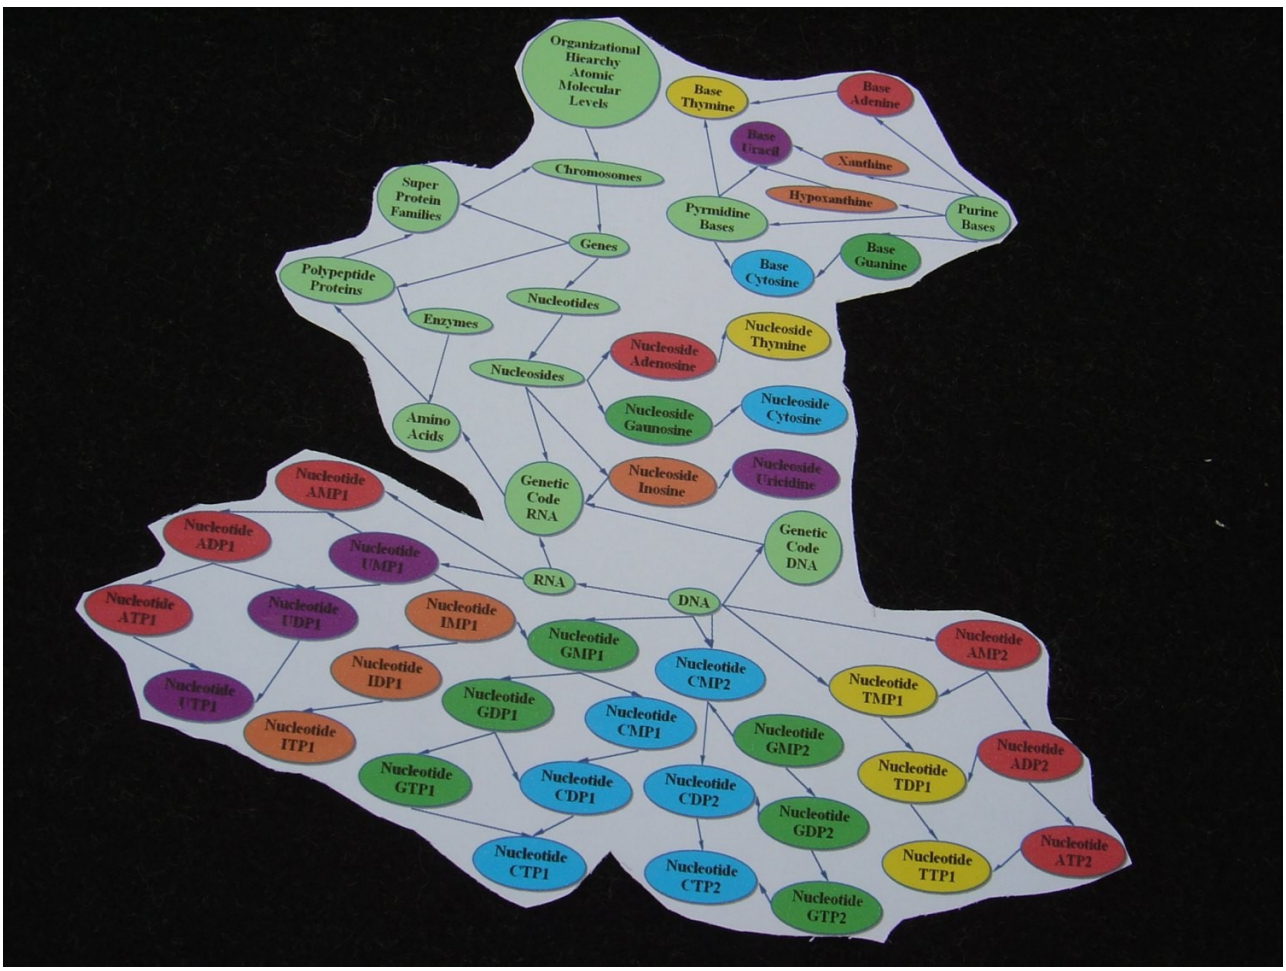

FIGURE 4 · THE NUCLEOTIDE LADDER, MONO TO TRI

The same six nucleotides carried up through their di- and triphosphates, with the genetic code of RNA and of DNA entered as nodes and inosine among them. The phosphate ladder of Part Thirty, drawn by hand.

120. Four and Four — What the Symmetry Licenses and What It Does Not ↩

The biosynthetic set has eight members; the coding set still has seven, and the difference matters

With orotate named, the two branches become symmetrical and the count becomes four against four.

family	members	note
PURINES	I · X · G · A	inosine, xanthine, guanine, adenine
PYRIMIDINES	O · C · U · T	orotate, cytosine, uracil, thymine
Total biosynthetic set	eight	four and four

The correction, applied consistently — and it removes a base rather than adding one. Xanthine and orotate are metabolic intermediates. Neither is read by a ribosome, neither is incorporated into a messenger RNA as a coding letter, and neither pairs across a duplex as an informational base. Applied to orotate alone, this rule would have been special pleading, because it applies to xanthine with exactly the same force. Applied consistently it removes both, and the coding set falls from seven to six: adenine, cytosine, guanine, inosine, uracil, thymine. Part Thirty-Eight records that revision and its consequences. Xanthine and orotate remain in this volume as what they are — obligate biosynthetic nodes that the canonical table omits — and they lose only their status as letters.

Stated precisely: the code has seven letters and a switch. The chemistry that manufactures those letters has eight nodes, of which two — xanthine and orotate — are obligate way stations that the notation omits. Those two omissions are the subject of this Part, and they are omissions of a different kind from the omission of inosine.

Seven letters and a switch, made from eight nodes. The table names five of the eight.

---

121. Both Epigenetic Currencies Are Carried on Sulfur ↩

The methyl rides a sulfonium; the acetyl rides a thioester; neither mark is written without element sixteen

Part Twenty of this volume treated the epigenetic marks as sulfur currencies. This section states the chemistry exactly, because it is the cleanest single demonstration of the volume's thesis available in human biology.

mark	carrier	the sulfur
Methylation	S-adenosylmethionine, SAM	the methyl sits on a positively charged trivalent sulfur — a SULFONIUM — and that charge is what makes the group

mark	carrier	the sulfur
		transferable
Acetylation	acetyl-coenzyme A	the acetyl is bonded to sulfur as a THIOESTER, the high-energy linkage of Part Thirty
The transferred group	one carbon, or two	in both cases from a sulfur atom to a nitrogen or an oxygen
The gene sequence record	nothing	the DNA letters are identical before and after

A methylated cytosine and an unmethylated cytosine are the same letter. An acetylated lysine and an unacetylated lysine are the same residue in the same protein encoded by the same codon. In both cases the difference in behavior is total and the difference in notation is nil, and in both cases the group that made the difference arrived on a sulfur atom.

Every epigenetic mark in a human cell is written by a sulfur atom handing something over, and read by a protein that never sees the sulfur.

---

122. The Citric Acid Cycle Meters Both Marks ↩

Acetyl-CoA is the cycle's entry point, and the nuclear acetyl pool is refilled from exported citrate

The two currencies are not independent of metabolism. They are metered by it, and the meter is the citric acid cycle.

glucose → pyruvate → ACETYL-CoA → citrate (mitochondrion) ↓
exported *citrate + ATP-citrate lyase → ACETYL-CoA (nucleus, cytosol)*
↓ *histone acetyltransferases → acetyl-lysine*

node	role in metabolism	role in the epigenome
Acetyl-CoA	the entry point of the cycle	and the sole donor for histone acetylation
Citrate	the cycle's first intermediate	exported to regenerate nuclear acetyl-CoA by ATP-citrate lyase
Methionine and SAM	the methyl cycle	fed by folate and cobalamin; SAM is consumed by every methyltransferase
The consequence	metabolic state sets mark availability	feed the cycle differently and the chromatin marks change

What this establishes and what it does not. Established: that acetyl-CoA is a thioester and the only acetyl donor for histone acetylation; that SAM carries its methyl on a sulfonium and is the donor for essentially all biological methylation; that citrate export and cleavage by ATP-citrate lyase supplies the nuclear acetyl-CoA pool; and that all three are metabolically regulated. Not established here: that any particular metabolic intervention produces any particular epigenetic outcome in a patient. The coupling is documented; its therapeutic exploitation is a program, not a result.

---

123. The Extended Ladder — From Minerals to the Organism

The central dogma stated at full length, with sulfur named at every rung where it acts

The dogma as usually taught runs DNA to RNA to protein: three terms and two arrows. The framework of this volume has been extending it in both directions throughout. Set out at full length, with the rungs the standard statement leaves out, it runs as follows.

rung	level	where sulfur appears
1	Minerals and metals	iron, nickel, molybdenum, zinc — and sulfide, forming the first iron–sulfur clusters
2	The four monomer classes	bases, amino acids, lipids, sugars — all four present in the Murchison meteorite
3	Thioester metabolism	acyl transfer at sulfur, before phosphate — acetyl-CoA is the survivor
4	RNA1	the first informational polymer; ribozyme catalysis
5	DNA	the archival strand; ribonucleotide reductase removes an oxygen using sulfur
6	RNA2	the working transcriptome of today, modified at over a hundred positions
7	tRNA and the synthetases	the unique covalent junction; sulfur at wobble U34
8	The peptide bond	made by a ribozyme; methionine first, always
9	Peptides and tripeptides	glutathione is a tripeptide, and its function is its cysteine
10	Alpha helix, beta sheet, beta turn	glycine and proline decide the corners
11	Tertiary structure	disulfide bonds fix it; the thiol is the crosslink
12	Enzymes	catalysis by positioned residues, cysteine among the most reactive
13	Stacked quadruplexes	four bases to a tetrad, stacked; topology set by rotations
14	Protocells	lipid vesicles with sugars and encapsulated polymers
15	Cells, and the organelles within them	compartments; the mitochondrion runs on iron–sulfur clusters

rung	level	where sulfur appears
16	Tissues	collagen, held by the glycine of Part Thirty-Five and crosslinked
17	Organs, organ systems, organism	the whole, including the human

Two notes on the ladder as drawn. First, organelles are inside cells rather than above them; the ordering here places them at the cellular rung rather than between cells and tissues, which is where an intuitive reading tends to put them. Second, the ladder is a summary of claims made and defended elsewhere in this volume, not an independent argument. Its purpose is to show that the same atom is named at every rung, which is the connective-tissue claim stated as a list.

Seventeen rungs from a mineral to a man, and element sixteen is doing something identifiable at every one of them.

---

124. What Would Show This Part Is Wrong ↩

Stated as instructions, as everywhere else in this volume

— Demonstrate a de novo pyrimidine biosynthetic route in any organism that does not pass through orotate, and the obligate-node claim in section 118 fails.

— Show that dihydroorotate dehydrogenase in a mammalian cell functions independently of the respiratory chain — that pyrimidine synthesis continues at normal rate with the electron transport chain inhibited and no alternative acceptor supplied — and the coupling in section 119 is not what it appears to be.

— Find orotate or xanthine incorporated as a coding base into a natural messenger RNA and read as such by a ribosome, and the six-base revision of Part Thirty-Eight is wrong and the seven- or eight-letter set must be restored.

— Establish a biological methyl transfer that does not proceed through a sulfonium and a biological acetyl transfer that does not proceed through a thioester, and section 121 is a generalization rather than a rule.

— Show that nuclear acetyl-CoA is supplied independently of citrate export in a normal cell — that ATP-citrate lyase inhibition leaves histone acetylation unchanged — and the metering claim in section 122 is broken.

The third of these is the one that would cost the most, because it would reverse the revision this volume has just made. It is listed for exactly that reason.

PART THIRTY-EIGHT · THE REVISION TO SIX

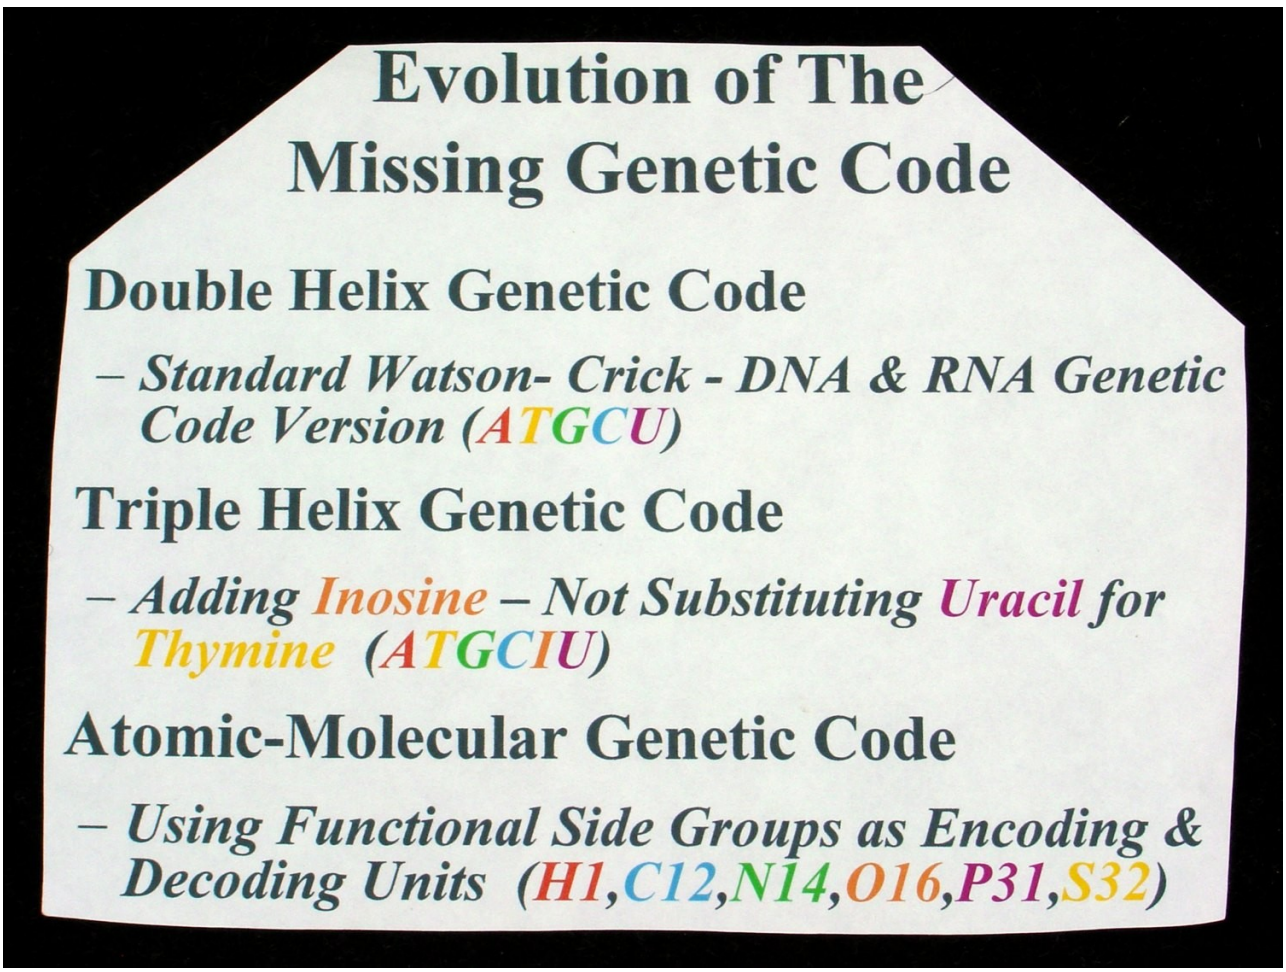

FIGURE 5 · EVOLUTION OF THE MISSING GENETIC CODE

The author's three-stage statement, made years before this volume. Double helix: the standard Watson-Crick code, ATGCU. Triple helix: adding inosine rather than substituting uracil for thymine, ATGCIU. And then the third line, which is what this volume argues — an atomic and molecular code using functional side groups as encoding and decoding units: H1, C12, N14, O16, P31, S32. Six elements, given by mass number, and phosphorus at thirty-one.

125. The Rule That Removed Two Letters ↩

Applied to orotate alone it was special pleading; applied consistently it takes xanthine with it

Part Thirty-Seven established orotate as the pyrimidine origin node and then excluded it from the coding set on a stated ground: no ribosome reads it, no duplex

pairs it, and it is never incorporated into a messenger RNA as a letter. That ground is correct. It was also applied to only one of the two molecules it covers.

Xanthine fails the same test in exactly the same way. It is an obligate intermediate of purine metabolism, it is a real base with a real nucleotide, and no ribosome has ever read it either. A rule that removes orotate and keeps xanthine is not a rule. It is a preference.

Applied once, the rule removes a candidate. Applied consistently, it removes two, and the coding set falls from seven to six.

letter	base	color	element
A	adenine	RED	H 1
C	cytosine	BLUE	C 6
G	guanine	GREEN	N 7
I	inosine	ORANGE	O 8
U	uracil	PURPLE	P 15
T	thymine	YELLOW	S 16

What this costs and what it does not. It costs the seven-letter set that earlier Parts of this volume used, the eight-position octagon built on it, and the eight-against-eight route to sixty-four. It does not cost any chemistry. Xanthine and orotate remain exactly what Parts Thirty-Two and Thirty-Seven show them to be — obligate biosynthetic nodes that the canonical table omits — and their omission from that table remains one of this volume's findings. What they lose is the status of letters, which was never established for either of them.

---

126. Six Elements, and They Are Not This Volume's Invention ↩

Removing xanthine removes selenium from the coded set, and what is left is CHNOPS

The color index of this volume assigned one element to each base. Xanthine's element was selenium. Removing xanthine therefore removes selenium from the coded set automatically — the two were the same row, and no separate decision is required.

What remains is carbon, hydrogen, nitrogen, oxygen, phosphorus and sulfur.

C H N O P S the standard six elements of terrestrial biochemistry

Why this is a gain rather than a loss. The seven-element set was this volume's own construction and had to be defended each time it was used. CHNOPS is not a construction. It is the canonical inventory of the elements of life, it appears in every textbook, and no reader has to be persuaded of it. The framework now maps one base to one element across a set that nobody disputes, and the mapping is one to one with nothing left over on either side.

Selenium is not deleted; it is relocated

Selenocysteine remains the twenty-first proteinogenic amino acid, remains encoded by UGA read through a SECIS element, and remains the natural precedent for the whole of genetic code expansion. Every claim this volume makes about it stands. What changes is only that selenium is not one of the six elements that carry the coding bases. It is the third chalcogen, standing immediately outside the coded set, and Part Twenty-Two treats it in that position.

Two chalcogens inside the six and one immediately outside it. Oxygen, sulfur, and selenium waiting.

---

127. Sixty-Four, Reached by an Identity Instead of a Construction ↩

Six positions with two states each is two to the sixth, and that is exact

Earlier editions of this volume reached sixty-four by placing eight positions on a ring and multiplying an inner ring by an outer one. That arrangement worked arithmetically and required an eighth face to exist. With six bases there is no eighth face, and the eight-against-eight route is gone.

The replacement is better, and it uses the ruling on the sugar switch rather than discarding it.

route	arithmetic	result
Six bases, triplet code	6^3	216 — no
Six against six, inner ring by outer	6 × 6	36 — no
Six bases times two sugars	6 × 2	12 nucleosides — correct, but not 64
Six positions, two sugar states each	2^6	64 — YES, exactly

The sugar switch was ruled to be a backbone property rather than a base property. A backbone property does not need a face of its own; it is a state available at every position. Six positions, each carrying one of six bases and readable on either of two sugars, is a six-bit register, and a six-bit register has sixty-four states.

$$2^6 = 64 \quad \textit{six positions} \cdot \textit{two sugar states each} \cdot \textit{sixty-four configurations}$$

Why an identity is worth more than a construction. Eight against eight equals sixty-four is true, but so is thirty-two against two, and sixteen against four. The arrangement had to be argued for. Two to the sixth is not an arrangement — it is what a six-position binary register is, and there is nothing to argue. The volume reaches the same number with one fewer assumption, and the assumption it drops is the one that was carrying the most weight.

---

128. The Hexagon, and Why It Has a Referent the Octagon Never Had ↩

Sixty degrees per step; twelve steps to the spinor closure; and twelve is the order of the tetrahedral group

property	value	note
Positions on the ring	6	one per base
Step angle	60°	360 divided by six
Geometric closure	6 steps × 60° = 360°	the ring returns
Spinor closure	12 steps × 60° = 720°	the object returns
And twelve is	|T|, the tetrahedral rotation group	the two solids of this volume finally agree on a number

The spinor argument of Part Thirty-Six is untouched. Three hundred and sixty degrees returns the ring; seven hundred and twenty returns the object; and the two circuits remain the two sugars. What changes is the step size and the number of steps, and the new step count is twelve rather than sixteen.

And the hexagon is in the molecule, which the octagon was not

A pyrimidine is a six-membered ring. A purine is a six-membered ring fused to a five-membered one. Every base in the coding set is built on a hexagon, and the ring that the framework now uses to arrange them is the same shape as the ring they are made of. The octagon had no such referent; it was a device for holding eight things.

Six bases on a hexagon, each of them built on a hexagon. The figure and the molecule are the same shape for the first time.

What is not claimed here. That the hexagonal arrangement is a physical structure, that bases are spatially arranged in a ring in any nucleic acid, or that the sixty-degree step corresponds to a measured angle in DNA or RNA. It is an arrangement of the coding set, chosen because six is the number of members and because a six-membered ring is the shape those members are built from. The claim is about bookkeeping and geometry, not about atomic positions.

---

129. What the Stella Octangula Keeps and What It Loses ↩

The tetrahedron still gives eight; it just no longer gives eight bases

Part Thirty-Six derived eight from the self-duality of the tetrahedron — four vertices and four faces — and from the stella octangula, whose vertex set is the eight corners of a cube. None of that geometry is affected by the revision. A tetrahedron is still self-dual, two interpenetrating tetrahedra still give a cube, and the binary tetrahedral group still has order twenty-four.

What is severed is the link between that eight and the number of coding bases. The eight of the stella octangula is a count of vertices. It was doing double duty as a count of ring positions, and that second job is now done by six.

claim	status	note
Tetrahedron self-dual, 4 + 4 = 8	KEPT	a theorem about a solid
Stella octangula vertex set = 8 = a cube	KEPT	the hexahedron of the corpus
|T| = 12, |2T| = 24 Hurwitz units	KEPT — and now load-bearing	12 is the hexagon's spinor step count
Eight vertices = eight ring positions	WITHDRAWN	the ring has six positions
Eight ring positions × eight = 64	WITHDRAWN	replaced by $2^6 = 64$

The tetrahedron kept its eight and lost its second job. The number that survived the revision and gained weight is twelve.

---

130. The Record of the Revision ↩

Why the superseded version is described here rather than deleted from the volume

Earlier Parts of this volume were written with seven coding bases, seven elements, seven colors and an eight-position ring. Those Parts have been corrected where the numbers appear, and this Part states what changed and why. The superseded arrangement is described rather than erased.

The reason, stated once. A framework that shows the revision it made is easier to trust than one that presents itself as having always been right. This volume's method — recording the arithmetic routes that fail, the reproduction that did not work, the trial that missed its endpoint, the alternative explanation that has not been excluded — would be inconsistent with quietly rewriting its own history. The seven-letter set was held for a long time and abandoned on a stated ground. That is a fact about the work and it belongs in it.

The revision in one line

SEVEN → SIX I X G A T U C → A C G I U T seven bases, one silent face six bases, switch at every position 8 × 8 = 64 $2^6 = 64$ 45° per step, 16 to close 60° per step, 12 to close

---

131. What Would Show the Revision Is Wrong ↩

Stated as instructions, as everywhere else in this volume

- Demonstrate ribosomal reading of xanthine or orotate as a coding base in any natural system, and the rule applied in section 125 is too strong; the seven- or eight-letter set returns.
- Show that inosine is not read as a coding base either — that its role at anticodon position 34 is decoding rather than being decoded, and that this disqualifies it by the same rule that removed xanthine — and the set falls from six to five. This is the most serious objection available to the revision and it is stated here rather than left for a reader to find.
- Establish a seventh natural coding base in any organism, and the hexagon and the six-bit register both require rebuilding.
- Show that the sugar identity is not a binary state at each position — that a third sugar occurs in a natural coding polymer — and 2^6 is the wrong arithmetic; three states across six positions would give 729.

The second bullet is the one that would hurt. Inosine is the base this whole volume was written to restore, and the rule that removed xanthine can be pointed at it. That the objection is available is not a reason to leave it unstated.

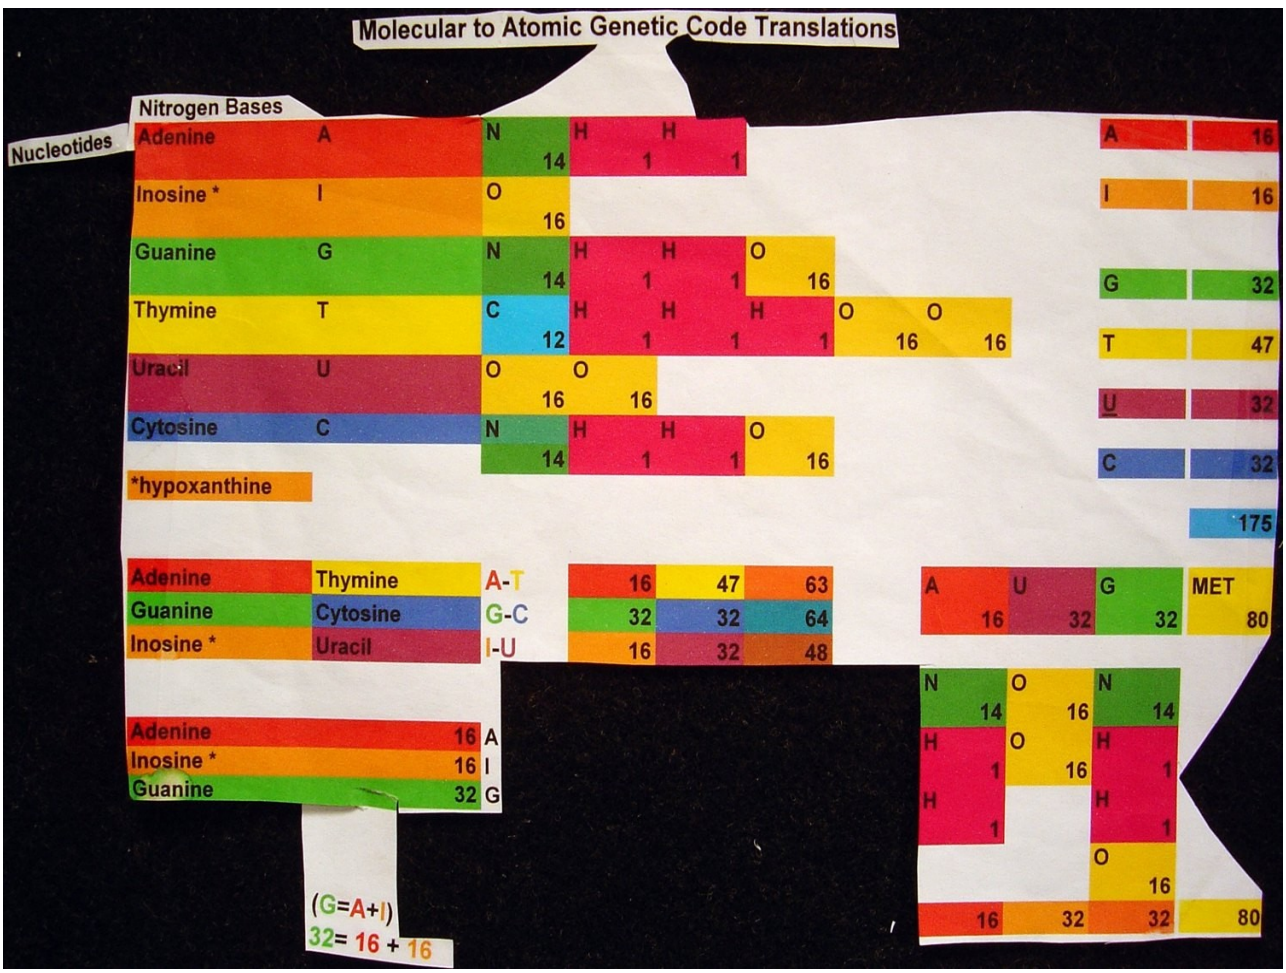

FIGURE 6 · MOLECULAR TO ATOMIC GENETIC CODE TRANSLATIONS

Each base resolved into its atoms and their masses, with hypoxanthine starred, and the pairs totaled: adenine-thymine, guanine-cytosine, inosine-uracil. At the foot of the sheet, in the author's hand: G = A + I, and 32 = 16 + 16. An attempt to read the code by atomic weight rather than by letter.

132. The Cardinal Error: Base, Nucleoside, Nucleotide ↩

A, T, G and C are bases; inosine is a nucleoside; IMP is a nucleotide — and the literature slides between them

The canonical table lists adenine, thymine, guanine and cytosine. Those are nucleobases. The molecule this volume has been arguing for is routinely called inosine, which is a nucleoside — a base with a sugar attached. Its base is hypoxanthine. To set inosine beside adenine is to compare a nucleoside with a base, and it is done constantly, in textbooks and in this volume's own earlier Parts.

Confusing hypoxanthine with inosine is the cardinal error of this field, and a reviewer who objects to inosine while writing A, T, G, C has committed it in the same sentence.

BASE	nucleoside	nucleotide	color	element
HYPOXANTHINE	inosine	IMP	ORANGE	O 8
ADENINE	adenosine	AMP	RED	H 1
GUANINE	guanosine	GMP	GREEN	N 7
CYTOSINE	cytidine	CMP	BLUE	C 6
URACIL	uridine	UMP	PURPLE	P 15
THYMINE	thymidine	TMP	YELLOW	S 16

Read the first column and the set is level-consistent with the canonical four: hypoxanthine, adenine, guanine, cytosine, uracil, thymine. Read the third and it is the author's preferred working level: IMP, AMP, GMP, CMP, UMP, TMP. The two are the same six molecules described at different depths, and every claim in this volume should name which depth it means.

The convention adopted from this Part forward. Where the claim is about pairing, hydrogen bonding, tautomers or the canonical table, the BASE name is used: hypoxanthine, adenine, guanine, cytosine, uracil, thymine. Where the claim is about a residue inside a polymer or about wobble reading at position 34, the NUCLEOSIDE name is used: inosine, adenosine, guanosine, cytidine, uridine, thymidine. Where the claim is about metabolism, biosynthesis or energy, the NUCLEOTIDE name is used: IMP, AMP, GMP, CMP, UMP, TMP. Earlier Parts of this volume are not consistent on this point, and that inconsistency is recorded here rather than hidden.

And it repairs the objection raised in section 131

The second falsification bullet of section 131 asked whether the rule that removed xanthine can be pointed at inosine — whether the molecule only decodes rather than being decoded. Stated at the correct level the answer is clean. ADAR deaminates adenosine to inosine within a messenger RNA; the base of that residue is

hypoxanthine; and the ribosome reads it as guanine. Hypoxanthine is therefore read as a coding base in a human cell, at a position whose editing is required for life. Xanthine is not read anywhere. The rule separates them, and it separates them at the level of the base rather than at the level of the nucleoside.

Hypoxanthine is read. Xanthine is not. Both statements are about bases, and that is why they can be compared at all.

---

133. Two Companion Papers, Placed Here Entire ↩

Both were written independently of this volume; both arrive at six

The two Parts that follow are complete papers, reproduced without abridgement. Neither was written for this volume and neither was derived from it, and that is the reason for including them whole rather than summarizing them. Their own internal section numbers have been prefixed with the Part number so that they do not collide with the running sequence of this volume; nothing else in them has been altered.

The first, the Berger Nucleotide Code, is dated 6 August 2026 — before the revision recorded in Part Thirty-Eight. It builds a quaternionic algebra on nucleotides rather than bases, takes IMP as its root, and requires exactly six generators. It reached six by computation while this volume was still arguing for seven.

The second, the Triplex Nervous System, sets thirty-five concept maps against seventeen position papers written over twenty-five years. The maps were analyzed from topology alone, with no access to the papers. Where two independent descriptions of one object agree, the agreement is evidence about the object rather than about either description, and the paper is placed here entire so that the reader can judge that for himself.

Two accounts, arrived at separately, and both of them land on six nucleotides with inosine at the root.

PART THIRTY-NINE · THE BERGER NUCLEOTIDE CODE

39.0 The Berger Nucleotide Code ↩

A quaternionic representation of nature's purine metabolism in nucleotides rather than bases, in which IMP is the root, the canonical purines are not primes, and the six-cell lattice is a theorem of the encoding rather than an observation added to it.

Dr. John Allen Berger Founder, NovagonDNA · PP-2026-BNC-01 v1 · DOI: pending deposit

Carlevaro, Irastorza and Vericat assigned prime integer quaternions of norm seven to the four bases, justifying the choice of primes on the grounds that primality gives the bases the character of elemental molecules. Two of those four are not elemental. AMP is IMP with a nitrogen loaded at C6. GMP is IMP oxidized to XMP and then aminated at C2. The parent is not in their set at all.

This paper constructs the alternative. Every generator is a nucleotide. The assignment is semantic rather than arbitrary — each quaternion component names a physical position on the molecule — and the consequences are computed rather than fitted. The construction is implemented, runs, and is included as source.

Six nucleotides, one root, three operators. Every consequence below is computed, not fitted.

39.1 The Encoding ↩

Four components, four physical facts

A nucleotide is written $q = (a_0, a_1, a_2, a_3)$. Nothing is arbitrary: each component names a position on the molecule where nucleotides actually differ.

a_0 — ring class and sugar. Magnitude is the ring count: 2 for a purine, 1 for a pyrimidine. Sign is the sugar: positive for ribo, negative for deoxy. A deoxynucleotide is therefore the negation of its ribo counterpart, which is correct — the sugar does not change the information-bearing face.

a_1, a_2, a_3 — the Watson-Crick face, in register. The three contact positions: purine C6 / pyrimidine C4, then purine N1 / pyrimidine N3, then purine C2 / pyrimidine C2. Values are +1 for a donor (exocyclic amine or ring N-H), −1 for an acceptor (carbonyl oxygen or ring nitrogen lone pair), and 0 for no contact (hydrogen at that position).

nucleotide	quaternion	norm	class	note
AMP	(2, +1, −1, 0)	6	purine · ribo	C6 donor, C2 unopened
IMP	(2, −1, +1, 0)	6	purine · ribo	root; C2 unopened
XMP	(2, −1, +1, −1)	7	purine · ribo	gate; both sockets open
GMP	(2, −1, +1, +1)	7	purine · ribo	C2 loaded
ZMP	(2, +1, −1, +1)	7	purine · ribo	2-aminoadenine, phage Z-genome
isoGMP	(2, +1, −1, −1)	7	purine · ribo	never observed in a genome
CMP	(1, +1, −1, −1)	4	pyrimidine · ribo	C4 donor
UMP	(1, −1, +1, −1)	4	pyrimidine · ribo	C4 acceptor
dAMP	(−2, −1, +1, 0)	6	purine · deoxy	= −AMP
dGMP	(−2, +1, −1, −1)	7	purine · deoxy	= −GMP
dCMP	(−1, −1, +1, +1)	4	pyrimidine · deoxy	= −CMP
dTMP	(−1, +1, −1, +1)	4	pyrimidine · deoxy	= −UMP

Thymidine monophosphate comes out as the exact negation of UMP, because the C5 methyl does not touch the Watson-Crick face. The methyl is a repair flag, not an information carrier, and the encoding says so without being told.

dTMP = −UMP. The fifth letter of DNA carries no information the fourth did not.

39.2 Derivation — the Canonical Four Are Not Primes ↩

An enzymatic substitution is an addition in one component

Each step of purine metabolism is a single quaternion addition, and the enzyme that performs it is named:

$$AMP = IMP + (2i - 2j)$$

Adenylosuccinate synthetase and lyase, nitrogen from aspartate, paid for in GTP.

$$XMP = IMP - k$$

IMP dehydrogenase, oxygen from water, not from dioxygen — which is why the ladder runs in an anoxic world.

$$GMP = XMP + 2k = IMP + k$$

GMP synthetase, nitrogen from the amide of glutamine, paid for in ATP.

The last line carries the gate. The net displacement from parent to green child is a single +k, but no enzyme performs it. The path is −k and then +2k, through XMP, and the algebra records the difference between a displacement and a route.

The norm counts opened sockets

IMP and AMP have norm 6. XMP and GMP have norm 7. The difference is exactly the C2 socket: unopened in the parent and in the adenine child, opened by IMPDH in everything downstream. Carlevaro assigns all four generators the same norm, 7, and calls them prime. Here the norm is a measurement, and the parent is distinguishable from the gate by arithmetic alone.

Deamination is subtraction, and two of the three are the same operator

AMP → IMP $\Delta = (0, -2, +2, 0)$

CMP → UMP $\Delta = (0, -2, +2, 0)$

GMP → XMP $\Delta = (0, 0, 0, -2)$

The main paper claims the three deaminations of nucleic acid chemistry are one accounting entry. The algebra sharpens that claim rather than confirming it: A→I and C→U are literally the same operator, and G→X is the same operation applied at the third contact instead of the first two. That is a refinement, and it should be stated as one.

39.3 Pairing — Hydrogen Bonds Fall Out of the Dot Product ↩

No parameters, six for six

Two nucleotides in Watson-Crick register are compared contact by contact. A product of −1 at a position is a complementary bond, donor facing acceptor. A product of +1 is a clash, donor facing donor or acceptor facing acceptor. Zero is no contact. The hydrogen-bond count is the number of −1 terms.

pair	contact terms	bonds	clashes	observed
G : C	[−1, −1, −1]	3	0	3 ✓
A : U	[−1, −1, 0]	2	0	2 ✓
I : C	[−1, −1, 0]	2	0	2 ✓
Z : T	[−1, −1, −1]	3	0	3 ✓

pair	contact terms	bonds	clashes	observed
X : C	[−1, −1, +1]	2	1	2 ✓
isoG : C	[+1, +1, +1]	0	3	0 ✓

Two of these are worth pausing on. The phage Z-genome result — 2-aminoadenine making three hydrogen bonds with thymine where adenine makes two — is not put in by hand; it is what the third contact returns once the C2 socket is loaded. And isoguanine returns zero bonds with three clashes against cytosine, because isoguanine's face is cytosine's own face. The sixth cell of the lattice is not empty for want of chemistry. It is empty because it collides.

I : C makes two bonds where G : C makes three. That is the inosine prediction of the main paper, stated in one line of arithmetic.

39.4 The Six-Cell Lattice, in Full ↩

Two times three. Not five, not seven.

The purine ring carries two sockets. C6 always bears a substituent and ranges over donor and acceptor. C2 ranges over donor, acceptor, and unopened. Two times three is six, and the count is a theorem of the encoding rather than an observation appended to it.

nucleotide	quaternion	C6	C2	status
IMP	(2, −1, +1, 0)	acceptor	unopened	root — where de novo synthesis closes
AMP	(2, +1, −1, 0)	donor	unopened	child — amination at C6
XMP	(2, −1, +1, −1)	acceptor	acceptor	gate — obligate passage, IMPDH
GMP	(2, −1, +1, +1)	acceptor	donor	child — amination at C2
ZMP	(2, +1, −1, +1)	donor	donor	occupied by phage Z-genomes
isoGMP	(2, +1, −1, −1)	donor	acceptor	never observed in a genome

Four of the six run the metabolism of every cell alive. The fifth was found in 2021, running whole phage genomes on a base outside the alphabet. The sixth is synthesizable, has never been found in a natural genome, and the algebra says why:

isoguanine's Watson-Crick face is cytosine's own face, so it returns zero bonds and three clashes against the partner it would need.

The sixth cell is not empty for want of chemistry. It is empty because it collides.

39.5 Verdict ↩

What the construction establishes

Derived, with no fitting and no free parameters

— The lattice has exactly six cells, as a consequence of the encoding rather than as an input to it.

— IMP is the root. AMP, XMP and GMP are each one named operator away, and every operator is a single quaternion addition with an enzyme attached to it.

— The norm counts opened sockets — 6 for the parent and the adenine child, 7 for everything downstream of IMP dehydrogenase. Carlevaro's four generators all carry norm 7 by construction and cannot make this distinction.

— The gate appears as a path rather than a displacement. GMP − IMP = +k, but no enzyme performs +k; the route is −k then +2k, through XMP.

— Hydrogen-bond counts, six of six, including the phage Z-genome at three where adenine gives two, and the isoguanine collision.

— Deamination as subtraction, with A→I and C→U the identical operator and G→X the same operation at the third contact.

Scope, stated plainly

This is a representation of purine metabolism in nucleotides. It is not a model of translation. Wobble reading at anticodon position 34 belongs to a later layer built on top of this one and governed by modifications — inosine, queuosine, lysidine, the thio-uridines — and it is deliberately out of scope. Nothing in this construction depends on it, and no claim here rests on codon degeneracy.

A representation built on nucleotides carries ancestry, carries operators, and returns the lattice as a consequence. A representation built on bases carries none of that.

That is the whole of the argument, and it is why the generators matter more than the algebra. Hamilton's quaternions are equally available to both constructions. What differs is what they were assigned to. Assign them to four bases held to be elemental and you have written a flat set of peers into the arithmetic, and the parent of two of them is nowhere in the notation. Assign them to nucleotides and the derivation tree, the gate, the norms and the lattice all follow without being asked for.

39.6 Reproducing This ↩

The construction is implemented in a single file, bnc.py, with no dependencies beyond the Python standard library. It prints the encoding table, checks each derivation, computes every pairing, and enumerates the lattice. Every number in this paper is printed by that script. Disagreement should take the form of an edit to it. © 2026 John Allen Berger. Licensed under CC BY-NC-ND 4.0. Companion to

PART FORTY · THE TRIPLEX NERVOUS SYSTEM

Comparison, integration, and the Z-axis problem

THE COMPLETED CIRCUIT — thirty-five maps and seventeen papers wired as one loop

Preliminary: Two Bodies of Work, Two Methods, One Result

The thirty-five concept maps were analyzed with no access to the position papers. The analysis proceeded from topology alone — arrow direction, arity, recurrence, and whether a circuit closed. It produced an anatomy: a relay, a regulator, a gate, a self-editing learning element, a set of motoneurons, and a lesion.

The seventeen position papers were written over twenty-five years and proceed from biochemistry, quaternion algebra, and the published literature. They produce a framework: three axes, seven bases, a Silent Seventh, a vortex still-point, and a selector.

These are the same object described twice, and neither description was derived from the other. That is the most important fact in this document, because independent derivation is the only kind of corroboration a framework of this sort can receive from inside itself.

What follows is the comparison in detail, then the integration, then the Z-axis question the papers leave open and the maps cannot answer alone.

40.1 COMPARISON: MAPS AGAINST PAPERS ↩

I.1 Structure — where the two accounts agree exactly

IMP: thalamic relay ≡ vortex still-point

The maps say: IMP has the highest total arity in the corpus. It is the only node drawn as a symmetric distributor — three inputs, three outputs — on more than one map. Every path from the energy stage to the code stage passes through it, with no alternative route in thirty-five sheets. Removing it disconnects the network rather than weakening it. Assigned to the thalamus on the grounds that everything ascending synapses there before reaching cortex.

The papers say: IMP is the first complete nucleotide of the ten-step de novo pathway. All purines derive from it; it is the source, not a product. In quaternion terms it corresponds to the scalar identity — all purine transformations reference IMP as origin. It is "the sphere at the origin of the nucleotide packing lattice." (PP-2026-IMP-INOSINE-01; IMP Vortex StillPoint Integration.)

Assessment. A relay and a scalar identity are the same object under two vocabularies. The thalamus is the structure through which all sensation passes and which adds nothing of its own; the scalar 1 is the element through which all multiplications pass and which changes nothing. The maps found this by counting arrows. The papers found it by reading the pathway. Convergent, and the convergence is not trivial — nothing about arrow-counting entails biosynthetic priority.

Site 34: basal ganglia gate ≡ Z-axis selector

The maps say: Site 34 is a gating structure — three third-position bases read as one instruction, eight motor programs released downstream. Assigned to the basal

ganglia because the ganglia do not generate movement, they select which prepared movement is released.

The papers say: Position 34 is the molecular instantiation of Z-axis selector logic inside a Y-axis molecule. Positions 35 and 36 require strict Watson-Crick pairing and are structurally fixed; position 34 alone is permitted to wobble. "The Z-Axis Selector does not change what amino acid is incorporated; it selects among multiple valid futures that all converge on the same translational outcome." (Berger Wobble ZAxis Selector, §3.3.)

Assessment. Selects among prepared alternatives without altering the product is the definition of basal ganglia function in motor neuroscience and the definition of the wobble in the papers. Identical. The papers add what the maps could not supply: the asymmetry of the anticodon — 36 fixed, 35 fixed, 34 free — which is the molecular fingerprint of axis differentiation inside one functional unit.

ADAR2: the only learning element ≡ the loop-closing enzyme

The maps say: ADAR2 edits the transcript encoding itself. Three units, self-connected, variable weight — formally a unit that sets its own gain, which is the definition of a learning element. The only such node in thirty-five maps; everything else is fixed wiring.

The papers say: ADAR is the enzyme that seals the primordial purine tetrahedron. A returns to I "not as an editing artifact but as the completion of the original molecular circuit." (PP-2026-INOSINE-TETRAHEDRON-01, §3.2.)

Assessment. Both accounts identify ADAR as the closure element. The maps identify it as the closure of a regulatory loop (gain-setting). The papers identify it as the closure of a metabolic loop (I → X → G → A → I). These are two different loops through the same enzyme, and neither document notices the other. That is a finding available only from the comparison: ADAR closes at two levels simultaneously, and the corpus has drawn each separately.

I.2 Function — where the papers supply what the maps only implied

Sulfur: the self-membership paradox, resolved

The maps say: Sulfur has weight 16, the highest in the corpus, and is drawn as a member of the set of six elements and as the controller of all six. The nervous-system reading assigned it to the hypothalamus and flagged the self-membership as a structural paradox — a regulator that is one of the things regulated.

The papers say: The quaternion backbone is DNA = 1, RNA = i, ANA = j, phosphorothioate = k = ij. Sulfur is not an axis. It is the product of two axes — the cross-axis torsional connector, with Rp/Sp chirality encoding non-commutativity. (Berger Triplex GeneticCode Integration §1; Berger Inosine AlternativeSplicing Integration §I.)

Assessment. This resolves the paradox. Sulfur is not a member of the set it controls; it is the operator that relates the members. In the anatomy, that is exactly correct for a hypothalamus: the hypothalamus is not a sensory area, a motor area, or an association area — it is the structure that sets the relations among them. The papers give the maps' highest-weight node its precise formal role, and the role is one the maps could not have derived, because arrow-counting cannot distinguish a member from an operator.

Consequence for the atlas: N. Sulfuris should be reclassified. It is not a nucleus of the hypothalamus proper. It is the hypothalamic–pituitary axis — the interface structure through which two systems are coupled and neither is subordinate.

The corridor and the branch point: XMP enters

The maps say: The two densest regions of the merged network are joined by exactly four edges, and all four pass through inosine. Remove inosine and the network falls into two disconnected halves.

The papers say: "There is no path from IMP to GMP that does not pass through XMP. IMPDH is the gatekeeper." (PP-2026-XANTH-7TH-01, §II.) Xanthosine is simultaneously the branch point of all purine anabolism and the convergence node of all purine catabolism — "X marks both ends of the purine metabolic arc."

Assessment. The maps have xanthine only as a catabolite, wired to uric acid and gout. The papers promote it to the seventh base and the obligate anabolic gateway. This is a genuine advance of the papers over the maps, and it adds a second bottleneck the map analysis missed. The network has not one corridor but two in series: IMP (origin) and XMP (gate). In anatomical terms, the atlas needs a structure between the thalamus and the cortex that everything must pass through — which is the internal capsule, and it is the correct assignment for XMP.

The wrong operator: a fourth instance

The maps say: The same formal error — substitution where addition was required — appears at three independent scales: the code (U for T), the methyl cycle (loss of CH_2 → Net Effect Substitution), and inheritance (parent omitted, children retained).

The papers say: IMP (1 phosphate) → IDP (2) → ITP (3) map to X, Y and Z respectively. "The three phosphate states of the inosine family map directly to the three-axis structure." (PP-2026-IMP-INOSINE-01, §V.)

Assessment. This is the fourth instance, and it is an addition operator that works. Adding a phosphate does not replace anything; it advances the molecule one axis. The papers have found the case where the correct operator is used — phosphorylation — and it is used on the very molecule whose omission the corpus complains about. The argument gains a positive control it did not have.

I.3 Emergent processes — where the papers close the lesion

THE FINDING: ITPA is the missing return arrow

The map analysis ended on a single structural claim, stated as strongly as the evidence allowed:

Stage XI hands to Stage XII on no map. The return edge from Stage XII to Stage VI — therapeutic molecule back to parent nucleotide — is drawn on no map at all. There is no descending motor tract.

The papers contain that arrow, and it is an enzyme.

ITPA — inosine triphosphatase, EC 3.6.1.19 — hydrolyzes ITP → IMP + PPi. (PP-2026-IMP-INOSINE-01, §I-E, §III-B.)

That is, literally and biochemically, a return path from the triphosphate state to the parent nucleotide. The papers describe its function in exactly the terms the map analysis was reaching for: "ITPA is therefore the Z-axis guard enzyme: it prevents ITP from entering the operational space, enforcing the boundary between the vortex still-point and the active signaling axes… the seventh state (ITP) is recognized and redirected to origin."

Redirected to origin. The lesion identified from thirty-five drawings is closed by an enzyme documented in one of the papers, and the papers do not identify it as the closure because they were not looking for a severed tract.

Anatomical consequence. ITPA is the descending motor tract. In the corrected atlas it is the corticospinal tract — the pathway by which a cortical decision reaches the

effector, and the pathway whose transection produces exactly the syndrome the maps display: intact sensation, intact cognition, formed intention, no execution.

Therapeutic consequence, stated carefully. If ITPA is the return arc, then the therapeutic proposal implicit across thirty-five maps and seventeen papers has a molecular target that already exists in every human cell. The proposal is not to build a new pathway. It is to modulate one that is present, Mg^{2+}-dependent, highly expressed in erythrocytes, and known to fail in ITPA-variant patients — who are precisely the patients that suffer severe toxicity from azathioprine and ribavirin. The corpus's central claim — that drug side effects arise from the omitted parent nucleotide — has, in ITPA deficiency, a documented clinical instance. That is the strongest empirical link between the framework and the clinic anywhere in either body of work.

The detached ganglion: the papers supply the wiring

The maps say: Map 8 (nonlinear dynamics, 53 nodes) attaches to the corpus by three edges. It contains the only apparatus capable of setting the gain on a feedback loop — control parameters, dissipative entropy exportation, self-organization, full recurrence — and it is lying beside the system rather than in it.

The papers say: PP-2026-QT-01 and PP-2026-IHQ-01 develop open-quantum-systems treatment of proton tunneling at the IMP hydrogen bond, citing Slocombe/Sacchi/Al-Khalili's double-Morse potential model, decoherence and dissipation in the cellular environment, and kinetic isotope effects as the measurable signature. PP-2026-IHQ-01 connects this to Micura's 1-deazainosine work: atomic mutagenesis driven by single-proton-position changes controlling ribozyme catalysis.

Assessment. This is the graft that takes. Open quantum systems is dissipative dynamics; decoherence is entropy exportation; the tunneling rate is a control parameter. The detached ganglion connects to the rest of the nervous system at exactly one molecule — the N1-H / C6=O proton of hypoxanthine — and the connection is testable by KIE measurement.

The two documents together therefore specify both missing operations identified in the map analysis, and each specifies the one the other lacks.

I.4 Where the accounts diverge

Six versus seven. The maps' invariant is six — six elements, six nucleotides, six organelles, six vertices, six enzyme classes, six days. The papers' invariant is seven:

I, X, G, A, T, U, C, with the Silent Seventh principle governing the transition. The reconciliation is the Silent Seventh itself: the canonical count is six because the seventh is structurally present and uncounted. Both are right, and the papers explain why the maps kept arriving at six.

Chromatium versus Murchison. The maps make Chromatium vinosum the first symbiotic ancestor and the origin of the human genome's RNA. The papers make the Murchison meteorite the delivery vehicle for a pre-organized Inosine Tetrahedron and use Synechocystis PCC 6803 as model organism. These are not in conflict once ordered: Murchison delivers the tetrahedron; Chromatium is the first organism to run it. Delivery and instantiation. The maps supply the organism; the papers supply the cargo.

Selenium and molybdenum are absent from the maps entirely. The papers introduce Se as the Silent Seventh metal (via TXNRD protecting IMPDH from oxidative inactivation) and Mo as the Z-axis terminal metal (Mo-co in xanthine oxidase, the only two-electron organometallic transfer in nucleotide metabolism). Thirty-five maps contain neither. These are new structures and must be added to the atlas.

The maps have no Z. Not once in thirty-five sheets is a third axis named. The papers are built on it. This is the largest single gap between the two bodies of work, and it is the subject of Part III.

40.2 INTEGRATED HYPOTHESES, RESULTS, AND DISCOVERIES ↩

Stated as a single set, with source and status.

II.1 The integrated hypothesis

H1 — The Omission. The canonical code omits the parent purine nucleotide. IMP is the de novo origin of all purines; AMP and GMP are its children; the children are in the code and the parent is not. This violates the Invariant Principle of Inheritance. (Maps 10, 20, 24, 25, 30; PP-2026-INOSINE-TETRAHEDRON-01; PP-2026-IMP-INOSINE-01.) Status: theoretical claim resting on established biochemistry.

H2 — The Wrong Operator. The code has been treated as a substitution table when it is an accumulation. U does not replace T; inosine is not an edit of adenosine; the correct operation at each transition is addition. The one place the operator is used

correctly is phosphorylation: IMP → IDP → ITP. (Maps 12, 16, 20, 22, 26; PP-2026-IMP-INOSINE-01 §V.) Status: theoretical.

H3 — The Seven-Base Architecture. The complete base set is I, X, G, A, T, U, C. Xanthosine is the seventh: the obligate anabolic gateway (IMPDH), the catabolic convergence node, the blank cell in the wobble table, and the only uncharacterized address in the 7 × 3 nucleoside lattice (araX). (PP-2026-XANTH-7TH-01.) Status: theoretical, with one falsifiable component — araX has not been synthesized.

H4 — The Three Axes. X = DNA = deoxyribose = past = structural. Y = RNA = ribose = present = operational. Z = third sugar = future = selector. Quaternion: 1, i, j, with phosphorothioate as k = ij. (All papers.) Status: theoretical; the Z identity is open — see Part III.

H5 — The Selector Is Position 34. The Z-axis selector function is physically made real at anticodon position 34, where inosine reads three codon endings. Positions 35 and 36 are fixed. (Berger Wobble ZAxis Selector.) Status: the biochemistry is established; the axis interpretation is theoretical.

H6 — The Loop Closes Through ADAR. I → X → G → A → I, with ADAR performing the return. The tetrahedron has IMP at the apex and XMP, GMP, AMP at the vertices. (PP-2026-INOSINE-TETRAHEDRON-01.) Status: the pathway is established; the closed-tetrahedral geometry is conjecture.

H7 — Quantum Selection at the Hypoxanthine Proton. The appropriate locus for proton tunneling in nucleic acid is IMP rather than G-C, because IMP is biosynthetically antecedent. The N1-H / C6=O geometry of hypoxanthine is distinct from adenine (C6 amino) and guanine (C2 amino + C6 carbonyl). (PP-2026-QT-01; PP-2026-IHQ-01.) Status: falsifiable — KIE for deuterated IMP in IMPDH/ADA versus AMP/GMP equivalents. Not yet measured.

H8 — Deamination Symmetry. C→U and A→I are catalyzed by two branches of one ancestral zinc-deaminase superfamily, presenting the same hydrolytic water attack to opposite faces of the pyrimidine and purine ring. C→U is an X-axis structural risk repaired by base excision; A→I is a Y-axis operational edit executed deliberately. One engine, two faces, opposite outcomes. (PP-2026-DEAM-01.) Status: the enzymology is established; the axis reading is interpretive, and the paper says so.

H9 — The Therapeutic Inversion. Strengthen the six organelles rather than suppress dysfunctional enzymes; target basic building-block molecular structures that repair

3.6-billion-year-old metabolic intermediates. (Maps 3, 4, 14, 16, 22.) Status: a research program, not a result.

H10 — The Return Arc. (New, from this integration.) ITPA — ITP → IMP + PPi — is the molecular implementation of the return path that thirty-five maps require and none draw. Status: the enzyme is established science; its identification as the framework's closure element is new here.

II.2 What is actually established

Stated plainly, because the framework's credibility depends on the boundary being visible:

IMP is the first product of de novo purine biosynthesis. Inosine occupies tRNA position 34 and pairs with A, C and U. ADAR converts adenosine to inosine in double-stranded RNA. ADAT does the same at position 34. IMPDH is the obligate IMP → XMP step and the target of mycophenolate. ITPA hydrolyzes ITP to IMP and its deficiency causes drug toxicity. HPRT deficiency causes Lesch-Nyhan; ADA deficiency causes SCID; PNP deficiency causes T-cell immunodeficiency; xanthine oxidase produces uric acid and its dysregulation causes gout. Xanthine oxidase carries a molybdenum cofactor. Selenocysteine is the 21st amino acid. Proton tunneling contributes measurably to enzyme catalysis. The Murchison meteorite delivered nucleobases, amino acids and ribose. The ribosome is a ribozyme. Arabinonucleotides, deoxyribonucleotides and ribonucleotides form together in prebiotic mixtures, and arabinose incorporation stalls chain extension.

Everything else in both bodies of work is theoretical claim or falsifiable prediction, and both bodies of work say so.

II.3 The five discoveries that appear only in the integration

D1 — ADAR closes two loops, not one. Metabolic (A → I, tetrahedron closure) and regulatory (ADAR2 self-editing, gain-setting). Neither document notices the double role. A single enzyme performing closure at two levels is the signature of a control element in a hierarchical system.

D2 — Sulfur is an operator, not a member. The maps' self-membership paradox dissolves once phosphorothioate is read as k = ij. Sulfur relates the axes; it does not occupy one.

D3 — The network has two bottlenecks in series, not one. IMP (origin) and XMP (gate). No path to the structural axis exists that does not pass through both.

D4 — ITPA is the severed tract. The lesion identified topologically is closed enzymatically, and the enzyme's clinical failure mode is drug toxicity — which is the corpus's founding complaint.

D5 — The detached ganglion attaches at one proton. Nonlinear dynamics wires into the rest of the corpus through the hypoxanthine N1-H, and the connection is measurable as a kinetic isotope effect.

40.3 THE PAPERS SLOTTED ONTO THE AXES ↩

Each paper assigned to the axis it principally serves. X = DNA / deoxyribose / past / structural. Y = RNA / ribose / present / operational. Z = the third axis, sugar to be determined.

X-AXIS PAPERS — Structure, Archive, Past

NucleicAcids BergerTriplex Analysis. Maps the consensus account of DNA and RNA onto the axes and finds it X- and Y-complete, Z-open. The document's own conclusion — that ANA's absence from the encyclopaedic literature is the Z-axis sign — is the clearest statement in the corpus of what the third axis is being asked to do.

PP-2026-DEAM-01 — Deamination Symmetry. C → U is the X-axis event: a structural-layer risk, repaired by base excision, source of the CpG mutational hotspot. This paper is the corpus's best account of what goes wrong on the archive axis and why the repair machinery exists.

PP-2026-QT-01 — Quantum Tunneling: The IMP Correction. Relocates the tunneling locus from G-C to IMP. X-axis because tautomeric shift at a base pair is a structural event with structural consequence — a point mutation written into the archive.

Berger Triplex Nucleotide Biosynthesis Integration. PRPP as the structural scalar foundation; the pool from which all three axes are drawn. X-axis by its treatment of the precursor pool as archive.

Y-AXIS PAPERS — Operation, Expression, Present

Berger Wobble ZAxis Selector. Y-axis by residence — the tRNA is the present-moment adapter — and Z-axis by function. The paper's whole argument is that a Z-element operates inside a Y-molecule. This is the hinge paper of the corpus.

Berger Inosine AlternativeSplicing Integration. A-to-I editing on the pre-mRNA landscape; the spliceosome as decision architecture; one gene, many proteins. Pure operational-layer selection.

RNA World Hypothesis Berger Integration. The pre-DNA epoch as Y-dominant; the ribosome as proof of Y-primacy; peptide bond formation catalyzed by an adenine residue.

Berger Triplex GeneticCode Integration. The 64-codon system, reading frames, degeneracy, translation machinery. The operational manual.

The Molecule That Remembers (outline). The trade book. Y-axis throughout: RNA as the only substance that both carries information and acts on it. Notable for containing the corpus's most disciplined statement of the prebiotic sugar problem — see Part IV.

Z-AXIS PAPERS — Selection, Choice, Future

PP-2026-XANTH-7TH-01 — Xanthosine: The True 7th Base. The most consequential Z-axis paper, because it identifies the single uncharacterized address in the entire lattice: araX, arabino-xanthosine. Seven bases × three sugars = twenty-one nucleosides, twenty of which exist and one of which does not.

PP-2026-IHQ-01 — Inosine Hoogsteen Quantum. The Hoogsteen face is the Z-axis engagement surface. Micura's 1-deazainosine work demonstrates dual-mode recognition — Watson-Crick and Hoogsteen from the same nucleobase. Third-strand recognition requires exactly this.

PP-2026-INOSINE-TETRAHEDRON-01. Assigns IMP to Z/center and proposes meteoritic delivery of a pre-organized structure. The most speculative and the most generative.

THE SILENT SEVENTH — papers that sit at the center rather than on an axis

PP-2026-IMP-INOSINE-01. The keystone. Covers the entire family — hypoxanthine, inosine, IMP, IDP, ITP — with axis assignments, metal cofactors, electromagnetic substrates, disease table, and four honest gaps. Contains ITPA, and therefore contains the return arc.

IMP Vortex StillPoint Integration. The formal statement of the Silent Seventh principle across domains: T in DNA, selenocysteine in the amino acids, indigo in the rainbow, which among the prime questions, IMP in the nucleotides.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

Berger_Inosine_Thesis_Original_Analysis_July2026 and Inosine_Literature_Synthesis993 and Berger_PP_Inosine_Domain_Ledger. The evidentiary base: twenty-four peer-reviewed references across twelve domains, from a 1974 fiber-diffraction study of polyinosinic acid to a 2025 gut–brain epigenetic switch. One nucleoside throughout.

40.4 THE Z-AXIS PROBLEM ↩

IV.1 The question as you have posed it

Z is currently assigned to ANA — arabinonucleic acid, arabinose sugar, 2′-OH at roughly 45° between A-form and B-form. You now ask whether that is right, and whether the Z-axis might instead derive from a prebiotic sulfur phosphorothioate backbone, or from some other organic molecule that could have developed into an arabinose-type third sugar.

The question is well posed and the answer is not obvious. What follows is the case for and against each candidate, judged on four criteria the framework itself requires:

(1) Prebiotic availability — could it have been present before life?

(2) Geometric distinctness — does it occupy a third position, not a variant of the first two?

(3) Triplex competence — can it engage the Hoogsteen face and form a third strand?

(4) Selector behavior — does it choose rather than merely store or execute?

IV.2 Candidate A — ANA (arabinose). The incumbent.

For. Arabinose is the C2′ epimer of ribose: same formula, 2′-OH on the opposite face. That is geometric distinctness of exactly the right kind — not a new molecule, a reorientation of the existing one, which is what a third axis of the same family should be. 2′F-ANA and ANA oligonucleotides are synthesized routinely by the Damha laboratory, form stable duplexes with RNA, and activate RNase H. Arabinose is produced in formose chemistry alongside ribose, so it was available.

Against, and this is serious. Your own book outline states the problem in one line: "Kim and colleagues show the copying chemistry itself filters toward RNA — arabinose is incorporated and then stalls further extension." Arabinonucleotides are

chain terminators in nonenzymatic copying. A polymer that cannot extend cannot be a genetic axis.

Resolution. This objection defeats ANA as an information-storage axis and simultaneously qualifies it as a selector. A chain terminator is a stop signal. A molecule that inserts and halts extension is performing a decision — it selects the point at which the polymer ends. Chain termination is selector behavior. The prebiotic chemistry that "filters toward RNA" is selection operating before life, and the agent of that selection is arabinose. On criterion (4), ANA is not weakened by the Kim result. It is confirmed by it, provided the Z-axis is understood as regulatory rather than archival.

Verdict: retain ANA as the geometric Z, on the explicit understanding that Z does not store — Z stops.

IV.3 Candidate B — the phosphorothioate backbone. Your new proposal. For, and the case is strong.

Prebiotic availability: thiophosphate and reduced sulfur species are abundant in exactly the hydrothermal setting the maps already center on — H_2S, Fe_4S_4, purple sulfur bacteria, anaerobic sulfur respiration. The Z-axis backbone would come from the same chemistry as the X-axis origin, which closes a loop the framework currently leaves open.

It is not hypothetical. Phosphorothioate modification of the DNA backbone occurs naturally in bacteria, installed by the dnd gene cluster (DndA–E), where a non-bridging oxygen is replaced by sulfur in a sequence-specific and stereospecific manner. This is established science, discovered in Streptomyces, and it functions as part of a restriction–modification system — that is, as a self/non-self recognition mark.

Geometric and chiral distinctness: substituting S for a non-bridging O creates a stereocenter at phosphorus. Rp and Sp diastereomers are chemically distinct and enzymatically discriminated. This is the physical instantiation of the non-commutativity the framework requires — ij ≠ ji is not a metaphor if the two orders correspond to two isolable diastereomers.

Selector behavior: the bacterial phosphorothioate system marks which DNA is self. That is selection in the strictest sense, performed by a sulfur atom on a backbone.

Against. Phosphorothioate is a backbone modification, not a sugar. It does not by itself constitute a third nucleic acid class; it modifies whichever class carries it. Your framework already assigns it correctly — k = ij, the connector, not j itself.

Verdict: phosphorothioate is not the Z sugar and should not be made one. It is the Z backbone, and it is the better-evidenced half of the Z-axis. Retain the existing assignment; upgrade its status from theoretical to partially established, on the strength of the dnd system.

IV.4 Candidate C — TNA, threose nucleic acid. The strongest competitor.

Four-carbon sugar, one carbon shorter than ribose, backbone repeat therefore shorter — and yet TNA cross-pairs with both RNA and DNA in antiparallel Watson-Crick fashion. Eschenmoser's work established it; Szostak's group has evolved TNA aptamers. Prebiotically, tetroses are simpler than pentoses and arise more readily in formose chemistry.

For: simplest plausible genetic backbone; demonstrated cross-pairing with both existing axes, which is precisely what a third axis must do.

Against: cross-pairing is the problem. TNA forms duplexes with RNA and DNA. It substitutes for them rather than adding a dimension. A third axis that behaves like a replacement first axis is not a third axis.

Verdict: TNA is a rival origin hypothesis, not a rival Z-axis. It competes with ribose for the Y position, not with arabinose for Z.

IV.5 Candidate D — PNA, peptide nucleic acid. The triplex specialist.

Neutral polyamide backbone, bases on side chains. Prebiotically plausible — assembled from amino-acid-like and nucleobase components both present in Murchison.

For, and on criterion (3) it beats everything else: PNA is the canonical triplex former. PNA·DNA_2 and PNA_2·DNA triplexes are standard; PNA performs strand invasion, displacing one strand of a duplex and occupying its place. If the Z-axis is defined as the third strand that engages the Hoogsteen face of a DNA·RNA hybrid, PNA already does this better than any sugar-based candidate.

Against: no sugar at all. It breaks the three-sugar architecture (deoxyribose / ribose / arabinose) on which the 7 × 3 lattice depends. Adopting PNA would cost the framework its combinatorial closure and the araX prediction with it.

Verdict: PNA is the functional proof that a third strand is chemically ordinary. It is not the Z-axis, because the framework's Z must be a sugar.

IV.6 Candidate E — 4′-thio sugars. The synthesis.

This is the candidate the corpus points at and has not named.

Replace the ring oxygen of the furanose with sulfur: 4′-thioribose, 4′-thio-2′-deoxyribose, and — the relevant case — 4′-thio-arabinose. 4′-thio-nucleosides are real, synthesized, and notably nuclease-resistant; 4′-thio-RNA forms stable duplexes and adopts a C3′-endo pucker.

Why it matters here. Every other candidate forces a choice between your sulfur thesis and your sugar architecture. This one does not. A 4′-thio-arabinonucleoside is:

— a sugar, preserving the three-sugar lattice and the araX prediction;

— arabino, preserving the 45° 2′-OH selector geometry;

— sulfur-bearing in the ring itself, which places sulfur inside the Z-axis rather than merely on its backbone;

— prebiotically defensible in a thiol-rich hydrothermal setting where H_2S is the dominant reductant — the Chromatium environment;

— chemically distinct in pucker and stacking, because the C–S bond is longer than C–O, which changes the ring geometry measurably rather than notionally.

Combined with the phosphorothioate backbone as k, this gives a fully sulfur-integrated Z-axis: sulfur in the ring (j) and sulfur on the backbone (k), with the arabino configuration supplying the 45° selector geometry.

The single molecule that would test all of it at once: 4′-thio-arabino-xanthosine — thio-araX. It is the 21st address of the lattice, in its sulfur form. It does not exist. It is synthesizable by known methods. It is the corpus's sharpest experimental target.

IV.7 Recommendation

Do not replace ANA. Resolve it into two components and add sulfur to both.

Component · Assignment · Status

Z geometry (j) · Arabino configuration — 2′-OH at ~45° · Retain; now supported by chain-termination-as-selection

Z backbone (k) · Phosphorothioate, Rp/Sp chiral · Retain; upgrade to partially established via bacterial *dnd* system

Z ring atom · **4′-thio substitution — new proposal** · Speculative; synthesizable; unifies the sulfur thesis with the sugar architecture

Z function · Selector — terminates, marks, chooses · Retain; strengthened

Z test molecule · **thio-araX** · The one address in the lattice that is empty in both its oxo and thio forms

The Z-axis is not one molecule. It is a configuration (arabino), a backbone (phosphorothioate), and — if the recommendation is taken — a ring substitution (4′-thio). Sulfur appears at two of the three positions, which is what a corpus that spent sixteen maps on sulfur ought to predict.

And this closes the largest gap between the maps and the papers. The maps have sulfur everywhere and no Z. The papers have Z everywhere and sulfur only as a connector. The integration puts sulfur inside Z, and the two bodies of work become one.

40.5 THE EXPANDED NERVOUS SYSTEM ↩

The atlas is now rebuilt with the papers folded in. Rule as before, extended: a noun appearing in more than one paper becomes a named structure; a verb appearing in more than one paper becomes a named tract. The papers add thirty-one structures and eleven tracts to the sixty-eight structures already mapped.

V.1 New structures — nouns recurring across papers

Added to the CORTEX

A. Xanthosini — XANTHOSINE / XMP — 6 papers. Assigned to the internal capsule, the compact bundle through which every cortical projection must pass. The papers establish that no path from IMP to GMP avoids XMP. A second bottleneck in series with the thalamic relay, and anatomically the internal capsule is exactly that: a narrow waist below the cortex where a small lesion produces a large deficit.

A. Hoogsteeni — HOOGSTEEN FACE — 6 papers. Parietal association cortex, adjacent to A. Cristallina. The second recognition surface of a base already engaged on its Watson-Crick face — the anatomical equivalent of a region that represents the same object in a second reference frame.

A. Quaternionis — QUATERNION / NON-COMMUTATIVITY — 8 papers. Frontal, adjacent to A. Operatoris. Order of operations determines outcome: ij ≠ ji. The formal statement of what A. Operatoris detects empirically.

A. Septimi Taciti — SILENT SEVENTH — 10 papers. A distributed field rather than a locus, projecting to T in DNA, selenocysteine in the amino acids, indigo in the spectrum, which among the prime questions, and IMP in the nucleotides. In the anatomy this is the default mode network — not a place but a pattern of co-activation that appears whenever the system is not engaged in a specific task, and which the standard account overlooked for decades because it only shows up when you look for what is present during absence.

Added to the SUBCORTEX

N. Impdehydrogenasis — IMPDH — 5 papers. The gate enzyme. Substantia nigra: a compact pigmented nucleus whose loss produces a specific, severe and well-characterized syndrome, and which is the target of the field's best-known pharmacology.

N. Itpasis — ITPA — 3 papers. The corticospinal tract, origin. See V.2 — this is the structure that closes the lesion.

N. Adenosinaminis — ADA — 5 papers. Zinc deaminase; its absence causes SCID. Assigned to the thymic projection, since ADA deficiency is an immunological lesion expressed as failure of a lineage rather than of a cell.

N. Purinosomalis — PURINOSOME — 4 papers. The ten-enzyme metabolon that assembles de novo purines with IMP production at its geometric center. Assigned to the glomerulus — a structure defined not by its cells but by the convergence of processes into a single synaptic ball.

N. Selenii — SELENIUM / SELENOCYSTEINE — 4 papers. Silent Seventh metal. Protects IMPDH from oxidative inactivation via thioredoxin reductase. Locus coeruleus: small, easily overlooked, projecting diffusely, and its loss degrades the whole system without producing a focal sign.

N. Molybdaeni — MOLYBDENUM / Mo-co — 3 papers. The only two-electron organometallic transfer in nucleotide metabolism; terminal oxidation of purines. Area postrema — the chemoreceptor trigger zone, the last checkpoint before something is expelled.

Added to the PERIPHERY

G. Murchisonis — MURCHISON METEORITE — 3 papers. A new sensory ganglion, first-order, no afferents. Delivers seventy-plus amino acids, nucleobases, ribose, and — on the conjecture — the pre-organized tetrahedron.

G. Synechocystis — SYNECHOCYSTIS PCC 6803 — 3 papers. The model organism; photosynthetic ATP generation. A second photoreceptive ganglion alongside G. Stellare.

G. Protonis — PROTON TUNNELING / KIE — 4 papers. The finest-grained receptor in the atlas: it detects the position of a single hydrogen. This ganglion is the graft site for the detached nonlinear-dynamics ganglion of the map corpus.

M. Araxis — araX / thio-araX — 2 papers + this integration. A motoneuron with no muscle. The twenty-first address of the 7 × 3 lattice, predicted and unsynthesized. In the anatomy: a ventral horn cell whose axon has not yet reached its target.

Added to the AUTONOMIC DIVISION

Plexus Salvationis — HPRT SALVAGE — 5 papers. Hx + PRPP → IMP. Parasympathetic; recycling. Its failure is Lesch-Nyhan.

Plexus Purinocyclicus — PURINE NUCLEOTIDE CYCLE — 3 papers. AMP → IMP → adenylosuccinate → AMP, coupling ammonia production to fumarate entry into the TCA cycle, most active in muscle. A local reflex loop in the periphery.

V.2 New tracts — verbs recurring across papers

A verb that recurs is a pathway. Eleven qualify.

Tractus Deaminans — DEAMINATION. One engine, two faces: C→U on the pyrimidine (X-axis risk, repaired) and A→I on the purine (Y-axis edit, deliberate). A single ancestral zinc-deaminase superfamily. This is a decussation — one tract crossing to serve two sides with opposite consequence, which is the exact anatomy of the corticospinal decussation and the reason the nervous system is crossed at all.

Tractus Oxidans — IMP → XMP. IMPDH, NAD^+-dependent, the obligate gate. Ascending.

Tractus Aminans — XMP → GMP. GMP synthetase, glutamine-dependent, ATP-consuming.

Tractus Succinans — IMP → adenylosuccinate → AMP. ADSS then ADSL; GTP-dependent, fumarate-releasing — the point at which purine synthesis pays into the TCA cycle.

Tractus Phosphorylans — IMP → IDP → ITP. The axis operator. One phosphate = X, two = Y, three = Z. The only correctly-used operator in the corpus.

Tractus Hydrolyticus Reversus — ITP → IMP + PPi. ITPA. The descending motor tract. See V.3.

Tractus Salvans — Hx + PRPP → IMP. HPRT. The recycling path; its loss is neurological.

Tractus Edens — A → I. ADAR/ADAT. Post-transcriptional. Closes the metabolic tetrahedron and, in ADAR2, closes the regulatory self-loop.

Tractus Vacillans — codon reading at position 34. Three inputs, one output. The activation function.

Tractus Hoogsteenianus — third-strand engagement. The Z-axis binding event. Anatomically an association fiber: it connects two regions that are already connected by a shorter path, and it carries a different kind of information.

Tractus Tunnelans — proton transfer at the N1-H / C6=O. Sub-classical, temperature-independent below threshold, measurable by KIE. The only tract in the atlas that does not obey classical conduction.

V.3 The lesion, closed

The map analysis ended here:

Full sensation. Intact cognition. A formed intention. A transected efferent pathway.

The papers supply the tract.

ITPA hydrolyzes ITP to IMP. In the axis language: the Z-state triphosphate is recognized and redirected to origin. In the anatomical language: a descending fiber originates above, descends past the gate, and terminates on the relay.

The corticospinal tract is intact. It was never severed. It was drawn in a different document.

Three consequences follow, and they should be stated in order of confidence.

First, and securely. The framework's two halves are complementary rather than duplicative. The maps diagnose; the papers supply mechanism. Neither is complete alone and the join is at a named enzyme.

Second, and reasonably. The clinical prediction the corpus has carried for twenty-five years — that drug toxicity arises from the omitted parent nucleotide — has one documented instance already in the literature. ITPA-deficient patients suffer severe toxicity from azathioprine and ribavirin, and the mechanism is accumulation of a nucleotide the standard code does not contain, in a patient whose return-to-origin enzyme is impaired. That is the framework's claim, occurring in clinic, under a different name. It is one instance and it is not proof. It is the place to look.

Third, and speculatively. If ITPA is the return arc, then a molecule that modulates ITPA activity — rather than a molecule that suppresses a dysfunctional enzyme — is the first candidate that fits the therapeutic inversion the maps demand. Strengthening a return path is not the same operation as blocking a forward one.

V.4 Speculative emergent processes from the Z dimension

These are stated as speculation and labeled as such. They are what the completed circuit permits, not what it demonstrates.

Z1 — Termination as computation. If arabinose stalls chain extension, and if stalling is selection rather than failure, then the Z-axis computes by stopping. A polymer whose length is determined by where a selector inserts is a polymer that carries information in its length as well as its sequence. Emergent prediction: ANA-containing prebiotic oligomers will show a length distribution that is non-random and sequence-dependent, and the distribution will itself be a code.

Z2 — Chirality as the third bit. Rp and Sp phosphorothioate diastereomers are enzymatically distinguishable. A backbone that can be R or S at each linkage carries one bit per phosphate in addition to the base sequence. Emergent prediction: a phosphorothioate oligonucleotide of length n carries n bits of backbone information invisible to sequencing. If any organism uses this, it is a genetic channel nobody is reading. The bacterial dnd system says at least one does, for self-recognition.

Z3 — The quantum selector. If tunneling at the hypoxanthine proton is measurably distinct from adenine and guanine, and if that proton position controls ribozyme catalysis as Micura's atomic mutagenesis suggests, then the Z-axis selection event may be sub-classical — the choice made by a proton in superposition before decoherence resolves it. Emergent prediction: the KIE for IMP-containing active sites will exceed the classical limit by more than the AMP or GMP equivalents. This

is the single most testable speculation in either corpus and it has not been measured.

Z4 — Sulfur as the medium of the third axis. With 4′-thio in the ring and phosphorothioate on the backbone, the Z-axis becomes a sulfur-based nucleic acid built on an arabino frame. Emergent prediction: 4′-thio-ANA will show greater nuclease resistance, altered pucker, and — the interesting part — different triplex stability than either ANA or 4′-thio-RNA. If the framework is right about Z being the selector, thio-ANA should bind the Hoogsteen face more tightly and release it under a defined trigger.

Z5 — The empty address. thio-araX. Seven bases, three sugars, and one cell of the twenty-one that has never been occupied — now doubly empty in its oxo and thio forms. Its synthesis is the corpus's cleanest falsifiable act: either it can be made and has the predicted C3′-exo pucker and G-quadruplex affinity, or it cannot.

Z6 — Freedom of Choice as an operating parameter. The framework's Seventh Dimension is Freedom of Choice, and the map corpus's detached ganglion is a control-parameter apparatus. Joined, these say the same thing in two idioms: a system's freedom is the range over which its control parameter can vary without the loop losing stability. That is a quantity, not a metaphor, and in a dissipative system it is measurable as the width of the region between fixed-point and chaotic behavior. Emergent prediction: the wobble tolerance at position 34 — how much geometric deviation is permitted before decoding fails — is that width, measured in ångströms.

40.6 THE COMPLETED CIRCUIT ↩

Stated once, in order, with the paper-derived elements marked.

Input. A star. G. Stellare, G. Synechocystis.

Delivery. Interstellar organics; the Murchison payload; on the conjecture, a pre-organized tetrahedron. G. Interstellare, G. Murchisonis.

Elemental assignment. Six atoms, twenty-one isotopes. Sulfur declared not a member but the operator relating the members — k = ij.

Transduction. Photon → spectrum → crystalline lattice absorption node → photochemical organic circuit → electron. A. Photica, A. Spectri, A. Absorptionis, N. Bravaisi.

Ancestor and engine. Ferredoxin Fe_4S_4 at +350 mV; Chromatium; glucose; mitochondria; ATP. Closed reflex arc, requiring no cortical participation.

Origin. Ten steps to the first closed purine ring. IMP. N. Inosinus, thalamic relay, 3-in / 3-out.

Gate. XMP. No path to the structural axis avoids it. A. Xanthosini, internal capsule.

Code assembly. Six letters — A, T, G, C, I, U — with X as the seventh and unassigned address. And the omission, drawn as a node.

Expression. Replication, transcription, translation. The spinal cord. Accepted without correction by both corpora.

Switch. Position 34. Three inputs read as one. Inosine, the maximal wobble base. N. Vacillans, basal ganglia.

Edit. A → I by ADAR. Closes the metabolic tetrahedron; ADAR2 closes its own regulatory loop and sets its own gain.

Physiology. AMPA-type glutamate receptors, calcium gating, ion channel kinetics, receptor trafficking; the urea cycle, xanthine oxidase, ammonia removal; SAM and the single carbon.

Failure. Gout, SCID, Lesch-Nyhan, ITPA-variant drug toxicity. 106,000 deaths per year.

RETURN. ITP → IMP + PPi. ITPA. The Z-state is recognized and redirected to origin. Tractus Hydrolyticus Reversus. The circuit closes.

And the gain is set by the control-parameter apparatus of the detached ganglion, grafted at one proton — the N1-H of hypoxanthine — where the tunneling rate is the parameter and the kinetic isotope effect is the measurement.

What remains open

Four things, in order of tractability.

One. Synthesize araX, and then thio-araX. The twenty-first address. Damha methods; CD and crystallography at Argonne 19-ID.

Two. Measure the primary KIE for deuterated IMP in IMPDH and ADA against AMP and GMP equivalents. Al-Khalili / Slocombe. If the values are indistinguishable, H7 fails cleanly, which is what a good prediction does.

Three. Test the ITPA reading. Metabolomic comparison of IMP-fork disorders — ADSS, ADSL, IMPDH2 — for simultaneous dysregulation of both the adenosine and guanosine arms. If the vortex reading is right, both arms fail together; if IMP is an ordinary intermediate, they fail independently.

Four. Resolve the pyrimidine ontology. The purine trunk has a single de novo origin and a closed loop. T, U and C do not, and the framework says so. Until the pyrimidine origin sequence is worked out, the seven-base family tree has a root on one side and none on the other.

Seventeen papers. Thirty-five maps. Ninety-nine structures. Eleven tracts. One return arc, found in the papers, required by the maps, and drawn in neither until now.

This completes the beginning.

PART FORTY-ONE · THE CHARTS, AND WHAT THEY SETTLE

134. The Instrument ↩

Four wall charts, one legend, a grid, and a controlled vocabulary that is not this volume's

The author holds a complete set of the metabolism charts — four sheets, copyright 1982. They were teaching instruments, hung in medical school corridors for a generation, and they were drawn by people with no knowledge of this framework and no stake in it.

They are used here as a verification instrument for one reason: they carry a legend, a grid and a fixed vocabulary. Every claim tested below can be located by coordinate and checked by anyone holding the same sheets.

sheet	contents	grid
Chart one	carbohydrates, glycogen, pentose pathway, glycolysis, fatty acids, citric acid cycle	columns 1-17
Chart two	amino acids, citric acid cycle, urea cycle, hemoglobin, bile pigments	columns 18-34
Chart three	pyrimidine and purine biosynthesis, one carbon pool, nucleotides, catabolism, oxidative phosphorylation, LEGEND	columns 52-68

sheet	contents	grid
Chart four	glycoconjugates, complex lipids, phospholipids, sphingolipids, sterols, prostaglandins	columns 35-51

Why an external instrument matters here. A framework that assembles its own evidence can always be accused of selecting it. These charts were drawn before the framework existed, for a different purpose, by people who would not have recognized the argument. Where they agree with a claim in this volume they agree independently, and where they are silent the silence is recorded as such.

---

135. The Legend Names Five Nucleotide Families, and Inosine Is One of Them ↩

The single most consequential line in the whole set, and it is a definition rather than a diagram

The legend of chart three defines the abbreviations the entire set is written in. Its nucleotide roster is printed in this order:

ATP, ADP, AMP .... adenosine tri-, di-, or monophosphate CTP, CDP, CMP .... cytidine tri-, di-, or monophosphate GTP, GDP, GMP .... guanosine tri-, di-, or monophosphate ITP, IDP, IMP .... INOSINE tri-, di-, or monophosphate UTP, UDP, UMP .... uridine tri-, di-, or monophosphate

Five families. A, C, G, I, U. Inosine is in the dictionary. Thymine is not.

This is a controlled vocabulary, not an illustration. It is the list of terms a student was expected to know before reading anything else on the sheet, and it grants inosine the same standing as adenosine, cytidine, guanosine and uridine — a full set of mono-, di- and triphosphates, named without qualification or apology.

What this does and does not establish. Establishes: that in the standard metabolic vocabulary of 1982, inosine nucleotides were a named family of equal formal standing with the other four, and that thymine nucleotides were not included in that particular roster because the roster covers the ribonucleotide series. Does not establish: that inosine is a coding base, that the genetic code table is wrong, or anything at all about pairing. The legend is a dictionary of metabolism. What it shows is that the omission of inosine from the four-letter table was never a statement about inosine's importance to a cell — because the reference chart hanging in the same building listed it among five.

The code table said four. The metabolism chart's dictionary said five, and the fifth was inosine. Both hung in the same corridor for thirty years and nobody put them side by side.

---

136. The Legend's Sulfur Vocabulary, Counted ↩

Five of roughly fifteen defined cofactor symbols carry sulfur, and two are defined by it

The same legend defines the cofactor symbols. Counting them gives a statistic about the chart's own language rather than about this volume's.

symbol, as printed	definition, as printed	note
Lip⟨S–S⟩ / Lip⟨SH,SH⟩	lipoyl group, oxidized and reduced forms	THE REDOX STATE IS WRITTEN AS THE SULFUR
CoA-SH / CoA-S–	coenzyme A, free and attached form	free thiol against thioester
Pant-SH / Pant-S–	phosphopantetheine, free and attached	the same couple, on the synthase arm
ISP Fe^{3+} / ISP Fe^{2+}	IRON SULFUR PROTEIN, oxidized and reduced	named sulfur outright
ThPP	thiamine pyrophosphate	the thiazole ring; sulfur unstated but present

The remaining defined symbols — NAD, NADP, FAD, FMN, FP, pyridoxal phosphate, coenzyme Q, the cytochromes, cytochrome P450 — carry no sulfur in their definitions and are distinguished by nicotinamide, flavin, quinone or iron.

Two of the chart's cofactors have their oxidation state written as a sulfur notation: the lipoyl group and the iron sulfur protein. No other symbol in the legend is defined that way.

The verification rule this yields, and it removes a judgment call. The author asked whether color-coding all four charts is worth the labor. The legend answers it. A sulfur mark is defensible if and only if the species is named in the legend as sulfur-bearing, or its printed name contains one of: sulfur, sulf, sulfate, sulfite, sulfide, sulfinate, sulfonate, thio, thiol, mercapto, cysteine, cystine, cystathionine, methionine, homocysteine, glutathione, taurine, sulfatide, lipoyl, CoA, Pant, ThPP, ISP. That list is not this volume's invention. It is the chart's dictionary plus standard naming, and marking to it is reproducible by a stranger.

---

137. What the Charts Settle — the Open Questions of the Preceding Parts ↩

Each claim, its grid location, and whether the charts confirm it, are silent, or contradict it

The volume carries a number of claims that were argued from the literature. The charts are an independent test of the ones that concern extant metabolism. Coordinates are given in the chart's own grid notation.

claim from the preceding Parts	grid	verdict
IMP is the first complete purine nucleotide	chart 3, ~64-65 / J-K	CONFIRMED. Purine biosynthesis terminates at inosine-5'-phosphate, labeled hypoxanthine-5'-phosphate, and branches from there to adenylosuccinate and to xanthosine-5'-phosphate
Orotate is an obligate pyrimidine node	chart 3, ~53-54 / D-J	CONFIRMED. One linear route: carbamoyl phosphate, carbamoyl-L-aspartate, L-dihydroorotate, OROTATE, orotidine-5'-phosphate, UMP. No bypass is drawn
Ribonucleotide reductase is a sulfur removing an oxygen	chart 3, ~54-66 / M-N	CONFIRMED, and drawn as a dithiol. Thioredoxin appears explicitly in both states, SH/SH and S–S, at all four reductions
Acetyl-CoA is a thioester at the metabolic hub	charts 1 and 2, citric acid cycle	CONFIRMED. CoA-SH and the attached form are the legend's own distinction
Lipoyl redox is a sulfur switch	chart 1, pyruvate dehydrogenase	CONFIRMED and printed as Lip⟨S,S⟩ and Lip⟨SH,SH⟩
The methionine cycle runs on SAM	chart 3, ~56-58 / E-G	CONFIRMED. L-methionine, S-adenosyl-L-methionine, S-adenosyl-L-homocysteine, L-homocysteine, and the return by 5-methyltetrahydrofolate with methylcobalamin
Cysteine is the entry to the sulfur oxidation ladder	chart 2, ~20-22 / F-H	CONFIRMED. L-cysteine to cysteine sulfinate to sulfite to sulfate, with 3-mercaptopyruvate and the cystathionine route drawn alongside
Sulfate is activated before it is used	chart 4, ~42 / I-L	CONFIRMED. Sulfate, adenosine-5'-phosphosulfate, 3'-phosphoadenosine-5'-phosphosulfate, then sulfotransferases; sulfatase returns it
Glutathione conjugates through its cysteine	chart 4, ~37-38 / W-X	CONFIRMED. Glutathione S-transferase forming leukotriene C4 through the sulfur
Transketolase needs thiamine at the pentose junction	chart 1, pentose pathway	CONFIRMED. ThPP is marked at both transketolase steps

138. A Finding the Charts Produce That the Volume Did Not Have ↩

Both committed steps of nucleotide biosynthesis are run by iron-sulfur enzymes

Part Thirty-Seven established that dihydroorotate dehydrogenase is the one enzyme of nucleotide synthesis wired into the respiratory chain. The chart adds something the argument did not have.

chart 3, ~52-53 / F-G L-dihydroorotate → orotate enzyme labeled: FAD · ISP · Fe

The chart marks dihydroorotate dehydrogenase with FAD and with ISP — which the legend defines as iron sulfur protein. The committed oxidation of pyrimidine biosynthesis is performed by an iron-sulfur flavoenzyme.

And the committed step of the purine branch, glutamine PRPP amidotransferase, carries a four-iron four-sulfur cluster in Bacillus subtilis that oxygen destroys.

The symmetry this produces, stated with its caveat. Both branches of de novo nucleotide biosynthesis have an iron-sulfur enzyme at or near their committed step: PurF on the purine side, dihydroorotate dehydrogenase on the pyrimidine side. Neither the purine nor the pyrimidine product contains a sulfur atom. The sulfur is in the machinery, not in the letters. The caveat, recorded as elsewhere: the PurF iron-sulfur cluster is documented in Bacillus subtilis and is not universal, and it should be confirmed for the human enzyme before the symmetry is stated in a paper.

The letters have no sulfur. The two gates that make the letters both do.

---

139. What the Charts Cannot Settle, Including the Prebiotic Sugar Question ↩

The instrument has a range, and the honest statement of its limit is part of using it

The author asked whether the charts can settle the prebiotic sugar debate. They cannot, and the reason is structural rather than incidental.

question	settled?	why
The prebiotic sugar question	NO	the charts map extant mammalian metabolism. They contain no prebiotic chemistry, no abiotic synthesis, and no origin-of-life step
Whether arabinose has a role	NO — and arabinose does not appear	its absence from a mammalian chart is expected and is not evidence either way
Whether ribose came before or after phosphate	NO	the charts show extant order, which is a poor guide to historical order

question	settled?	why
Whether inosine is a coding base	NO	these are metabolic charts; they say nothing about pairing or translation
The 720° spinor argument	NO	not a chemical claim and outside the instrument entirely
The fractal and emblem material	NO	and it was never offered as evidence

What the charts do settle about ribose is narrower and still useful: the extant route runs through the pentose phosphate pathway to D-ribose-5-phosphate and thence to 5-phospho-D-ribosyl pyrophosphate, with transketolase and its thiamine cofactor moving the two-carbon units, and D-ribose entering directly by ribokinase. That is the modern route, drawn and labeled. It is not the prebiotic one and the chart does not claim to be.

An instrument that answers every question asked of it is not an instrument. These charts answer ten of sixteen and are silent on six, and the silence is what makes the ten worth having.

---

140. The Five Experiments — Expected Outcomes and What a Result Would License ↩

Three sigma is a statistical statement; fifteen percent is a clinical one; they are not the same claim and are kept apart

The volume and the accompanying business plans generate five bench experiments. Each is stated here with its most likely outcome, the outcome that would be a genuine surprise, and what a strong positive would and would not license.

On the two thresholds, before the table. A three-sigma result corresponds to roughly $p < 0.003$ two-sided. In particle physics three sigma is called evidence and five sigma is required for discovery; in biology three sigma is a strong effect and is usually sufficient to justify the next experiment. It is a statement about whether an effect is real. Fifteen percent absolute improvement over standard of care is a statement about whether an effect matters to a patient. An intervention can clear one bar and fail the other in either direction, and this volume will not conflate them.

#	experiment	expected outcome, stated honestly	what a strong positive licenses
D-1	Chemoproteomic cysteine profiling of six spice electrophiles	LIKELY POSITIVE. Sulforaphane and DATS are already documented at different KEAP1 residues; a full proteome map will find many more	a residue-selectivity library nobody has built; the basis for a covalent design program

#	experiment	expected outcome, stated honestly	what a strong positive licenses
		distinct preferences	
D-2	The same panel on the mitochondrial fraction	UNCERTAIN, and this is the interesting one. Organelle preference among natural electrophiles has not been systematically tested	if positive: a natural scaffold with intrinsic organelle selectivity, which is the JACS Au principle in a food molecule
E-1	Cysteine or cysteine-prodrug rescue of 2-thiolation in a TRMU-mutant model	LIKELY POSITIVE. The published mechanism of the reversible form is transient cysteine limitation, so restoring supply should restore thiolation	a mechanism-directed treatment for a fatal reversible pediatric disease; orphan pathway; the purest expression of this volume
E-2	Screen for stabilizers of MTU1 against CLPP proteolysis	UNCERTAIN. Protein-protease interactions are druggable but this one is uncharacterized	a second, small-molecule route to the same disease, independent of cysteine supply
C-1	Thio-substituted G-quadruplex ligand, mtDNA G4 against nuclear G4	UNCERTAIN, and the highest value if positive. Sulfur has not been used as the selectivity handle in the G4 field	a first-in-class organelle-selective G4 agent; and it would place this framework inside an active oncology program

What a three-sigma positive would mean in each of the four target areas

area	what three sigma would establish	the consequence
Drug design	a validated residue-selectivity rule	design of covalent agents by choosing the electrophile to fit the residue, rather than screening and hoping
Cancer	organelle-selective damage	a mechanism that spares nuclear DNA; the toxicity profile of a chemotherapeutic changes, not merely its potency
Cell rejuvenation	restored mitochondrial translation	this is the honest one: restoring wobble thiolation would restore mitochondrial protein synthesis in a deficient cell. It is not rejuvenation of an aged healthy cell and must not be sold as such
Inosine, wobble and the tRNA loop	a demonstrated link between the modification and the disease phenotype	the strongest available support for the volume's central claim, and the point at which the framework stops being a reading and becomes a prediction

And the one that must be said about the beta turn, the beta sheet and the one-to-one mapping. The author has asked repeatedly about the beta turn, the T-loop, the beta sheet and their one-to-one correspondence with the code. None of the five experiments tests that correspondence, and none of the charts speaks to it. It remains the least supported claim in the framework, and it is listed here rather than left implied. If it is to be tested, the experiment has not yet been designed, and designing it is the outstanding work.

141. What Would Show This Part Is Wrong ↩

Stated as instructions, as everywhere else in this volume

— Produce an edition of the metabolism charts whose legend does not list ITP, IDP and IMP, and the central finding of section 135 is an artifact of one printing rather than a fact about the standard vocabulary.

— Show that dihydroorotate dehydrogenase carries no iron-sulfur center in the human enzyme, and the symmetry claimed in section 138 holds for one branch only.

— Find a de novo route to a purine nucleotide that does not pass through IMP, or to a pyrimidine that does not pass through orotate, at any coordinate on chart three, and the confirmations in section 137 are incomplete.

— Demonstrate that marking to the legend's vocabulary produces a materially different sulfur census when performed by two independent readers, and the verification rule of section 136 is not reproducible and should be withdrawn.

The charts were drawn in 1982 by people who had never heard of this framework. That is the whole reason they are worth citing, and it is also the reason a single contrary printing would cost more than any argument could.

PART FORTY-TWO · WHAT THE COLOR COUNT FOUND ON THE 1982 MAP

Sections 142 to 149 · Four findings from a wall-sized 1982 metabolic chart, colored atom by atom and read at four distances

---

142. The Method, and Why It Required an Eye ↩

Every atom symbol on the nucleotide and nucleic acid sections of the 1982 metabolic wall chart was marked by hand in a fixed color key — oxygen orange, hydrogen red, nitrogen green, phosphorus purple, carbon blue, sulfur yellow — and the colored chart was then photographed and examined at magnifications from roughly 0.5 to 4.7.

The multi-scale reading is not incidental. It is the instrument.

A metabolic chart of this kind defeats the reader by detail. At normal reading distance the eye is captured by whatever text is nearest, and the global structure is invisible. Color works because of the way the eye is built. A patch of one color sitting among patches of another color is found in about a fifth of a second, and — this is the part that matters — the time does not go up when there are more patches to search through. The eye takes in the whole sheet at once. Finding a letter among other letters is nothing like that. It has to be done one item at a time, and it gets slower the more letters there are. Treisman and Gelade established this in 1980 and it has been measured many times since. Coloring the chart by element therefore turns a search that would have to be done word by word into one the eye finishes in a single look. And standing at a different distance changes what can be seen. Close in, the reader sees a molecule. Standing back, he sees where a whole class of atom does and does not occur on the sheet.

A two-dimensional chart of this size hides its own architecture behind its own detail. The only way through is to look at it from more than one distance, and that is a perceptual operation rather than an analytical one.

The standing of what follows

Sections 143 to 146 report what the colored chart shows. They are observations about a printed document, and the document is named, dated and obtainable. Anyone who disputes them can buy the same chart, color it, and look.

Section 148 states what is claimed and what is not. Section 149 states the conditions under which each finding would be wrong.

---

143. The Free Bases Live in the Catabolism Boxes ↩

The observation

Find every occurrence on the chart of a free base — adenine, guanine, hypoxanthine, xanthine, uracil, thymine, drawn without a sugar and without a phosphate.

They are almost entirely inside the two boxes ruled and titled PURINE CATABOLISM and PYRIMIDINE CATABOLISM.

In the anabolic territory above those boxes — the whole expanse from the one-carbon pool, through the phosphoribosyl intermediates, through IMP and orotidine

monophosphate, out to the triphosphates and the arrows marked RNA and DNA — the free base is essentially absent as an intermediate.

Why, and this is the part that turns an observation into a finding

In de novo purine synthesis the base is never free, at any stage, in any organism.

The ring is assembled on top of the ribose phosphate, atom by atom, from glycine, formate, glutamine, aspartate and carbon dioxide, across ten enzymatic steps. The chart draws every one of them, and every one carries the sugar and the phosphate already attached.

step on the chart	what it carries
5'-phosphoribosylamine onward	ribose and phosphate, from the first committed step
5'-phosphoribosyl-5-aminoimidazole	ribose and phosphate
5'-phosphoribosyl-5-aminoimidazole-4-carboxamide	ribose and phosphate
5'-phosphoribosyl-5-formamidoimidazole-4-carboxamide	ribose and phosphate
IMP — the first complete purine nucleotide	ribose and phosphate

The purine ring has never, in its existence, been a separate molecule. It is built in place on a sugar that was there before it was.

The pyrimidine branch does it the other way and arrives at the same conclusion. There the ring is built first — carbamoyl phosphate to aspartate to dihydroorotate to orotate — and then, at the single step catalyzed by orotate phosphoribosyl transferase, it is joined to PRPP. Free orotate exists for exactly one step, and the moment it becomes a coding pyrimidine it is already a nucleotide.

What a free base therefore means on that chart

a free base means	the pathway
something is being taken apart	catabolism: IMP to inosine to hypoxanthine to xanthine to uric acid
something is being recovered	salvage: HGPRT and APRT reattaching a base to PRPP

Both are downstream operations. Neither is construction.

The four letters of the genetic alphabet name molecules that, in the anabolic direction, occur nowhere on the chart. They are names for the wreckage and for the scrap yard.

Why this is the strongest of the four findings

It requires no theory, no citation and no argument. It is a statement about where ink of a particular kind falls on a particular printed sheet, and the reason for it is standard textbook biochemistry that has not changed since the chart was drawn.

And it is the volume's thesis stated by geography rather than by assertion.

---

144. Every Arrow into RNA and DNA Leaves from a Triphosphate ↩

The observation

The chart marks its two destinations with heavy black arrows labeled RNA and DNA. Trace back from every one of them.

destination	the molecules the arrows leave from
RNA	ATP, GTP, CTP, UTP
DNA	dATP, dGTP, dCTP, dTTP

Not one arrow to a polymer leaves from a base. Not one leaves from a nucleoside. Not one leaves from a monophosphate or a diphosphate.

Eight arrows, eight triphosphates, no exceptions on the sheet.

The chemistry the chart is drawing

Both polymerases take the nucleoside triphosphate as substrate. The 3'-hydroxyl of the growing chain attacks the alpha phosphate, and pyrophosphate leaves. Its subsequent hydrolysis by inorganic pyrophosphatase is what makes the reaction effectively irreversible.

Every phosphodiester bond in every nucleic acid on Earth was paid for by throwing away a pyrophosphate. The triphosphate is not a storage form of the letter. It is the only form the machinery will accept.

The distinction this establishes, stated carefully

The genetic code is the mapping from codon to amino acid. It does not code for triphosphates, and this volume does not claim that it does.

What the chart establishes is a different and previously unstated separation:

the letters	what the polymer is read as
the triphosphates	what the polymer is made from

The alphabet names the product. The chart shows the substrate. They are not the same molecule, and the difference is three phosphate groups and the entire energy budget of replication and transcription.

A sequence file records the first and is silent about the second. That silence is the same silence this volume has documented for oxidation state, for bond order, and for the sulfur atom itself.

---

145. Blue Is Nearly Absent, and the Reason Is the Argument ↩

The observation

On a map made entirely of organic chemistry, the carbon color scarcely appears.

Across the whole nucleotide and nucleic acid region, blue lands on almost nothing: the 5' methylene carbon written as CH2, a carboxylate, a released CO2. Perhaps a dozen marks on a sheet containing many thousands of carbon atoms.

Why

In a skeletal formula a carbon atom is a vertex — a corner where two lines meet, or the end of a line. The letter C is written only where omitting it would be ambiguous. The rings of every purine and every pyrimidine on that chart, the five-membered ring of every ribose, the backbone of every chain: all carbon, none of it labeled.

Carbon is the most abundant atom on the chart and the least visible one, because the notation represents it by absence. The color count could not find it because it was never written down.

And this is the thesis, in a second medium

The volume's central claim is that the four-letter notation omits the material that decides function. Section 145 is an instance of the same phenomenon at a different level:

A structural formula omits the element that constitutes it.

Neither omission is an error. Both are efficient conventions, adopted because the omitted thing is everywhere and drawing it would obscure what varies. But in both cases a reader who takes the notation for the material will conclude that the omitted thing is not there.

That is how carbon came to be treated as the definition of organic chemistry while being invisible on every page of it, and it is how sulfur came to be absent from a genetic alphabet it is required for.

---

146. What Orange, Red and Green Count ↩

Oxygen and hydrogen dominate the variation

Orange and red are the two commonest marks on the colored chart, and between them they are water.

water as a fraction of adult body mass	**about 60 percent — 55 in women, higher in infants**
water as a fraction of the molecules in a human body	about 99 percent

Ninety-nine molecules in every hundred. The second figure is the one that carries the point, and it is the more startling of the two.

And the oxygens and hydrogens are where the structures differ from one another. Hydroxyl against hydrogen at the 2' position is the entire chemical difference between RNA and DNA. Ketone against amine on the ring is the difference between one base and another. The variation between the molecules is carried very largely in orange and red.

Green is the anchor, and it barely moves

base	nitrogens	green marks
adenine, guanine	5	5
hypoxanthine, xanthine	4	4

base	nitrogens	green marks
cytosine	3	3
uracil, thymine, orotic acid	2	2

Four or five green marks for every purine; two or three for every pyrimidine. The division between the two classes of base is legible from the green count alone, before any label is read.

And adenine to hypoxanthine is the subtraction of exactly one green mark. That is the deamination ADAR performs, rendered as arithmetic. Guanine to xanthine is the same operation on the other purine.

Purple is the discriminator

Phosphorus appears once on a monophosphate, twice on a diphosphate, three times on a triphosphate — and the purple count is therefore the direct visual readout of how much energy a molecule is carrying.

On the colored chart, the reader can see the charge state of a nucleotide from across the room. No other color on the sheet reports a thermodynamic quantity.

---

147. The Four Scales, and What Each One Showed ↩

Recorded because the method is reproducible and should be stated as a procedure.

viewing scale	what resolves
closest	the identity of individual atoms; the 2'-OH against 2'-H distinction
mid-close	the structure of one molecule; the purple count; the green count
mid-far	the local pathway; which molecule feeds which
farthest	the territory. Where a class of atom occurs and where it does not. The catabolism boxes as regions rather than as boxes

Finding 143 is invisible at every scale except the farthest, and findings on individual atoms are invisible at that one. A single viewing distance cannot produce this set.

---

148. What Is Claimed and What Is Not ↩

Claimed

That on the named 1982 chart, free bases occur essentially only within the two catabolism boxes. That the de novo purine route builds the ring on an already-attached ribose phosphate and never produces a free base. That all eight arrows into RNA and DNA leave from triphosphates. That the carbon color is nearly absent because skeletal notation does not write carbon. That the purine and pyrimidine classes separate by nitrogen count alone.

Not claimed

That the genetic code codes for triphosphates. The code is the codon-to-amino-acid mapping. What is claimed is the narrower and defensible thing: the letters name what the polymer is read as; the triphosphates are what it is made from.

That the bases are unimportant. They carry the pairing and therefore the information. The finding is about where they occur as free molecules, not about what they do when they are part of a nucleotide.

That carbon is unimportant. It is the scaffold of everything on the sheet. The finding is about notation, not about chemistry.

And one framing marked as what it is

The author's account of the triphosphate, diphosphate, monophosphate and base as four generations of a family — grandparent, parent, child, and the remains of the dead — is a mnemonic and is recorded here as one.

It is a good one, and it should be marked rather than smuggled. In the anabolic direction the chemistry runs the opposite way to the story: the monophosphate is made first and the triphosphate is the mature form, so the accumulation is of charge rather than of wisdom. The mnemonic and the mechanism disagree about direction, and a reader is entitled to know which he is being handed.

---

149. What Would Show These Findings Are Wrong ↩

— Identify a free base occurring as an obligate intermediate of de novo purine or pyrimidine synthesis in any organism, and section 143 is broken and the alphabet is restored to the anabolic pathway.

— Identify a polymerase that accepts a nucleoside monophosphate or diphosphate as substrate for chain extension, and section 144's eight-for-eight becomes a generalization with exceptions.

— Show that the free bases appear outside the catabolism boxes on the same chart at a frequency comparable to their appearance inside them, and the observation is an artifact of where the reader looked rather than of where the ink is.

— Produce a structural convention in general use that writes every carbon explicitly, and section 145's claim about notation is a claim about one drawing style rather than about chemical notation.

— Color the same chart independently, by a second party working from the same key, and obtain a different distribution, and the method is not reproducible and none of this stands.

The last of these has not been done. Until it is, these are one reader's observations of one sheet, stated precisely enough that a second reader can disagree with them.

PART FORTY-THREE · THE FERROPTOSIS LANDSCAPE

Sections 150 to 157 · Where sulfur and fatty acids collide, what the field has built there, and the gap it has stated about itself

---

150. Why This Territory ↩

Ferroptosis is iron-dependent lipid peroxidation — the destruction of polyunsaturated fatty acids inside a membrane, propagating as a radical chain, ending in loss of membrane integrity and death.

It is regulated by sulfur, and the regulator is made of selenium.

element of the mechanism	what it is	which of this volume's subjects
the substrate being destroyed	polyunsaturated fatty acyl phospholipids	the fourth monomer
the brake	GPX4, glutathione peroxidase 4	—
what the brake consumes	glutathione	sulfur

element of the mechanism	what it is	which of this volume's subjects
what the brake is built from	selenocysteine at position 46	selenium — sulfur's conjugate partner in group sixteen
the supply line	system xc-, the cystine/glutamate antiporter	cystine — the disulfide

A fatty acid dies because a sulfur ran out, and the enzyme that would have saved it is a cysteine with the sulfur replaced by selenium.

This volume has spent forty-two Parts arguing that sulfur is the connective tissue between levels. Ferroptosis is the place where that claim stops being an argument and becomes a mechanism with a death phenotype.

And it corrects an error in this volume's own accounting

Part Forty-Two recorded that fatty acids contain no sulfur — three colors, carbon, hydrogen and oxygen. That is correct and it is not the whole picture.

stage	the molecule	the sulfur
the primer	acetyl-CoA	thioester
the extender	malonyl-CoA	thioester
the assembly line	acyl carrier protein and its phosphopantetheine arm	a free thiol at the tip
every elongation cycle, all seven	acyl-ACP	thioester
every round of beta oxidation	acyl-CoA	thioester
release	thioesterase	cuts the sulfur bond

A palmitate is sixteen carbons and no sulfur. It is covalently attached to a sulfur atom for every instant of its construction and every instant of its destruction, and it exists as a free molecule only in between.

The purine ring is never free of its ribose. The fatty acyl chain is never free of its sulfur. Both are built on a tether, and in both cases the notation records only the product.

---

151. What the Field Has Printed About Its Own Chemistry ↩

According to PubMed, two papers a decade apart say the same thing about every GPX4 inhibitor ever made.

Eaton, Furst, Ruberto, Moosmayer, Hilpmann, Ryan and colleagues — Broad Institute and Bayer AG — in Nature Chemical Biology, 2020:

"all existing inhibitors of GPX4 act covalently via a reactive alkyl chloride moiety that confers poor selectivity and pharmacokinetic properties."

Their contribution was to replace the alkyl chloride with masked nitrile-oxide electrophiles, reporting improved proteome-wide selectivity and improved pharmacokinetics. DOI 10.1038/s41589-020-0501-5.

Cao, Wu, Xu and colleagues, Shanghai Institute of Materia Medica, in the European Journal of Medicinal Chemistry, 2023, restate the position including the newer chemistry:

"So far, all existing GPX4 inhibitors covalently bind to GPX4 via a reactive alkyl chloride moiety or masked nitrile-oxide electrophiles with poor selectivity and pharmacokinetic properties, and most were obtained by cell phenotype-based screening."

DOI 10.1016/j.ejmech.2023.116044.

Two independent groups, one American and one Chinese, three years apart, publishing the same sentence about the state of the art: the chemistry is covalent, it is not selective, and its pharmacokinetics are poor.

---

152. The Finding — the Screen Was Run on the Wrong Atom ↩

What the 2023 paper reports about its own assay

Selenoproteins are difficult to express recombinantly, because selenocysteine insertion requires a UGA codon read through a SECIS element and a dedicated tRNA. So the high-throughput screening assay was not run on GPX4.

U46C. Selenocysteine forty-six, mutated to cysteine. The selenium replaced by a sulfur, so that the protein could be made.

Compounds were therefore selected against a sulfur enzyme and are intended for a selenium enzyme.

Why that substitution is not conservative, in the vocabulary this volume already uses

Sulfur and selenium are conjugate partners in group sixteen. They are not interchangeable, and the difference is quantitative and large.

	cysteine thiol	selenocysteine selenol
pKa	about 8.5	about 5.2
ionization state at pH 7.4	partly ionized	essentially fully ionized
nucleophilicity	high	higher — the selenolate is among the best nucleophiles in biology
oxidation	reversible, slower	faster, and reversible over a wider range
consequence for a covalent drug	the reference case	a different rate, a different selectivity, and a different resting state

More than three log units of difference in pKa between the residue used in the screen and the residue in the patient.

And the same difference is the selectivity handle the field says it lacks

The stated problem is proteome-wide selectivity: chloroacetamides and related electrophiles hit cysteines everywhere.

But the target residue is not a cysteine. It is the most reactive selenol in the cell, sitting three pH units below every thiol in the proteome, and it is fully ionized at physiological pH when almost nothing else is.

That difference is a selectivity axis, and the published chemistry does not exploit it. The electrophiles in use were developed for cysteine and are being applied to selenocysteine, and the compounds that reach that residue were chosen using a protein in which the residue had been changed to a cysteine.

This volume claims no compound and proposes no molecule. It observes a gap between an assay and a target, and the gap is one atom of group sixteen.

---

153. The Clinical Landscape — What Is Actually in the Registry ↩

A registry search on ferroptosis returns a field that is almost entirely observational.

study	what it is
Erciyes University, coronary artery disease	ferroptosis biomarkers before and after cardiac rehabilitation
University Hospital Antwerp, 600 patients	cell-death diagnostics to stratify sepsis, trauma and subarachnoid hemorrhage
Northern Jiangsu, two studies	Nrf2-dependent ferroptosis and exposure to particulates, and to lead
Assiut University	GPX4 as a detection marker in ankylosing spondylitis
University Hospital Bordeaux	ferroptosis in SF3B1-mutant myelodysplastic syndrome
Poznan University of Physical Education	ferroptosis markers in rowers

Biomarkers, stratification, exposure studies and correlation analyzes. Almost no interventional program aimed at the mechanism itself.

Roughly five hundred papers on the GPX4-glutathione-lipid intersection in the literature, and a clinical registry that contains, in effect, no drugs.

That is the largest gap between a literature and a clinic this survey has encountered.

---

154. Where the Money Is Instead ↩

The commercial effort in the fatty liver is enormous, and none of it is aimed at the sulfur side.

program	sponsor	enrollment	mechanism
Pegozafermin, two Phase 3 trials	89bio	1,350 and 762	FGF21 analog
Efruxifermin	Akero	1,650	FGF21 analog
Efimosfermin alfa, three Phase 3 trials	GlaxoSmithKline	1,740, 1,250, 380	FGF21 analog
Survodutide	Boehringer Ingelheim	1,800	glucagon / GLP-1 dual agonist
Tirzepatide and retatrutide, master protocol	Eli Lilly	4,500	incretin agonists

More than thirteen thousand patients in Phase 3 for metabolic liver disease, across FGF21 analogs and incretin agonists.

Neither class touches sulfur chemistry. The incretins act on satiety and insulin; the lipid effect is downstream of reduced intake. The FGF21 analogs act on a hormonal axis. Neither addresses the peroxidation of the lipid, and neither engages glutathione, cystine import or GPX4.

---

155. What This Framework Brings That the Field Does Not Have ↩

Not a molecule. A vocabulary in which four separate literatures are one subject.

the literature	what it studies	what this volume already calls it
redox biology	glutathione, cystine, system xc-	the cysteine relay; the six-rung ladder
selenium biology	GPX4, selenoproteins, SECIS	the third chalcogen, standing outside the coded set
lipid biology	polyunsaturated phospholipids, peroxidation	the fourth monomer, built on a thioester tether
oncology	therapy-resistant persister cells	the clinical destination

In the standard organization these are four fields with four sets of journals. In this framework they are one atom at four levels, and the ferroptosis mechanism is the place where the four are demonstrably the same story.

One. The U46C substitution as a stated methodological gap, expressed in group-sixteen terms with the pKa arithmetic attached.

Two. The selenol-versus-thiol reactivity difference framed as an unexploited selectivity axis rather than as an inconvenience.

Three. The thioester tether account of fatty acid synthesis and oxidation, which places the substrate of ferroptosis inside the same sulfur economy as its regulator.

Four. The corpus's standing method: every claim printed with the conditions under which it would be wrong.

---

156. What Would Be Worth Doing, in Order of Cost ↩

First, and cheapest. Compare the potency of the published GPX4 inhibitors against the selenocysteine enzyme and against the U46C cysteine mutant, side by side, in

the same assay. If the ratio is near one, the substitution is harmless and section 152 is a false alarm. If it is not, every structure-activity relationship built on the mutant needs re-examination. This is a bench experiment with existing compounds and existing proteins.

Second. Ask whether any electrophile has been designed for a selenol rather than adapted from thiol chemistry. A literature question, answerable in a week.

Third. Test whether cystine availability, rather than GPX4 inhibition, is the more tractable handle in liver disease, given that system xc- is upstream and that the liver is where cysteine metabolism is concentrated.

Fourth, and the expensive one. A program.

---

157. What Would Show This Survey Is Wrong ↩

- Show that GPX4 inhibitors are equipotent against the selenocysteine enzyme and the U46C cysteine mutant, and section 152's central observation is void.
- Identify a published GPX4 inhibitor whose electrophile was designed for selenol reactivity rather than adapted from cysteine-directed chemistry, and the claim that the selectivity axis is unexploited is false.
- Produce interventional trials of ferroptosis-directed agents that the registry search did not return, and the clinical gap of section 153 is an artifact of the search rather than a fact about the field.
- Show that FGF21 analogs or incretin agonists act materially through lipid peroxidation or glutathione, and the claim that the commercial effort avoids sulfur is wrong.
- Show that the thioester tether is dispensable — that a fatty acid can be synthesized or oxidized without covalent attachment to a sulfur at any stage — and section 150's correction to Part Forty-Two collapses.

The first of these is a two-week experiment and it decides the value of everything above it.

NCT number. All retrieved through PubMed and the clinical trials registry, and all checkable by identifier.

PART FORTY-FOUR · THE BIFURCATION

Sections 158 to 164 · The iron-sulfur protein named on the 1982 chart, measured at one hundred microseconds

---

158. The Paper, and What It Measured ↩

Zhu, Egawa, Yeh, Yu and Yu, Proceedings of the National Academy of Sciences, 2007, using an ultra-fast microfluidic mixer and a freeze-quenching device coupled to electron paramagnetic resonance, with stopped-flow for the slower components.

The paper was edited by Helmut Beinert — the man who discovered iron-sulfur proteins and gave them their name.

The object

The cytochrome bc1 complex, also called ubiquinol-cytochrome c reductase, also called Complex III. It takes electrons from ubiquinol, delivers them to cytochrome c, and pumps protons across the membrane to make the gradient that drives ATP synthase.

group	what it is
cytochrome bL (b566)	low-potential heme
cytochrome bH (b562)	high-potential heme
cytochrome c1	the exit
the Rieske center	a high-potential 2Fe-2S iron-sulfur cluster

The bovine complex has eleven subunits. Three carry the redox groups. Eight carry none.

The measurement

species	onset	half-time
iron-sulfur protein	as early as 100 microseconds	250 microseconds

species	onset	half-time
cytochrome bL	the same	the same
cytochrome bH	—	1.7 milliseconds, 403 per second
cytochrome c1	—	4.2 milliseconds, 164 per second

The iron-sulfur protein and cytochrome bL are reduced simultaneously, and no ubisemiquinone was detected at the site where the reaction happens.

---

159. The Rieske Center — Two Ligands That Are Not Sulfur ↩

The substitution

An ordinary plant-type 2Fe-2S ferredoxin holds its cluster with four cysteines. Four sulfur ligands, and a midpoint potential in the region of minus three hundred to minus four hundred millivolts.

The Rieske center holds the same 2Fe-2S cluster with two cysteines and two histidines.

	ferredoxin-type 2Fe-2S	the Rieske center
ligands	4 cysteine — four sulfurs	2 cysteine, 2 histidine — two sulfurs, two nitrogens
midpoint potential	about −300 mV	about +300 mV

Replace two of the four sulfur ligands with nitrogen and the redox potential of the same iron-sulfur cluster moves by roughly six hundred millivolts. More than half a volt, from two atoms.

Why this belongs in this volume rather than in a footnote

This is the volume's thesis in its most quantitative form yet.

The cluster is the same. The two irons are the same, the two bridging sulfides are the same, the fold is a beta sandwich in both cases. What changes is the identity of two ligating atoms — sulfur out, nitrogen in — and the change is worth six hundred millivolts of driving force.

A sequence records the substitution as two letters. It records nothing about the six hundred millivolts, and the six hundred millivolts is the whole reason the protein can do its job.

And it is the same experiment as the ferroelectric nematic series of the Overview — take a molecule, swap one chalcogen for its neighbor, and measure what changes. Here the swap runs the other way, sulfur to nitrogen, and the readout is in volts rather than in phases.

---

160. The Bifurcation ↩

What happens at the Qp site, and why it is unlike anything else in the chain

Ubiquinol arrives at the Qp site carrying two electrons. They leave in opposite directions.

electron	destination	the chain	the potential
the first	the Rieske iron-sulfur protein, then cytochrome c1	the high-potential chain	uphill in energy terms — about +300 mV
the second	cytochrome bL, then bH, then the quinone at the Qn site	the low-potential chain	downhill — around −100 mV

One donor. Two electrons. Two paths of opposite thermodynamic direction. This is the bifurcation, and it is the step that makes the proton gradient possible.

It is the reason the complex can pump. Without the split, both electrons would take the easy path and no proton motive force would be generated.

And the iron-sulfur protein is the referee

The Rieske center is the acceptor for the electron that goes the hard way. Its unusually high potential — the six hundred millivolts of section 159, bought with two ligand substitutions — is what makes that branch thermodynamically possible at all.

Take the two histidines away and put cysteines back, and the potential collapses, and the bifurcation stops.

---

161. What the 2007 Paper Settles, and What It Does Not ↩

The controversy the paper addresses

account	the claim
sequential	the first electron goes to the iron-sulfur cluster; the resulting ubisemiquinone then reduces cytochrome bL
concerted	both electrons leave together, with no free semiquinone intermediate

The difficulty was that the reduction of the iron-sulfur protein is hard to follow optically, so direct evidence for its early involvement did not exist.

The result

Freeze-quench EPR at microsecond resolution shows the iron-sulfur protein and cytochrome bL reduced on the same timescale — onset by 100 microseconds, half-time 250 microseconds for both.

The two acceptors fill together. The intermediate that the sequential mechanism requires was not there to be found.

What is claimed and what is not

Claimed. That the measured kinetics are consistent with concerted oxidation and are difficult to reconcile with a sequential mechanism requiring a discrete semiquinone at the Qp site.

Not claimed. That the question is closed. The paper itself notes that plausible explanations for the absence of the radical have been offered by others, and that evidence supporting both accounts exists in the literature. The mechanism of bifurcated oxidation at the Qp site is described in the paper's own words as still a matter of controversy, and this volume records it that way.

One detail of method worth keeping

The intertwined dimer of the complex was confirmed in solution by engineering two pairs of cysteines and letting them form intersubunit disulfide bonds — one pair linking the iron-sulfur protein head domain to cytochrome b, the other linking its tail domain to cytochrome b of the other monomer.

Sulfur used as the measuring instrument. Two disulfide bonds installed on purpose to prove that two proteins are in contact.

162. The Quinone That Joins This Part to Part Forty-One ↩

The connection the charts did not draw

Part Forty-One reported, from the four 1982 charts, that dihydroorotate dehydrogenase is labeled FAD · ISP · Fe — an iron-sulfur flavoenzyme, and the only enzyme of nucleotide biosynthesis wired directly into the respiratory chain.

What it is wired into is ubiquinone. DHODH oxidizes dihydroorotate and passes the electrons to the quinone pool, reducing ubiquinone to ubiquinol.

And the bc1 complex takes them out again. Ubiquinol arrives at the Qp site and the bifurcation begins.

	the enzyme	what it does to the quinone	the iron-sulfur
in	dihydroorotate dehydrogenase	reduces ubiquinone to ubiquinol	ISP, on the 1982 chart
out	cytochrome bc1 complex	oxidizes ubiquinol at the Qp site	the Rieske 2Fe-2S center

The committed step of pyrimidine synthesis and the electron-bifurcating step of respiration share a quinone pool, and both ends of that pool are held by iron-sulfur proteins.

Every pyrimidine in the reader's body was made by an enzyme that put its spare electrons into the same lake the Rieske protein drinks from. The charts print both enzymes. They do not draw the line between them, because the line is a shared small molecule rather than an arrow.

---

163. The Qp Site as a Drug Target ↩

One of the most commercially successful targets in the history of the field

The site where the bifurcation happens is druggable, and it has been drugged repeatedly.

agent	what it is	where it binds
Atovaquone	antimalarial; also used against Pneumocystis and Babesia	the Qp site of parasite cytochrome b
Strobilurin fungicides — azoxystrobin, kresoxim-	derived from strobilurin A, a natural product of the	the Qp site — the QoI class

agent	what it is	where it binds
methyl, trifloxystrobin, picoxystrobin	mushroom Strobilurus tenacellus	
Myxothiazol	natural product of the myxobacterium Myxococcus fulvus	the Qp site
Stigmatellin	natural product; locks the iron-sulfur head domain in one position	the Qp site
Antimycin A	the classical respiratory inhibitor	the Qn site — the other quinone pocket

The QoI fungicides became one of the largest-selling classes of agricultural fungicide in the world, and resistance to them arises through a single amino acid change in cytochrome b. Atovaquone resistance arises the same way, at a different residue.

A single-residue change in one subunit defeats a drug class worth billions, because the pocket is small and the bifurcation is precise.

And there is sulfur in one of them

Myxothiazol contains a bithiazole — two thiazole rings joined, each carrying a ring sulfur.

A sulfur-heterocycle natural product, made by a soil bacterium, that shuts down the site where an iron-sulfur protein takes its electron. The corpus records this in the pharmacopoeia's own terms: a sulfur ring aimed at a sulfur cluster's workplace.

Not claimed: that the thiazole sulfurs interact with the iron-sulfur cluster. They do not; myxothiazol binds the quinol pocket of cytochrome b. The observation is about the chemistry of the inhibitor, not about its contact.

---

164. What Would Show This Part Is Wrong ↩

— Show that the simultaneous reduction of the iron-sulfur protein and cytochrome bL is an artifact of the freeze-quench method — that a semiquinone forms and decays inside the hundred-microsecond dead time — and section 161's reading of the result fails, and the sequential mechanism is restored.

— Construct a Rieske center with four cysteine ligands that retains a potential near +300 mV, and the six hundred millivolts of section 159 is not attributable to the ligand substitution.

— Show that dihydroorotate dehydrogenase delivers its electrons to an acceptor other than the ubiquinone pool that feeds the bc1 complex, and the junction claimed in section 162 does not exist.

— Demonstrate that human PPAT does not carry an iron-sulfur cluster — the open question carried since Part Forty-One — and the both-gates symmetry weakens, though section 162's quinone junction survives it, because that junction rests on DHODH alone.

— Show that the Qp-site inhibitors act by a mechanism unrelated to the bifurcation, and section 163 is a list of drugs rather than an argument.

Section 161 records that the concerted-versus-sequential question is described as controversial by the paper's own authors. This Part does not settle it and does not claim to.

Source. Zhu, Egawa, Yeh, Yu & Yu, "Simultaneous reduction of iron-sulfur protein and cytochrome bL during ubiquinol oxidation in cytochrome bc1 complex," Proceedings of the National Academy of Sciences, 2007. Ligand identities, midpoint potentials and inhibitor binding sites are standard bioenergetics and are not from this paper.

PART FORTY-FIVE · THE PANEL THAT IS NOT ONLY ABOUT AMINO ACIDS

Sections 165 to 172 · A panel titled AMINO ACIDS that draws the neurotransmitters, the polyamines, the porphyrins and a nucleotide cofactor

---

165. The Panel, and What It Is Called ↩

Chart two of four of the metabolism charts, copyright 1982

Texas at Dallas. The same instrument used in Part Forty-One and colored atom by atom in Part Forty-Two.

The largest panel on the sheet carries a two-word title in red capitals: AMINO ACIDS.

What the observation is

Read across that panel and count what is drawn on it. Very little of it is an amino acid.

The title names the raw material. It does not name the products, and the products are the reason the panel is the largest on the chart.

---

166. What Is Actually Drawn There ↩

The products, all downstream of an amino acid, none of them an amino acid

on the panel	what it is	made from
dopamine, noradrenaline, adrenaline	the catecholamines	tyrosine
serotonin — 5-hydroxytryptamine	an indoleamine	tryptophan
histamine	a biogenic amine	histidine
GABA — gamma-aminobutyrate	the principal inhibitory transmitter	glutamate
creatine, phosphocreatine, creatinine	the muscle phosphagen	glycine, arginine, and a methyl
putrescine, spermidine, spermine	the polyamines	ornithine, and a sulfur donor
NAD and NADP, via quinolinate	a nucleotide cofactor	tryptophan
urea	the nitrogen exit	the urea cycle
heme, biliverdin, bilirubin, stercobilinogen	a porphyrin and its pigments	glycine and succinyl-CoA

Nine classes of product. Not one of them is an amino acid. Four of them are the molecules by which the nervous system operates, and one of them is a nucleotide.

The point stated plainly

The panel is not about amino acids. It is about nitrogen metabolism, and the amino acids are the doorway rather than the room.

A reader who takes the title at its word will look at that panel and see twenty molecules he already knows. A reader who looks at what is drawn will see the chemistry by which a body signals, pigments, detoxifies and remembers.

---

167. The Amino Acids on the Panel That Have No Codon ↩

Named, with their positions on the same sheet

These are amino acids by definition, they are drawn on the panel, and none of them is installed by a ribosome.

on the panel	where it sits
ornithine	the urea cycle
citrulline	the urea cycle
argininosuccinate	the urea cycle
homocysteine	the sulfur thread
cystathionine	the sulfur thread
cysteine sulfinate	the sulfur thread
GABA	the glutamate branch
saccharopine	lysine catabolism
L-alpha-aminoadipate	lysine catabolism
L-pipecolate	lysine catabolism
N-formimino-L-glutamate	histidine catabolism

Eleven, on one panel, by inspection. A reader holding the same chart can find every one.

And the scale of the omission beyond that panel

More than five hundred naturally occurring amino acids are known. Twenty have codons.

Hydroxyproline and hydroxylysine are not on the list of twenty either, and collagen — the most abundant protein in the human body — is built from them. They are made after translation, by an iron enzyme that requires vitamin C, which is why scurvy dissolves connective tissue.

---

168. Who Decided Twenty ↩

Nobody decided

Twenty is the number of amino acids the ribosome can install directly from the standard code, plus selenocysteine and pyrrolysine reached by recoding.

It is a count of what the translation machinery can be instructed to do. It is not a count of what exists, and it was never intended as one.

The error the title makes, and the volume has made it before

The twenty are a notation limit mistaken for a material limit — the same error this volume identified in the four letters.

the notation	what it counts	what it is mistaken for
A, G, C, T	the bases a polymerase pairs	the material of heredity
the twenty	the residues a ribosome installs	the amino acids of biology

Both counts are correct about the machine and wrong about the world. And in both cases the molecules left outside the count are the ones that carry sulfur, metals and charge.

---

169. The Sulfur Thread Across the Panel ↩

Traceable end to end on the colored sheet

methionine\n-> S-adenosyl-L-methionine (the sulfonium; the methyl donor)\n-> S-adenosyl-L-homocysteine (spent)\n-> homocysteine\n-> cystathionine\n-> cysteine\n-> cysteine sulfinate -> sulfite -> sulfate

With two branches drawn on the same panel. 5-methylthioadenosine leaves the sulfonium and goes to the polyamines. Beta-mercaptopyruvate leaves cysteine by transamination.

And the thioesters run beneath all of it

Acetyl-CoA, succinyl-CoA, propionyl-CoA, methylmalonyl-CoA, butyryl-CoA, glutaryl-CoA, isovaleryl-CoA — every acyl intermediate on the panel is carried on a sulfur.

Thiamine pyrophosphate and the lipoyl disulfide are drawn at both alpha-keto dehydrogenase complexes, printed on the chart as ThPP and Lip-S-S.

The panel titled AMINO ACIDS contains, by count, more sulfur chemistry than the panel titled NUCLEOTIDES. None of it is in the title.

And an RNA runs on the same sulfonium

Chen, Okuda, Lenz, Scheitl, Schindelin and Höbartner reported the crystal structures of SAMURI in Nature Chemical Biology 22:938 to 947, January 2025. SAMURI is a site-specific alkyltransferase ribozyme. It uses S-adenosylmethionine, or a stabilized analog of it, to transfer a methyl or a propargyl group onto the N6 position of an adenosine. The structures show a three-helix junction with the catalytic core folded into four stacked layers, holding the cofactor and the modified nucleotide together.

The comparison the authors draw is with SAM riboswitches, which bind the same cofactor and must avoid methylating themselves. SAMURI does the opposite deliberately. Their closing suggestion is that S-adenosylmethionine and its analogues may serve as substrates for a range of RNA-catalyzed reactions whose ribozymes have not yet been found.

The methyl donor this Part traces across the amino acid panel is not a protein invention. An RNA can hold the sulfonium, position it, and use it. The sulfur chemistry the panel is full of does not require the panel.

---

170. The Methyl That Changes a Hormone, and the Metals That Make One ↩

One carbon, delivered by sulfur, converts one hormone into another

The chart draws it explicitly. Noradrenaline plus S-adenosyl-L-methionine gives adrenaline plus S-adenosyl-L-homocysteine.

A single methyl group, carried on a sulfonium, is the entire difference between the hormone of vigilance and the hormone of emergency. The transfer is drawn on the panel and the atom that carried it is not in the title.

And the hydroxylations run on metals, also drawn

enzyme	cofactor drawn on the chart	metal
phenylalanine hydroxylase	biopterin H4	non-heme iron

enzyme	cofactor drawn on the chart	metal
tyrosine hydroxylase	biopterin H4	non-heme iron
tryptophan hydroxylase	biopterin H4	non-heme iron
dopamine beta-hydroxylase	ascorbate	copper — Cu2+ printed on the sheet

Three biopterin cycles are drawn side by side on that panel, each regenerating the reduced cofactor through dihydropteridine reductase and NADPH.

Every neurotransmitter on that panel is made by a hydroxylation on a metal or a methylation from a sulfur. The amino acid supplies the skeleton. The metals and the sulfur supply the function.

---

171. What Is Claimed and What Is Not Claimed ↩

Claimed

That the panel titled AMINO ACIDS draws nine classes of product that are not amino acids. That eleven amino acids without codons are drawn on the same panel and can be found by inspection. That more than five hundred naturally occurring amino acids are known and twenty have codons. That the sulfur thread and the thioester series run across the whole panel and are absent from its title.

Not claimed

That the chart is in error. It is a teaching chart, its title identifies the section by its starting material in the ordinary way, and the convention is universal. The observation is about what a title does to a reader, not about a mistake by the cartographer.

That the twenty are unimportant. They are the residues from which every protein is built and the volume has argued their case for forty-four Parts.

That the number should be different. Twenty is correct as a count of coded residues. The claim is only that it is a count of the machine, and that it is routinely read as a count of the world.

---

172. What Would Show This Part Is Wrong ↩

— Show that the products listed in section 166 are amino acids by any standard definition, and the misnomer claim fails.

— Show that ornithine, citrulline, homocysteine, cystathionine, GABA, saccharopine, alpha-aminoadipate or pipecolate are installed by a ribosome from a codon, and section 167 is wrong about them.

— Establish that the number of known naturally occurring amino acids is of the order of twenty rather than of the order of five hundred, and section 167's scale claim fails.

— Show that the catecholamines and serotonin are made without a metal-dependent hydroxylation and without a sulfonium methyl donor, and section 170 has misread the panel.

— Find a teaching chart of comparable scope whose corresponding panel is titled by its products rather than by its inputs, and the convention identified in section 171 is not universal, and the reading offered here is weaker than stated.

PART FORTY-SIX · THE ONE COBALT

Sections 173 to 179 · One cobalt atom, the only carbon-metal bond in human biology, and both of its jobs done on sulfur

---

173. One Instance on the Whole Sheet ↩

Reading the colored 1982 chart for metals, cobalt appears once.

It is printed as 5'-deoxyadenosyl cobalamin, beside the step that converts L-(R)-methylmalonyl-CoA to succinyl-CoA, in the propionate entry to the citric acid cycle.

Iron appears many times — the hemes, the hydroxylases, the iron-sulfur proteins, the ferrochelatase step of the porphyrin route. Copper appears at dopamine beta-hydroxylase. Molybdenum appears at the purine oxidases on the companion sheet. Cobalt appears once.

One atom of element twenty-seven, on a chart of several thousand structures, and it is carrying the strangest bond in the human body.

---

174. Why That Bond Is Unique ↩

The only carbon-metal bond in human biology

Cobalamin holds a cobalt inside a corrin ring, coordinated by four ring nitrogens, and above the ring it carries a sixth ligand bonded directly to carbon.

form	the upper ligand	what it does
adenosylcobalamin	a 5'-deoxyadenosyl group	the radical rearrangement
methylcobalamin	a methyl group	the methyl transfer

A cobalt-carbon bond. There is no other carbon-metal bond in human biochemistry, and both of the enzymes that use one are on this chart.

And the two cleavages are not the same cleavage

Adenosylcobalamin breaks the Co-C bond homolytically. One electron goes each way. The products are a 5'-deoxyadenosyl radical and cob(II)alamin — a genuine radical pair, two unpaired spins, generated together.

Methylcobalamin breaks it heterolytically, transferring the methyl as a cation and leaving cob(I)alamin behind. Cob(I)alamin is among the most powerful nucleophiles known in chemistry.

Same bond, two cleavage modes, two entirely different chemistries — decided by the enzyme and not by the cofactor.

---

175. Both Human B12 Enzymes Act on Sulfur ↩

The finding

Humans have exactly two cobalamin-dependent enzymes. Both of their substrates carry sulfur.

enzyme	cofactor	substrate	the sulfur
methylmalonyl-CoA mutase	adenosylcobalamin	methylmalonyl-CoA to succinyl-CoA	a thioester, on both sides of the reaction

enzyme	cofactor	substrate	the sulfur
methionine synthase	methylcobalamin	homocysteine to methionine	a thiol to a thioether

The only organometallic bond in human biology exists to serve two sulfur reactions, and the chart draws both of them.

Why the coincidence is not a coincidence

Cobalt is a soft metal. Sulfur is a soft ligand. In the hard-soft framework this volume uses throughout, they belong to the same side of the table — and cobalamin's own biosynthesis and trafficking run through glutathione-bound and thiolate-bound intermediates, which is why cellular processing of B12 is a thiol-dependent business.

Methionine synthase is the more instructive of the two. It sits exactly where the sulfur thread of Part Forty-Five crosses the one-carbon pool: it takes a methyl from folate, hands it through the cobalt, and puts it onto a sulfur.

Three carriers in series — folate, cobalt, sulfur — and the chart draws all three.

---

176. Cobalt-59 and Phosphorus-31 ↩

Two elements central to this work, and both are monoisotopic

	phosphorus	cobalt
stable isotopes	exactly one — 31P	exactly one — 59Co
natural abundance	100%	100%
nuclear spin	one half	seven halves
NMR-active	yes — the basis of 31P spectroscopy of living tissue	yes

Roughly twenty elements on the whole periodic table have only one stable isotope. Two of them are the elements this volume has spent the most time on.

Part Four of the Handoff paper established the phosphorus case: every phosphorus atom in every ATP molecule in every living cell is 31P, and its spin of one half is why the energy state of a working muscle can be read without opening it.

And the seven halves is the part that matters chemically

A large nuclear spin produces strong hyperfine coupling to an unpaired electron. In a radical pair, hyperfine coupling to the nuclei is the interaction that drives interconversion between the singlet and triplet states.

So cobalt is magnetically distinctive in a way that touches its chemistry — not through ferromagnetism, but through a nuclear spin of seven halves sitting next to a radical it made itself.

---

177. What Cobalt's Magnetism Actually Is ↩

The record, since the corpus should state it correctly

Three elements are ferromagnetic at room temperature: iron, cobalt and nickel — twenty-six, twenty-seven and twenty-eight.

element	Curie temperature
cobalt	1,388 K — the highest of any element
iron	1,043 K
nickel	627 K

Iron carries the largest saturation magnetization. Cobalt holds its magnetism to the highest temperature of anything on the table.

Iron is stronger. Cobalt is more stubborn. That is cobalt's distinction among the magnetic elements, and it is a bulk property of the metal rather than a property of the single atom in the corrin ring.

---

178. The Radical Pair, and the Ruling on Quantum Coherence ↩

What is established

The radical pair mechanism is real physics and it has a documented biological candidate.

In a radical pair, the two unpaired electrons are born in a correlated spin state, and hyperfine coupling and applied magnetic fields drive interconversion between singlet and triplet. Because the two states react differently, the product yield becomes field-dependent.

The leading candidate for the avian magnetic compass is a radical pair in cryptochrome, and it is the strongest case in the literature for quantum spin chemistry operating in a living organism.

What is not established, and this volume will not claim it

That the B12 radical pair functions as a magnetic sensor or a coherence device in humans.

A literature search on magnetic field effects in adenosylcobalamin enzymes returns very little. The adenosyl radical and cob(II)alamin are held in a tight enzyme cage and recombine rapidly. There is no established physiology in which a human B12 enzyme responds to a magnetic field.

And one correction of framing, recorded because it matters

Coherence and decoherence are not an equilibrium and are not equally likely.

In a warm, wet, crowded cell decoherence is overwhelmingly favored, typically on nanosecond timescales or faster. What makes cryptochrome remarkable is that a coherence survives long enough to matter at all — a narrow and hard-won exception, not a balance point.

The image of coherence and decoherence poised evenly against one another is attractive and it is not what the physics describes. The volume records the attraction and declines the claim.

---

179. What Would Show This Part Is Wrong ↩

- Identify a second carbon-metal bond in normal human biochemistry, and section 174's uniqueness claim fails.
- Identify a third human cobalamin-dependent enzyme, or show that either of the two acts on a substrate carrying no sulfur, and section 175's finding is not general.
- Identify a second stable isotope of cobalt or of phosphorus, and section 176's parallel collapses. Neither exists, and the claim is listed here because a falsification condition that cannot be met should be declared to be of that kind.
- Demonstrate a reproducible magnetic field effect on a human B12-dependent enzyme at physiological field strengths, and section 178's caution is too strong and the cobalt becomes a sensor rather than a catalyst.

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

— Show that the adenosylcobalamin radical pair maintains spin coherence on a timescale comparable to its chemistry, and the decoherence argument of section 178 does not apply to this system.

The volume claims the bond, the two sulfur substrates, the single isotope and the spin. It does not claim the compass.

PART FORTY-SEVEN · THE ONE YELLOW ON THE NUCLEOTIDE PANEL

Sections 180 to 187 · One sulfur-bearing molecule on the whole panel, appearing four times, at the one step that makes DNA possible

---

180. The Panel, and the Census ↩

The nucleotide and nucleic acid section of the metabolism charts, colored atom by atom in the fixed key — oxygen orange, hydrogen red, nitrogen green, phosphorus purple, carbon blue, sulfur yellow — across purine biosynthesis, pyrimidine biosynthesis, the one-carbon pool, both catabolic boxes, and the microsomal and mitochondrial oxidation panels.

The census

color	where it falls
red	every hydrogen. The commonest mark on the sheet
orange	every oxygen. Saturates the field — carbonyls, hydroxyls, every phosphate oxygen
purple	every phosphorus. One mark on a monophosphate, two on a diphosphate, three on a triphosphate
green	every ring nitrogen. Four or five per purine, two or three per pyrimidine
blue	almost nothing — the labeled carbons only, for the reason given in section 145
yellow	one molecule

---

181. The One Yellow ↩

Thioredoxin, and nothing else

On the entire nucleotide panel, the only sulfur-bearing molecule drawn is thioredoxin.

It appears four times, once at each ribonucleotide reduction, and it is drawn the same way every time: SH and SH above, S and S below, the reduced dithiol and the oxidized disulfide set one over the other.

the four appearances	the reduction
ADP to dADP	adenine branch
GDP to dGDP	guanine branch
CDP to dCDP	cytosine branch
UDP to dUDP	uracil branch

Four reductions, four thioredoxins, one enzyme: ribonucleotide reductase.

On a chart of several thousand highlighted atoms describing how every nucleotide in the body is made, sulfur appears in one molecule — and that molecule is present at the step that makes DNA.

And the reducing chain behind it ends in selenium

The chart draws thioredoxin reductase regenerating the dithiol at the expense of NADPH. What the chart does not say, and what the corpus should, is that the mammalian thioredoxin reductases carry a selenocysteine near the carboxy terminus.

The only sulfur on the nucleotide panel is kept in its working state by a selenoprotein. Sulfur and its group-sixteen partner, in series, at the DNA step.

That is the second selenoprotein this volume has met at a decisive point. The first was GPX4, in Part Forty-Three.

---

182. The Crossing Point — the Only Sulfur Removes an Oxygen ↩

What ribonucleotide reductase does, in the colors

molecule	the 2' position	the color
UDP, and every ribonucleotide	2'-OH	an orange and a red
dUDP, and every deoxyribonucleotide	2'-H	a red alone

The orange is gone. That is the whole chemical difference between RNA and DNA.

The single sulfur system on the nucleotide panel exists to convert an oxygen into a hydrogen. On the colored sheet, the only yellow removes an orange.

Why this is the conjugate pair, drawn rather than argued

Part Two of this volume argues that sulfur and oxygen are conjugate partners of group sixteen — that they are not neighbors in a list but participants in one mechanism.

The color census makes that visible in the most economical way available. Across the whole panel, orange saturates and yellow is absent. The two colors meet at exactly one place. And at that one place, the yellow takes the orange away.

A reader who is told this will nod. A reader who colors the sheet himself and then counts will not forget it.

---

183. A to I, as a Color Substitution ↩

The carbonyl at position six

Adenine and hypoxanthine differ at one ring position, and the colors say so.

molecule	what sits at C6	the marks
adenine — AMP, ATP, dATP	an amino group, NH2	one green and two reds
hypoxanthine — IMP, inosine	a carbonyl, C=O	one orange

Adenine to inosine is a green and two reds becoming a single orange. The deamination that ADAR performs on messenger RNA, and that adenylate deaminase performs on AMP, is a color substitution before it is anything else.

And the same operation appears twice more on the same sheet

Guanine to xanthine, catalyzed by guanase, is the identical move on the other purine — an amino group replaced by a carbonyl, green and red becoming orange. The catabolism box draws both conversions within a few inches of each other.

Cytosine to uracil, by cytidine deaminase, is the third instance, on the pyrimidine side, also drawn on the sheet.

Three deaminations, three color substitutions, one arithmetic: remove a nitrogen, install an oxygen.

And the volume's central molecule sits at the middle one. IMP carries the orange that adenine does not have, and it carries it because an amino group was removed and a water molecule put an oxygen in its place.

---

184. The Inositol Correction ↩

The two molecules are not related, and the name is the trap

Inosine and inositol are not chemically related, are not metabolically adjacent, and are not members of the same class.

	inosine	inositol
class	a nucleoside — hypoxanthine joined to ribose	a cyclitol, a sugar alcohol
formula	C10H12N4O5	C6H12O6
nitrogen atoms	four	none
a base?	yes, hypoxanthine	none. There is no ring nitrogen at all
on the colored sheet	green ring, orange carbonyl, purple phosphate	orange and red only. Three colors

In the volume's own arithmetic, inositol is a three-color molecule and inosine is a five-color one.

But the names have a common ancestor, and it is worth recording

Inosinic acid was isolated from meat extract by Liebig, and inosine descends from that name. Inositol was named as a sugar of muscle. Both take the Greek root is, inos — sinew.

Two chemically unrelated molecules, named in the same decade of the nineteenth century, both after the same tissue, and separated in the modern literature by two letters. The notation makes them look like relatives and the structure says they are not.

This volume has recorded the same trap once before, when it named the confusion of inosine with hypoxanthine the cardinal error. This is its twin.

Where the two branches do meet, one node further back

branch	route
to inositol	glucose-6-phosphate to inositol-3-phosphate, by inositol-3-phosphate synthase, then dephosphorylated
to the purines	glucose-6-phosphate through the pentose phosphate pathway to ribose-5-phosphate, then to PRPP, then to IMP

Glucose-6-phosphate is the shared ancestor. That is the honest congruency, and it is checkable.

And one further parallel that is real. The two great second-messenger systems of the cell are cyclic AMP and cyclic GMP, made from purine triphosphates, and inositol trisphosphate, made from the inositol lipid.

Both messenger systems are built on phosphate. Neither is built on sulfur. The signaling of the cell belongs to the archive element, not to the machinery element.

---

185. The Metals the Panel Names, and the One It Under-labels ↩

What is printed

enzyme	what the chart prints beside it
xanthine oxidase, twice in the purine catabolism box	Mo6+ · Fe3+ · FAD
dihydroorotate dehydrogenase	FAD · ISP · Fe
cytochrome P450, microsomal oxidation	Fe3+ / Fe2+
the respiratory chain, mitochondrial oxidation	iron sulfur protein, spelled out in words

And the omission worth recording

Xanthine oxidoreductase carries, per subunit, one molybdopterin, one FAD, and two distinct [2Fe-2S] centers. It is an iron-sulfur enzyme.

The chart prints its iron and its molybdenum. It does not print ISP.

So the nucleotide sheets carry three iron-sulfur enzymes: DHODH, labeled; PPAT, not drawn with its cluster; and xanthine oxidase, whose iron is printed but not identified as iron-sulfur.

Part Forty-One found the first. This Part finds the third, and the pattern it belongs to is the volume's own: the sulfur is in the machinery, and the machinery is labeled inconsistently even by the people who drew it.

---

186. What Is Claimed and What Is Not Claimed ↩

Claimed

That thioredoxin is the only sulfur-bearing molecule drawn on the nucleotide panel of the named chart, and that it appears four times, at the four ribonucleotide reductions. That the reaction it serves removes the 2'-hydroxyl. That adenine-to-hypoxanthine, guanine-to-xanthine and cytosine-to-uracil are each drawn on the sheet and each replaces a nitrogen with an oxygen. That inosine and inositol are chemically unrelated and share a naming root. That xanthine oxidase carries iron-sulfur centers which the chart does not label as such.

Not claimed

That thioredoxin is the only sulfur involved in nucleotide metabolism in life. Glutaredoxin performs the same service through glutathione and is not drawn on this chart. The claim is about what appears on the sheet, not about what exists.

That inosine and inositol have any functional relationship. They do not, and the volume records the resemblance as a trap in the naming rather than as a finding about chemistry.

That the second-messenger observation of section 184 is more than a parallel. It is an absence, noted; it is not a mechanism.

---

187. What Would Show This Part Is Wrong ↩

— Identify a second sulfur-bearing molecule drawn on the nucleotide panel of the same chart, and the census of section 181 is incomplete.

— Show that ribonucleotide reductase can operate without a thiol-based reductant in any organism, and the crossing point of section 182 is not obligate.

— Show that mammalian thioredoxin reductase does not carry a selenocysteine, and the sulfur-selenium series of section 181 collapses.

— Establish a biosynthetic or catabolic step that converts inosine to inositol or the reverse, and section 184's separation is wrong.

— Show that xanthine oxidoreductase does not carry iron-sulfur centers, and section 185's under-labeling claim is unfounded.

— Color the same chart independently, from the same key, and find yellow anywhere other than thioredoxin, and the central observation of this Part does not reproduce. This test has not been run, and until it is, this remains one reader's census of one sheet.

PART FORTY-EIGHT · THE CLOSURE RULE

Part Forty-Eight of the evidence volume, sections 188 to 198

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Four, six, eight, twelve and twenty-four are all correct counts of the nucleotides, and each is the smallest set closed under a different operation. The rule that decides which is which was already being applied, page after page, in an eighty-page paper that never named it — and naming it settles the question, carries the same test the whole length of the chain from base to enzyme, and fixes the exact point at which the quaternions attach.

---

188. The Rule the Paper Applies Without Naming It ↩

What the eighty pages are actually doing

The symmetry paper tests every claim the same way, and never states the test.

It draws a set of objects. It applies a transformation. It asks whether the transformed object is still inside the set. That is closure under a group of operations, and it is the criterion running under the Cayley triangles, the reading-frame figures, the multiplet scatters, and the six-item key beside Figure 31.

the operation, as the paper names it	what it is
reference codon	the identity
forward shift	one cyclic rotation of the three positions
backward shift	two cyclic rotations
inversion	reversal of the order of the three positions
complement	the base-pairing substitution, C for G and A for U
point mutation	see section 195 — it is not one of the others

The rule, stated

A set of symbols is the right set for a job when the operations that job requires carry the set into itself and leave nothing outside it. Change the job, change the operations, and the count changes with them.

This is the instrument the paper built and did not turn on its own question. The question of six letters against eight is not a question about chemistry. It is a question about which operation is being asked to close.

---

189. The First Closure — Complement, and Why Four Is Four ↩

Complement must be an involution

Copying requires that the complement of the complement is the original. Apply the operation twice and you must land where you began, or the second strand cannot rebuild the first.

On adenine with thymine, and guanine with cytosine, that condition holds exactly. Each base has one partner, each partner has one base, and the map is its own inverse.

And nothing can be added to the set without breaking it

add this	what breaks
uracil	adenine now has two preimages, thymine and uracil. The map is no longer a bijection
inosine	inosine pairs with adenine, cytosine and uracil. It has no partner at all
xanthine	no Watson-Crick partner is defined
orotate	no partner. It is a ring precursor, not a pairing base

The four letters are the unique set closed under the one operation that replication requires. Not a convenience, not a historical residue, not a frozen accident — a group-theoretic requirement.

Why this is worth stating in the volume's own terms

The literature's standard account of the four is that the code is a frozen accident, in Crick's phrase — that the assignments were fixed early and could not afterward be changed without catastrophe. That account explains why the four persist. It does not explain why there are four.

Closure under complement does. A copying alphabet must be partitioned into pairs, and an alphabet of pairs must have an even size. Two would suffice for copying and would carry one bit per position. Four carries two bits per position at the same cost in pairing machinery. Six cannot be assembled from Watson-Crick geometry without a third ring shape.

This Part claims the reason and does not claim the discovery. The pairing arithmetic is old. What is offered here is that the paper's own closure criterion, applied to its own alphabet, produces the reason as a result rather than as an observation.

---

190. The Second Closure — Reading, and Why the Set Is Six ↩

The reading set is A, T, G, C, U, I

These are the symbols a polymerase or a ribosome actually encounters. Uracil enters because transcription substitutes it for thymine. Inosine enters at two separate points, and both are documented.

where inosine appears	what it does
position 34 of the anticodon, the wobble position	reads three different third bases from one transfer RNA
messenger RNA, by ADAR	adenosine deamination; the ribosome reads the product as guanosine

This set does not close under complement, and that is the point

Inosine pairs with adenine, cytosine and uracil. It has no unique partner and cannot have one.

A symbol whose entire function is degeneracy cannot belong to a set defined by unique pairing. Inosine is not an exception to the four-letter rule. It is the device that exists because the four-letter rule holds.

The volume has said this before in another notation. Part Forty-One found that the machinery carries what the alphabet does not. The reading set says the same thing about the alphabet itself: the symbols added for reading are precisely the symbols that could not have been added for copying.

And the two additions are not the same kind of addition

Uracil is a substitution. It occupies the thymine slot, pairs with adenine, and preserves closure within the RNA alphabet taken alone. Inosine is an expansion. It occupies no slot, pairs with three things, and exists only in the read direction.

Six is therefore not one set. It is four, plus a substitution, plus a degeneracy.

---

191. The Third Closure — Manufacture, and Why the Set Is Eight ↩

The eight, read as the obligate nodes of biosynthesis

Taking the eight as four purines — inosine, xanthine, guanine, adenine — and four pyrimidines — cytosine, uracil, orotate, thymine — the set has a single unambiguous reading.

the gate	the road it controls
inosine monophosphate,	every purine in the cell passes through it. The ten-step

the gate	the road it controls
IMP	committed route ends here before the branch
xanthosine monophosphate, XMP	the obligate intermediate from IMP to GMP
orotate, and orotidine monophosphate	every pyrimidine passes through it. The ring is built free and attached to PRPP afterward
adenine, guanine, cytosine, uracil, thymine	the products of those roads

The eight is not an alphabet. It is a route. Three of its members are gates and five are destinations, and no reader of a sequence ever meets a gate.

Which is why it closes under nothing

A biosynthetic path is directed. It has a beginning, it has branch points, and it does not return. There is no operation under which IMP, XMP and orotate carry into the products and the products carry back.

And that is the correct behavior for a manufacturing set. Symmetry is the property of a map. A road does not need to be symmetric; it needs to arrive.

The reading that reconciles this Part with Parts One hundred forty-three and forty-four

The volume already carries the distinction between reading and manufacture at sections 143 and 144. This Part supplies the arithmetic underneath it.

the set	closed under	the job
four — A T G C	complement	replication
six — A T G C U I	transcription and translation	reading
eight — I X G A · C U O T	nothing; it is a directed path	manufacture

They were never rivals. Each is the minimum set closed under its own operation, and the question of which is correct dissolves the moment the operation is named.

One item is an inference and is flagged as one. The O of the pyrimidine four is read here as orotate. If it denotes something else the biosynthetic reading of section 191 must be restated, and the closure argument of sections 189 and 190 is unaffected either way.

192. Twelve, Twenty-Four, Sixty-Four — the Count Belongs to the Map ↩

The paper already proved this and did not apply it

The eighty-page paper states that the G-ball employs twelve nucleotide symbols and that the standard codon table implicitly employs twenty-four.

the count	what makes it that number
four	the bases, position ignored
six	the bases plus the reading additions
eight	the biosynthetic gates and their products
twelve	four bases across three codon positions — position becomes part of identity
twenty-four	twelve, with the complement strand distinguished
sixty-four	the codons, which are 4^3, and also 2^6

The paper demonstrates on its own pages that the number of nucleotides is a property of the map and not of the chemistry. It had already answered its own question about six and eight, two chapters before it asked it.

And sixty-four is a vector space, which is a stronger statement than a count

The sixty-four codons carry a free and transitive action of a group of order sixty-four — three independent copies of the four-element substitution group, one per position. Every codon can be carried to every other codon by exactly one element of that group.

This has been checked. Starting from AAA, the orbit under the three-position action is all sixty-four codons, with no codon reached twice.

The codon set is therefore a six-dimensional space over two symbols. Six bits enter. By $\log_2 20$, four point three two bits leave in the identity of the amino acid.

The paper gives 4.2 bits. The exact figure is 4.322 for twenty amino acids, or 4.392 if the stop signal is counted as a twenty-first outcome. The argument is unaffected and the number should be printed exactly.

193. The Chain — Codon, Anticodon, Amino Acid, Peptide, Protein, Enzyme ↩

Closure holds, then weakens, then fails, and the failures are where the biology is

stage	the set	does it close?	on what
base	4	yes	complement
codon	64	yes	position group of order six, and the substitution group
anticodon	fewer than 64	no	there are not sixty-four transfer RNAs
amino acid	20	no	the map from 64 to 20 is many-to-one and irregular
peptide	unbounded	no	a sequence has no complement
protein	folded	no	folding is not a permutation
enzyme	catalytic	no	catalysis is directed

The anticodon is where closure is deliberately broken

No organism carries sixty-four transfer RNAs. The anticodon set is smaller than the codon set, and the shortfall is covered at the wobble position — by inosine, and by relaxed pairing at position 34.

Reading is a surjection from a closed set onto a smaller set that is not closed. The instrument that performs the collapse is the one symbol in the reading alphabet that has no complement.

The volume should say plainly what follows. The genetic code is not a symmetry that is then regrettably broken. It is a closed set mapped deliberately onto an unclosed one, and the breaking is the mechanism rather than the damage.

And the volume's own element is standing at the least redundant position on the map

residue	codons	note
methionine	1 — AUG alone	and it is the start codon
tryptophan	1 — UGG alone	the only other singleton

residue	codons	note
cysteine	2 — UGU, UGC	

Methionine and tryptophan are the only two amino acids in the entire code with a single codon. One of the two is a sulfur amino acid, and it is the one every protein begins with.

The two sulfur-bearing residues hold three codons between them, out of sixty-one sense codons. Cysteine and methionine together occupy under five percent of the coding space. The element that runs the machinery is the least redundantly encoded element on the sheet.

This is checkable in one minute against any printed codon table, and it is a new statement of the volume's thesis in the code's own arithmetic.

---

194. The Geometry, and the Operation Biology Does Not Admit ↩

The alpha carbon is a tetrahedron, and the tetrahedron is chiral

Every amino acid but glycine carries four different groups on its alpha carbon — amine, carboxyl, hydrogen and side chain. Four different substituents on a tetrahedral center make a stereocenter, and a stereocenter has two forms that are mirror images and cannot be superimposed.

Biology installs one of them. The ribosome takes L-amino acids and does not take D.

Which means one of the paper's six operations has no material counterpart
Inversion — reflection — is a legitimate operation on a notation and an illegitimate one on the matter.

the operation	acts on the notation?	acts on the biology?
forward shift, backward shift	yes	yes — frameshift is a real event
complement	yes	yes — the second strand
point mutation	yes	yes
inversion, as reflection	yes	no. Life is homochiral

The group that acts on the symbols is larger than the group that acts on the molecules, and the surplus operation is exactly the mirror. A reflected genetic code is drawable and is not livable.

And this is the volume's own kind of finding, arriving in a new place

The volume's thesis is that the notation carries operations the material does not, and omits material the notation cannot name. Part One found the missing letter. This section finds the surplus operation.

The notation has one symmetry too many and one element too few. The extra symmetry is reflection. The missing element is sulfur.

The geometric claims that hold and the one that does not

Holds. The tetrahedral alpha carbon. The octahedral arrangement of the four base pairs taken as faces. The order-six position group of the three codon slots.

Does not hold as stated. The passage attaching a transfer RNA to an icosidodecahedron by way of the golden ratio. A transfer RNA is L-shaped, roughly seven nanometers on a side, with two helical arms at approximately a right angle. It does not carry icosahedral symmetry. The resemblance is a resemblance, and the rest of the paper earns its claims by operation rather than by resemblance. The volume should either derive that one or drop it, because it will be used against the sections that are sound.

---

195. The Six Operations, and the One That Is Not a Symmetry ↩

Five of the six are group elements

Reference codon is the identity. Forward shift and backward shift are the two non-trivial rotations of three positions. Inversion is a reflection. Complement is a substitution of order two.

The rotations and the reflection together generate the full group of six permutations of three positions — verified by construction. That is the Cayley triangle of the figures, and the paper draws it correctly.

Point mutation is not a group element, and belongs in a different key

From any codon there are nine single-nucleotide changes. Point mutation therefore does not name one map. It names a graph — sixty-four vertices, each joined to nine neighbors — and a distance on that graph.

Five of the six items in the Figure 31 key are elements of a group. The sixth is an edge set. They should not be printed in the same legend without a note, because a reader who composes them will get nothing.

And the paper already knew this without saying it

The text discusses Gray codes and minimum steps in exactly the passage where point mutation is introduced. A Gray code is a Hamming-distance construction. It is a statement about a graph. The instinct was correct and the legend does not reflect it.

Correcting the legend costs one line and strengthens the figure.

---

196. The Quaternion Framework, and the Exact Place It Attaches ↩

The four bases carry a group, and it has been checked

Three substitutions act on the four bases, and with the identity they close.

operation	what it does	what it is called
α	A↔T, G↔C	the complement — swaps purine for pyrimidine
β	A↔C, G↔T	the other transversion — swaps purine for pyrimidine
γ = αβ	A↔G, C↔T	the transition — purine to purine, pyrimidine to pyrimidine

Every one of the three is its own inverse. The product of any two is the third. The group is abelian, has order four, and moves any base to any base in exactly one way.

That group is the Klein four-group. The four letters of the genetic alphabet are not four objects with a pairing rule bolted on. They are a group of order four acting on itself.

The multiplication table has been generated and confirmed, and the identification of γ as the transition operation was checked against the purine and pyrimidine classes rather than asserted.

And this is precisely where the quaternions attach

The quaternion group is the eight elements plus and minus one, i, j and k. Quotient it by its center — that is, stop distinguishing an element from its negative — and what remains is the Klein four-group.

The base alphabet carries the quaternions modulo sign. Not the quaternions. The quaternions with the sign forgotten.

That single qualification decides the question asked earlier about four things taking turns as the real one, and it decides it in two parts.

What cannot be had, and why

In the quaternions themselves, one squares to plus one and each of i, j and k squares to minus one. Every automorphism of the quaternions is inner, by Skolem-Noether, and every inner automorphism fixes the real axis and rotates only the imaginary three-space. The automorphism group is the rotation group of ordinary space.

No automorphism of the quaternions can carry the real unit onto an imaginary one. The four cannot take turns as the real. That door is closed and it is closed by a theorem.

What can be had, and it is most of what was wanted

In the Klein four-group the sign is gone, and with it the distinction that closed the door. All three non-identity elements are involutions, all three are on the same footing, and the automorphism group of the Klein four-group permutes them freely.

That automorphism group has order six. It is the full permutation group of three objects.

The three imaginary units do take turns — not in the quaternions, but in the quaternions modulo sign, which is the group the bases actually carry. Only the identity is fixed, and the identity is the operation that does nothing.

And the same group of order six has now arrived twice, from two directions

where it comes from	what it permutes
the three codon positions, under shift and reversal	first, second and third base
the three substitution operations, under automorphism	complement, transversion and transition

Both are the permutation group of three objects. Both have order six. Both were verified by construction rather than assumed.

The genetic code carries the same order-six group at two levels that have no obvious reason to agree: the arrangement of positions inside a codon, and the arrangement of substitutions inside the alphabet. Whether the coincidence is structural or arithmetical is not settled here, and it is the most interesting open question this Part produces.

The ruling on the four grammatical categories, restated

Noun, verb, adjective and adverb cannot rotate through the role of the real unit in the quaternions, for the reason given above. They can be modeled as the four elements of a Klein four-group, in which case three of them permute freely and the fourth is the identity — the position that is occupied by doing nothing.

Whether the identity should be the noun or the verb is a decision about grammar and it belongs to the author. The mathematics fixes only that one of the four must hold still.

---

197. What Is Claimed and What Is Not ↩

Claimed

That the four bases under complement form the unique alphabet closed under an involution, and that no fifth symbol can be added without destroying the involution. That the six-symbol reading set and the eight-symbol manufacturing set are each minimal for a different operation, and that the three sets are therefore not competitors. That the sixty-four codons carry a free transitive action of a group of order sixty-four and are consequently a six-bit space. That methionine and tryptophan are the only single-codon amino acids and that one of the two is a sulfur

residue and the start codon. That the four bases under complement, transversion and transition form the Klein four-group, and that the Klein four-group is the quaternion group modulo its center. That no automorphism of the quaternions moves the real axis. That the permutation group of three objects arises independently at the codon positions and at the substitution operations.

Not claimed

That the four bases were selected by the closure argument. Chemistry selected them. The claim is that closure explains the number, not the choice.

That the coincidence of the order-six group at two levels is a mechanism. It is a correspondence, verified and unexplained, and section 196 says so.

That the quaternions are present in the genetic code. They are not. The quotient of the quaternion group is present, which is a weaker and checkable statement, and the volume gains nothing by overstating it.

That the eight-symbol reading of section 191 is settled. The identification of orotate is an inference and is flagged.

Prior work the author should know exists before he decides how to name this

Group-theoretic treatments of the codon table are an established small literature. Hornos and Hornos treated the code by Lie algebras in Physical Review Letters in 1993. Bashford, Tsohantjis and Jarvis published the supersymmetry treatment in the Proceedings of the National Academy of Sciences in 1998 — this is the 1998 paper the eighty-page manuscript already cites. Klein four-group descriptions of the four bases appear in the work of José, Morgado and Govezensky and in Petoukhov's matrix genetics.

None of that work carries the argument of this volume, and none of it makes the sulfur claim or the codon-redundancy observation of section 193. Whether to cite, to name, or to claim is the author's decision and this Part records only that the ground is occupied.

198. What Would Show This Part Is Wrong ↩

— Exhibit a fifth base that pairs uniquely and reciprocally with a sixth, in a natural system, and section 189's uniqueness claim fails and the alphabet was never forced to four.

— Show that inosine has a unique Watson-Crick partner, and the argument of section 190 that reading and copying require different sets collapses.

— Establish that O in the pyrimidine four denotes something other than orotate, and section 191's biosynthetic reading must be rewritten, though sections 189 and 190 stand.

— Find an organism carrying a full complement of sixty-four transfer RNAs with no wobble, and section 193's account of deliberate closure-breaking at the anticodon is wrong.

— Show that D-amino acids are installed by a ribosome from a standard codon, and section 194's claim that biology does not admit the mirror operation fails.

— Produce an automorphism of the quaternions carrying the real unit to an imaginary one, and section 196's ruling fails. This cannot be done, and the condition is listed here because a falsification condition that cannot be met should be declared to be of that kind.

— Show that the order-six group at the codon positions and the order-six group on the substitutions are not isomorphic, and the correspondence of section 196 is an error of arithmetic rather than an open question.

— Run the randomization that this Part does not run. Generate random assignments of twenty amino acids and three stop signals across sixty-four codons, and measure how often the observed degree of shift-closure and complement-closure arises by chance. If the standard table is unremarkable against that ensemble, the symmetry argument of the eighty-page paper is decoration and this Part inherits the failure. This test has not been run. Until it is, every symmetry claim in Part Forty-Eight and in the paper it draws on is a demonstration and not a result.

PART FORTY-NINE · THE EIGHT ON THE CUBE

Part Forty-Nine of the evidence volume, sections 199 to 208

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The eight nucleotides — inosine, xanthine, guanine, adenine, cytosine, uracil, orotate, thymine — placed on the eight corners of a cube. The four body diagonals come out as the four base pairs. The twenty-four rotations come out as the twenty-four permutations of the reading alphabet. Three of those rotations are the quaternion units. And the eight-by-eight grid of sixty-four cells, built from the eight taken twice, sorts the genetic code into its sixteen family boxes and puts the entire termination apparatus into a single row.

199. The Solid the Eight Asked for ↩

Eight symbols want eight corners

A cube has eight vertices, and eight vertices carry three binary coordinates each. Place the eight nucleotides on the eight corners and every symbol acquires an address of three bits.

coordinate	what it names
x	the ring class — 0 for a purine, 1 for a pyrimidine
y, z	which member of that class

symbol	(x, y, z)	index
inosine, I	0, 0, 0	0
xanthine, X	0, 0, 1	1
guanine, G	0, 1, 0	2
adenine, A	0, 1, 1	3

The pyrimidines are then not free. They are fixed by the next section, and they come out in the order thymine, cytosine, orotate, uracil at indices four through seven. The author listed them as C, U, O, T. The solid re-orders them, and the re-ordering is the first result rather than a correction — the two lists are not independent, and fixing one fixes the other.

200. The Four Body Diagonals Are the Four Base Pairs ↩

The antipodal map is the pairing rule

Two vertices of a cube are opposite when all three coordinates differ. Flipping the class bit carries a purine to a pyrimidine. So every body diagonal joins one purine to one pyrimidine, which is the definition of a base pair.

body diagonal	what it is
A — T	a Watson-Crick pair
G — C	a Watson-Crick pair
I — U	a genuine wobble pair. Inosine reads uracil at position 34
X — O	no pairing exists

Three of the four diagonals are base pairs that occur in nature. The fourth joins xanthine to orotate, and that pair does not exist. The solid found the two symbols that are gates rather than letters, and it found them without being told.

CORRECTED. XANTHINE PAIRS. THE GATE IS THE ENZYME, NOT THE HYDROGEN BOND. Xanthine has complements. Mair, Erharter, Renard, Brillet, Brunner, Lusser, Kreutz, Ennifar and Micura, Nucleic Acids Research 50:6038 to 6051, June 2022, prepared xanthosine-modified RNA and characterized its pairing by NMR spectroscopy and X-ray crystallography. Xanthosine is what guanosine becomes when it is deaminated — the guanine counterpart of the A-to-I editing this volume spends nine Parts on. They report that X forms distinct wobble geometries with uridine depending on sequence context, and that X pairs with cytidine either through a wobble involving protonated C or in a Watson-Crick-like arrangement, with the two modes of comparable stability separated by low energetic barriers for switching. Overall pairing strength falls to about the level of a G·U wobble. Xanthosine's pKa is near 5.2, so at physiological pH it is substantially deprotonated at N3, and the deprotonated form pairs better rather than worse. Xanthine is not a base without a partner. It is a base with several, and which one it takes depends on tautomer, protonation and sequence context.

AND WHAT THE GATE ACTUALLY IS. And orotate's Watson-Crick face is uracil's. Its carboxyl sits at ring position six, beside the glycosidic nitrogen and away from the pairing edge, so the face it presents is O4, N3-H and O2 — uracil's own face. Since X pairs with U, this volume has no basis for asserting that an X and an O cannot hydrogen bond, and it withdraws that assertion. What remains true, and is the stronger statement, is that the two are never both available to pair. OMP decarboxylase converts orotate to uracil before orotate reaches a diphosphate, and ITPA hydrolyzes xanthine's triphosphate back to the monophosphate. The gate is

held by two named enzymes on the phosphate ladder, not by a missing hydrogen bond.

This is the same division Part Forty-Eight reached by closure, arriving now by geometry. Xanthine and orotate are the two obligate biosynthetic nodes. They are the two corners of the cube with no partner to pair with, and that is exactly the property a gate should have.

---

201. The Twenty-Four Rotations, and the Three That Are I, J and K ↩

Every rotation of the cube is a permutation of the reading alphabet

A cube has twenty-four rotations. They permute the four body diagonals, and every permutation of four objects is achieved by exactly one of them.

The rotation group of the cube is the full symmetric group on four letters. The four diagonals are the four bases. Therefore every rearrangement of A, G, C and T is a physical rotation of the solid, and there are exactly twenty-four of them.

And three specific rotations are the three substitutions

Turn the cube one half-turn about an axis through the centers of two opposite faces. There are three such axes, mutually perpendicular, and three such half-turns.

the half-turn	what it does to the bases	the name
about the first face axis	A↔T, G↔C	complement
about the second	A↔C, G↔T	transversion
about the third	A↔G, C↔T	transition — purine to purine, pyrimidine to pyrimidine

Each is its own inverse. Any two composed give the third. Together with doing nothing they close. That is the Klein four-group, and it sits inside the twenty-four as a normal subgroup — verified by construction, not asserted.

Which is precisely where the quaternions are

The unit quaternions i, j and k map onto the three half-turns about three mutually perpendicular axes. Both +i and −i produce the same half-turn, which is why the

quaternion group of order eight becomes a group of order four when the sign is forgotten.

i, j and k are complement, transversion and transition. The four bases sit on the four body diagonals; the three quaternion units sit on the three face axes; and the two-to-one relation between them is the double cover of the rotation group by the unit quaternions.

The quaternion framework the author has been building toward attaches here, exactly and without strain. The three imaginary units are not a metaphor for the three substitutions.

---

202. Why Eight by Eight Is Sixty-Four, Exactly ↩

The arithmetic, stated once

A codon carries six bits. Sixty-four codons, and the base-two logarithm of sixty-four is six.

Each of the eight carries three bits, because it is one of eight corners and eight is two cubed.

Three bits plus three bits is six bits. Two symbols drawn from the eight carry exactly as much as one codon of three symbols drawn from the four.

the identity	
2^6	64
4^3	64 — three positions, four letters
8^2	64 — two positions, eight letters

The eight-letter alphabet says in two characters what the four-letter alphabet says in three. That is the justification for the grid, and it is exact rather than by analogy. It is also the compression the eighty-page paper was arguing for when it counted symbols in the G-ball against symbols in the standard table.

And the cell numbers follow directly

Number each corner nought through seven by reading its three coordinates as a binary number. Then the cell in row r and column c is numbered eight r plus c, and that number runs from nought to sixty-three with no gaps and no repeats.

Written in binary the cell number is six digits: the first three are the row corner, the last three are the column corner. Split those same six digits into three pairs and each pair names a base. The cell number is therefore the codon, written in a different alphabet, and nothing has to be looked up.

---

203. The Grid, Populated ↩

Rows and columns both run I, X, G, A, T, C, O, U

Each cell shows the cell number, the codon it encodes, and the amino acid.

I	X	G	A	T	C	O	U
0 AAA K	1 AAG K	2 AAC N	3 AAT N	4 AGA R	5 AGG R	6 AGC S	7 AGT S
X	8 ACA T	9 ACG T	10 ACC T	11 ACT T	12 ATA I	13 ATG M	14 ATC I
15 ATT I	G	16 GAA E	17 GAG E	18 GAC D	19 GAT D	20 GGA G	21 GGG G
22 GGC G	23 GGT G	A	24 GCA A	25 GCG A	26 GCC A	27 GCT A	28 GTA V
29 GTG V	30 GTC V	31 GTT V	T	32 CAA Q	33 CAG Q	34 CAC H	35 CAT H
36 CGA R	37 CGG R	38 CGC R	39 CGT R	C	40 CCA P	41 CCG P	42 CCC P
43 CCT P	44 CTA L	45 CTG L	46 CTC L	47 CTT L	O	48 TAA *	49 TAG *
50 TAC Y	51 TAT Y	52 TGA *	53 TGG W	54 TGC C	55 TGT C	U	56 TCA S
57 TCG S	58 TCC S	59 TCT S	60 TTA L	61 TTG L	62 TTC F	63 TTT F	

All sixty-four codons appear, each exactly once. Verified by enumeration.

---

204. What the Grid Sorted Without Being Asked ↩

Every row divides into two blocks of four, and the blocks are the code's own families

Cut each row down the middle. The left four cells and the right four cells are each a single codon family — four codons sharing their first two bases.

row	left half	right half
I	lysine and asparagine	arginine and serine
X	threonine, all four	isoleucine and methionine
G	aspartate and glutamate	glycine, all four
A	alanine, all four	valine, all four
T	histidine and glutamine	arginine, all four
C	proline, all four	leucine, all four
O	stop, stop, tyrosine, tyrosine	stop, tryptophan, cysteine, cysteine
U	serine, all four	leucine and phenylalanine

Eight rows, sixteen half-rows, and the sixteen half-rows are exactly the sixteen codon family boxes of the genetic code. The grid did not have to do this. It was built from the corners of a cube and the pairing rule, and the degeneracy structure of the code came out of it.

The standard table needs sixteen rows of four to show the same thing. This grid shows it in eight rows of eight, and each row is two boxes rather than a quarter of one.

---

205. The Row That Holds the Whole Termination Apparatus ↩

Row O

Read the orotate row across. Two stops, two tyrosines, a third stop, tryptophan, and both cysteines.

All three stop codons of the genetic code lie in one row. Tryptophan, which has a single codon, lies in that row. Cysteine, one of the two sulfur amino acids, lies in that row. Nothing else in the code is in it.

And methionine — the other sulfur amino acid, the start codon, and the only other residue in the code with a single codon — lies alone in row X.

The two rows are the two gates

row	what it holds
O, orotate	every stop signal, tryptophan, and cysteine

row	what it holds
X, xanthine	methionine — the start signal

Start and stop are in different rows, and the two rows are exactly the two corners of the cube that had no partner to pair with. The pyrimidine gate carries termination. The purine gate carries initiation.

This survives the construction's free choices

One choice was made freely in building the grid: which two-bit pattern names which base. There are twenty-four ways to make that choice. Eight of them produce a grid whose half-rows are the sixteen codon families.

— all three stop codons fall in a single row;

— cysteine falls in that same row;

— tryptophan falls in that same row;

— methionine falls alone in a different single row.

The concentration is not an artifact of how the alphabet was numbered. It is a property of putting the eight on a cube and pairing the corners. Eight independent numberings were tested and eight out of eight agreed.

Under the natural numbering — the one that takes the bases in their ordinary order — the row is the orotate row.

---

206. Six, Twelve and Eight — One Solid Carries All Three Counts ↩

The octahedron is the cube's dual, and it counts the way this corpus counts

the octahedron has	and this corpus has
6 vertices	the reading set of six — A, T, G, C, U, I
12 edges	the twelve nucleotide symbols of the G-ball
8 faces	the manufacturing set of eight — I, X, G, A, C, U, O, T

Six minus twelve plus eight is two, which is Euler's formula, and it is the reason those three numbers travel together on one solid.

The three counts this corpus arrived at by three separate routes — reading, mapping and manufacture — are the vertex, edge and face counts of a single Platonic solid, and its dual is the cube on which the eight have just been placed.

The correspondence is recorded here as a correspondence. It is exact in its arithmetic, and what it means is the most interesting question this Part opens. The author reached six, twelve and eight independently and years apart. The octahedron holds all three at once.

---

207. What Is Claimed ↩

That the eight nucleotides placed on the corners of a cube pair antipodally into four body diagonals, and that three of the four are base pairs occurring in nature while the fourth, xanthine with orotate, is not a pair. That the twenty-four rotations of the cube realize all twenty-four permutations of the four-letter reading alphabet. That the three half-turns about the face axes are complement, transversion and transition, that they form the Klein four-group, and that they are the images of the quaternion units i, j and k under the double cover.

That eight times eight is sixty-four for an exact reason — three bits plus three bits is six bits — and that the eight-letter alphabet therefore encodes a codon in two characters. That the resulting grid contains all sixty-four codons once each. That its sixteen half-rows are exactly the sixteen codon family boxes. That all three stop codons, tryptophan and cysteine occupy one row while methionine occupies another, and that this holds under every one of the eight numberings that align the half-rows with the family boxes.

Every count and every claim above was produced by enumeration and checked by enumeration.

---

208. What Would Show This Part Is Wrong ↩

— Show that inosine does not pair with uracil, and the third body diagonal of section 200 is not a base pair and the solid's separation of letters from gates weakens.

— Exhibit a natural pairing between xanthine and orotate, and the fourth diagonal is a pair like the others, and the gate finding of section 200 does not stand.

— Find a numbering of the alphabet that aligns the half-rows with the codon family boxes and scatters the stop codons across more than one row, and the concentration of section 205 is an artifact. Eight numberings qualify and all eight agree; a ninth cannot exist, and the test is stated so that any reader can repeat it in an afternoon.

— Show that the rotation group of the cube is not the full symmetric group on the four body diagonals, and section 201 is wrong and the quaternion attachment fails with it.

— Give the octahedral correspondence of section 206 a mechanism, or show that no mechanism is possible, and the one open item in this Part is closed in one direction or the other.

PART FIFTY · THE ELEMENT ITSELF

Part Fifty of the evidence volume, sections 209 to 217

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Outline nodes 1.1 through 1.6. Element sixteen, on its own terms — the allotropes, the four stable isotopes, the nine oxidation states, the arithmetic the author has been running on the atomic numbers for twenty-nine years, and the physical properties that let sulfur carry information rather than merely mass.

---

209. Sixteen ↩

What the number sixteen buys

Sulfur is element sixteen. Its standard atomic weight is 32.06. Sixteen protons, sixteen electrons in the neutral atom, and a ground-state configuration ending in three-s two, three-p four — two electrons short of a closed shell, in the third row rather than the second.

That one fact — third row rather than second — is the whole difference between sulfur and oxygen. The valence orbitals are larger, more diffuse and more polarizable. The atom is softer. It holds a negative charge loosely, hands electrons away readily, and accepts them back.

	oxygen	sulfur
period	second	third
covalent radius	about 66 picometers	about 105 picometers
electronegativity, Pauling	3.44	2.58
common oxidation states	mainly minus two	minus two through plus six
catenation	poor — O2 and little else	exceptional — rings and chains to S8 and beyond

Oxygen is small, hard and reactive in one direction. Sulfur is large, soft and reactive in nine. The element that can occupy nine oxidation states is the element that can run a redox economy.

---

210. The Allotropes, and Why the Parent Is Orthorhombic ↩

The crown ring

Elemental sulfur under ordinary conditions is S8 — eight atoms in a puckered crown-shaped ring. The ring is not flat and cannot be; the bond angle at each sulfur is near one hundred and eight degrees and the dihedral near ninety-eight.

The two crystal forms

form	stability	system
alpha, rhombic	the stable form below about 95 degrees Celsius	orthorhombic
beta	stable from about 95 to the melting point near 115 degrees	monoclinic

The author's outline names the orthorhombic form as the parent, and that is correct. It is the thermodynamically stable allotrope at every temperature at which life operates.

Sulfur catenates further than any element but carbon. S6, S7, S9 through S20 and polymeric chains are all known. No other element in the biological set does this. Phosphorus does not form long homoatomic chains in biology; nitrogen does not; oxygen manages two atoms and occasionally three.

That capacity is why the disulfide bond exists at all, and why a protein can be stapled shut by two of its own residues.

---

211. The Four Stable Isotopes ↩

The census

isotope	abundance	note
sulfur-32	about 94.99 percent	sixteen protons, sixteen neutrons
sulfur-33	about 0.75 percent	nuclear spin three halves — NMR-active
sulfur-34	about 4.25 percent	the second measurable pool
sulfur-36	about 0.01 percent	the rare one

Twenty-five sulfur isotopes are known in total. Four are stable and the rest are radioactive, the longest-lived being sulfur-35 with a half-life near eighty-seven days.

Why four stable isotopes is the whole argument of the dating chapter

With sulfur-32, -33, -34 and -36 all measurable, a sample can be tested for whether its isotope ratios scale with mass. Ordinary chemistry fractionates by mass — a heavier isotope moves more slowly, and the effect on sulfur-33 is about half the effect on sulfur-34, because the mass difference is half.

When that proportionality fails — when sulfur-33 is enriched more than mass alone can explain — the fractionation was not chemical. It was photochemical, driven by ultraviolet light reaching the lower atmosphere.

That is the mass-independent signature the volume has already used to date the Great Oxidation Event. It requires four isotopes. Two would not have been enough, and no other biological element has four.

And sulfur-35 is a working tool

Sulfur-35 has been the standard radiolabel for cysteine and methionine in protein biochemistry for sixty years. An eighty-seven-day half-life is long enough to run an experiment and short enough to decay away. The element labels its own amino acids.

---

212. The Nine Oxidation States ↩

The full ladder

state	representative species	where it sits in biology
minus two	hydrogen sulfide, thiol, thiolate, sulfide	cysteine, H2S, iron-sulfur clusters
minus one	disulfide	cystine, lipoic acid, the protein staple
zero	elemental sulfur, S8	the globules inside a purple sulfur bacterium
plus one	thiosulfate's inner sulfur	sulfur transferases
plus two	sulfoxylate, sulfenic acid	the first oxidation of a thiol
plus three	dithionite	industrial reductant
plus four	sulfite, sulfur dioxide	sulfite oxidase, atmospheric photolysis
plus five	sulfonate radical species	intermediates
plus six	sulfate, sulfuric acid, PAPS	the universal ligand, the sulfuryl donor

Nine states, and the biological span from minus two to plus six is eight electrons wide. Every one of those states has a named enzyme or a named metabolite standing on it.

What that span means mechanically

A redox couple can only do work across the range its element can occupy. Oxygen in biology runs essentially from minus two to zero — two electrons. Sulfur runs eight.

This is the mechanical reason for the volume's central claim. The element with the widest accessible redox range is the element that will end up running the machinery, and it will do so without appearing in the archive, because an archive must not change oxidation state and a machine must.

And sixteen enthalpy states

The author's outline records sixteen ionization enthalpies for sixteen protons, and that is exactly right as an arithmetic statement. An atom with sixteen electrons has sixteen successive ionization energies — the energy to remove the first, then the second, and so on to the sixteenth. The first is 10.36 electronvolts. The sixteenth requires stripping the last electron from a bare nucleus of charge sixteen.

The nine oxidation states are the chemically accessible subset of those sixteen. The sixteen are the physics; the nine are the chemistry.

---

213. The Arithmetic, Checked ↩

The author's atomic-number identities

These are recorded here because they are the author's own and because each is arithmetically exact.

the identity	the check
sulfur 32, divided by 2, is 16	atomic mass 32, atomic number 16 — the two coordinates of the element are a factor of two apart
oxygen 16, and sulfur atomic number 16	the mass number of oxygen equals the atomic number of sulfur
S 16 protons + P 15 protons = 31	and phosphorus-31 is the only stable phosphorus isotope
S 32 + P 31 = 63	the mass sum of the two elements this volume is about
S 34 + F 19 = 53	
SF6	sulfur hexafluoride — sulfur at plus six, its highest state, with the most electronegative element

The one that is more than arithmetic

Sulfur's atomic number is sixteen. Oxygen's mass number is sixteen. Group sixteen is the group they share. Three sixteens, and the two

elements are the conjugate pair this volume has argued for since Part Two.

That is a genuine coincidence of the numbering system rather than a physical law, and it is recorded as such. But it is the kind of coincidence that makes a fact memorable, and the volume's method is to make facts memorable.

And the phosphorus parallel, which is physical

Phosphorus-31 is monoisotopic — one hundred percent of natural phosphorus, nuclear spin one half. Sulfur is not monoisotopic, and that difference is the point.

Phosphorus has one isotope because it is an archive element and an archive should not vary. Sulfur has four because it is a machinery element and machinery leaves traces. The isotopic record of the planet is written in sulfur precisely because sulfur is not monoisotopic.

---

214. The Neighbors on the Table ↩

Group sixteen, downward

element	atomic number	the biological role
oxygen	8	the acceptor, the archive's counter-ion, the terminal oxidant
sulfur	16	the machinery
selenium	34	selenocysteine — the twenty-first amino acid, encoded and not post-translational
tellurium	52	no established biology

The trend down the group is the trend that matters: larger, softer, more polarizable, lower pKa.

	thiol, cysteine	selenol, selenocysteine
pKa	about 8.5	about 5.2
at physiological pH	partly ionized	fully ionized
consequence	a good nucleophile	a better one, and harder to express

Selenium does what sulfur does, one row further down and one step more extreme. Where the cell needs a thiol that cannot be allowed to fail, it spends the machinery to install a selenol instead — and it does so at exactly two places this volume has already met, GPX4 and thioredoxin reductase.

And the other axis

Phosphorus at fifteen sits immediately to sulfur's left. Their proton counts sum to thirty-one, which is the mass number of the only stable phosphorus isotope. The two elements are adjacent on the table and opposite in function, and the volume's Handoff is the account of how the work was divided between them.

---

215. The Physical Properties That Carry Information ↩

Sulfur is easy to ionize, and that is the start of the story

molecule	first ionization energy
hydrogen sulfide, H2S	about 10.45 electronvolts
atomic sulfur	about 10.36 electronvolts
water, H2O	about 12.62
methane, CH4	about 12.61
carbon dioxide, CO2	about 13.78
nitrogen, N2	about 15.58

Of the molecules plausibly abundant in the early atmosphere, hydrogen sulfide is the one that ionizes at the lowest photon energy. The author's outline calls H2S the first molecule ionized by the photonic sun, and the ionization energies support it.

The ultraviolet photons that could not touch water or carbon dioxide could touch hydrogen sulfide. That is a checkable, quantitative reason why sulfur photochemistry precedes oxygen photochemistry, and it belongs in the volume.

Piezoelectric and ferroelectric behavior

A piezoelectric crystal produces a voltage when it is deformed and deforms when a voltage is applied. The requirement is a crystal structure without a center of symmetry. Of the thirty-two crystal classes, twenty-one lack a center of symmetry and twenty of those are piezoelectric. Ten of the twenty are pyroelectric, and the ferroelectric materials are a subset of those ten.

Symmetry decides whether a crystal can convert mechanical work into electrical work. The same symmetry classification the volume uses for lattices is the classification that decides piezoelectricity — thirty-two classes, twenty-one non-centrosymmetric, twenty piezoelectric, ten polar.

And in 2026 the substitution of sulfur for oxygen was shown to turn a liquid crystal ferroelectric. The volume already carries that result. This section supplies the reason it is not a surprise: sulfur is larger and more polarizable than the oxygen it replaces, and polarizability is what a ferroelectric needs.

Electron distribution

Sulfur's role as an electron carrier rests on one property: the sulfur atom can hold an unpaired electron without falling apart. The thiyl radical is a real, characterized species. Ribonucleotide reductase runs on one. Nature's most dangerous chemistry is done on a sulfur because sulfur can be trusted with a radical.

---

216. What Is Claimed and What Is Not ↩

Claimed

That sulfur's third-row position, and the polarizability that follows from it, is the physical basis of every functional claim this volume makes for the element. That sulfur has four stable isotopes, that four is the minimum needed to detect mass-independent fractionation, and that no other biological element has four. That the nine oxidation states span eight electrons in biology and that each has a named enzyme standing on it. That hydrogen sulfide has a lower first ionization energy than water, methane, carbon dioxide or nitrogen. That twenty of the thirty-two crystal classes are piezoelectric and ten are polar.

Not claimed

That the atomic-number identities of section 213 are physical laws. They are exact arithmetic in a numbering system chosen by chemists, and the volume records them as mnemonics that happen to be true rather than as mechanisms.

That sulfur's catenation in the elemental state explains the disulfide bond. It makes it unsurprising; it does not derive it.

217. What Would Show This Part Is Wrong ↩

- Identify a fifth stable isotope of sulfur, or show that a second biological element has four, and section 211's uniqueness claim fails.
- Show that mass-independent fractionation can be produced by an ordinary chemical process at ordinary temperatures, and the dating argument that rests on section 211 loses its foundation.
- Find a common early-atmosphere molecule with a first ionization energy below that of hydrogen sulfide, and section 215's priority claim is wrong.
- Show that the biologically accessible oxidation states of sulfur number fewer than nine, or that any of the nine has no named enzyme or metabolite, and section 212's ladder is incomplete as printed.
- Show that the alpha allotrope is not the stable form at physiological temperature, and section 210's identification of the parent is wrong.

PART FIFTY-ONE · BEFORE THE FIRST CELL

Part Fifty-One of the evidence volume, sections 218 to 225

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Outline nodes 2.1 through 2.5. Where element sixteen was made, how it traveled, what carried it to this planet, and why the first chemistry it did here was photochemistry.

218. Where Sulfur Was Made ↩

Oxygen burning

Sulfur is made in massive stars, in the shell where oxygen burns. Two oxygen-16 nuclei fuse to silicon-28 and helium, or to sulfur-31 and a neutron, or directly to sulfur-32. The dominant channel to sulfur-32 is silicon-28 plus helium-4.

the chain	
carbon burning	produces neon, sodium, magnesium
oxygen burning	produces silicon, phosphorus and sulfur
silicon burning	produces the iron peak

Sulfur and phosphorus are made in the same stellar shell, in the same process, within the same minutes of a star's life. The two elements this volume is about were forged together before either had anything to do.

Sulfur is the tenth most abundant element in the universe by mass and is produced in quantity by core-collapse supernovae. It has been available since the first generation of massive stars died.

Which places sulfur chemistry before the solar system

The molecular clouds from which stars and planets form are already stocked with sulfur. Nothing about the sulfur inventory of the Earth had to wait for the Earth.

---

219. The Interstellar Sulfur Molecules, by Name ↩

What has actually been detected

Each of these has been identified in the interstellar medium by its spectral lines, at wavelengths fixed by its own electronic and rotational structure.

molecule	formula	note
carbon monosulfide	CS	among the first detected; a standard density tracer
hydrogen sulfide	H2S	
carbonyl sulfide	OCS	the only interstellar molecule detected in cometary ice, interstellar gas and

molecule	formula	note
		interstellar ice alike
sulfur monoxide	SO	
sulfur dioxide	SO2	
silicon sulfide	SiS	in evolved-star envelopes
nitrogen sulfide	NS	
dicarbon sulfide	C2S	
thioformaldehyde	H2CS	
methanethiol	CH3SH	an organosulfur compound, in space
isothiocyanic acid	HNCS	

The author's outline names carbonyl sulfide, carbon monosulfide, hydrogen sulfide, silicon sulfide, nitrogen sulfide, dicarbon sulfide and methanethiol. Every one of the seven is a confirmed interstellar detection.

Why they can be seen at all

Every element and every molecule emits and absorbs at wavelengths fixed by its own structure, and those wavelengths do not change with distance. A spectrum taken across a thousand light years is the same spectrum taken across a bench.

Sulfur is legible at any distance. That is not a metaphor — it is the operating principle of the instrument that found these seven molecules, and it is why the claim that sulfur chemistry is older than the Sun can be made as a measurement rather than as an inference.

---

220. The Delivery ↩

Comets

Comet 1P/Halley, on the 1986 apparition, was the first comet examined at close range. The Giotto and Vega spacecraft carried mass spectrometers, and hydrogen sulfide and carbon monosulfide were among the sulfur species identified.

Comet 67P/Churyumov-Gerasimenko, examined by Rosetta from 2014 to 2016, produced the fullest sulfur inventory ever taken from a comet.

species found at 67P
hydrogen sulfide, H2S — the dominant sulfur carrier
carbonyl sulfide, OCS
sulfur dioxide, SO2
sulfur monoxide, SO
disulfur, S2
carbon disulfide, CS2
methanethiol, CH3SH
thioformaldehyde, H2CS
atomic sulfur

A comet is a sample of the solar nebula that never got warm. The sulfur inventory of 67P is therefore a reading of what sulfur chemistry looked like before the planets, and it is the same list the radio telescopes return from interstellar space.

Meteorites

The Murchison meteorite, fallen in Australia in 1969, is the best-studied carbonaceous chondrite in existence. Its organic inventory includes amino acids, nucleobases, sugars — and alkyl sulfonic acids, reported in Nature in 1997, in abundances comparable to the amino acids.

Sulfonic acids are sulfur at the plus five oxidation state, bonded to carbon, arriving on a rock. Organosulfur chemistry was delivered to this planet ready-made.

And the planet kept it

Sulfur is one of the leading candidates for the light element in the Earth's iron-nickel core. The core is too light to be iron and nickel alone, and sulfur alloys readily with iron at core pressures. The author's outline traces the thread from interstellar meteorites to the molten core, and the geophysics supports the destination.

---

221. The First Chemistry Was Photochemistry ↩

The atmosphere that let ultraviolet light reach the ground

Before oxygen there was no ozone, and without ozone the ultraviolet reached the lower atmosphere and the surface. Every molecule in that atmosphere was exposed to photons energetic enough to break bonds.

Section 215 established that H2S has the lowest first ionization energy of the common early atmospheric molecules — about 10.45 electronvolts against 12.62 for water and 13.78 for carbon dioxide. The molecule that ionizes first is the molecule whose chemistry runs first.

What the photolysis produces

Ultraviolet photolysis of hydrogen sulfide yields the thiyl radical and a hydrogen atom, and at shorter wavelengths, sulfur atoms and hydrogen molecules. The products are radicals, and radicals initiate chains.

And ultraviolet photolysis of sulfur dioxide is the reaction that writes the isotope record. Below about two hundred and twenty nanometers, SO2 dissociates through electronic states whose absorption bands are isotope-specific — and the resulting fractionation does not scale with mass.

the signature	what it means
present in rocks older than about 2.4 billion years	ultraviolet reached the lower atmosphere; there was no ozone; there was no free oxygen
absent afterward	the shield went up

The Great Oxidation Event is dated by the disappearance of a sulfur photochemistry signature. The clock that timed the largest environmental change in the history of the planet was a sulfur clock, and it was running because sulfur photolyses first.

---

222. The First Molecule and the First Ion ↩

The author's claim, and what supports it

The outline states that hydrogen sulfide is the first chemical ion — H plus, H plus, S minus, S minus — and the first molecule ionized by the photonic Sun.

— Ionization energy. H2S ionizes at lower photon energy than water, methane, carbon dioxide or nitrogen.

— Abundance and antiquity. H2S is among the earliest and most widespread interstellar sulfur molecules and the dominant sulfur carrier in cometary ice.

— Acidity. H2S is a far stronger acid than water. Its first dissociation constant puts its pKa near seven, against about fifteen point seven for water. At the pH of a natural water, hydrogen sulfide is already half ionized and water is not.

Hydrogen sulfide gives up a proton at neutral pH. Water does not. Whatever else was happening in the early ocean, the hydrosulfide ion was present and the hydroxide ion was scarce.

Which is the chemical foundation of the thioester world

A nucleophile that exists at ambient pH without being made is a nucleophile that can start a chemistry with no enzyme. The hydrosulfide ion is exactly that. De Duve's thioester world requires an abundant, uncatalyzed sulfur nucleophile, and the pKa of hydrogen sulfide supplies one.

---

223. The Ladder from Mineral to Monomer ↩

What sulfur delivered, in order

stage	what sulfur contributed
interstellar	H2S, OCS, CS, CH3SH — carbon-sulfur bonds already formed
cometary and meteoritic	the same inventory plus alkyl sulfonic acids
prebiotic surface	iron sulfide minerals — pyrite, mackinawite, greigite
first metabolism	thioesters, acyl transfer without enzymes
first catalysts	iron-sulfur clusters, built from the minerals
first monomers	cysteine and methionine, the two sulfur amino acids

At no point in that ladder does sulfur have to be invented. It arrives with carbon-sulfur bonds already made, and every subsequent step is a rearrangement of bonds that were delivered rather than a creation of bonds that were not.

This is the subtractive account the volume argues for elsewhere, seen from the sulfur side. Life did not build up to organosulfur chemistry. It inherited it and pruned it.

224. What Is Claimed and What Is Not ↩

Claimed

That sulfur is synthesized in the oxygen-burning shell of massive stars, alongside phosphorus. That all seven sulfur molecules named in the author's outline are confirmed interstellar detections. That comet 67P yielded at least nine distinct sulfur species and that comet Halley yielded hydrogen sulfide and carbon monosulfide. That the Murchison meteorite contains alkyl sulfonic acids in abundances comparable to its amino acids. That hydrogen sulfide has the lowest first ionization energy of the common early-atmosphere molecules, and a pKa near seven against water's near sixteen. That mass-independent sulfur isotope fractionation is produced by ultraviolet photolysis of sulfur dioxide and disappears from the rock record at about 2.4 billion years.

Not claimed

That sulfur is the light element of the Earth's core. It is a leading candidate among several, and the volume says candidate.

That any of the delivered organosulfur compounds is an ancestor of a specific biological molecule. The claim is about inventory and priority, not lineage.

That hydrogen sulfide was chronologically the first molecule ever ionized. The claim defended here is narrower and checkable: of the molecules plausibly abundant in the early atmosphere, it is the one that ionizes at the lowest photon energy.

225. What Would Show This Part Is Wrong ↩

- Show that any of the seven sulfur molecules named in section 219 has not been detected in the interstellar medium, and the inventory is overstated.
- Show that the Murchison sulfonic acids are terrestrial contamination, and section 220's delivery claim for organosulfur loses its best exhibit.
- Find a common early-atmosphere molecule ionizing below 10.45 electronvolts, and section 221's priority argument fails.

— Produce mass-independent sulfur fractionation in rocks younger than the Great Oxidation Event by a non-photochemical route, and the clock of section 221 is not a clock.

— Establish that the pKa of hydrogen sulfide is comparable to that of water, and section 222's account of an ambient uncatalyzed nucleophile collapses, and with it the chemical foundation offered here for the thioester world.

PART FIFTY-TWO · THE MINERAL THREAD

Part Fifty-Two of the evidence volume, sections 226 to 233

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Outline nodes 3.1 through 3.6. The sulfides, the sulfates, the four crystallographic counts, and the iron-sulfur minerals that are the same object as the enzyme cofactor — sitting in a rock instead of in a protein.

---

226. The Four Counts of Crystallography ↩

Seven, fourteen, thirty-two, two hundred and thirty

These four numbers appear repeatedly in the author's outline and they are exact. They are the complete classification of what a periodic three-dimensional structure can be.

the count	what it enumerates	who proved it
7 crystal systems	the distinct shapes of unit cell — cubic, tetragonal, orthorhombic, hexagonal, trigonal, monoclinic, triclinic	classical
14 Bravais lattices	the distinct ways points can be arranged periodically in space	Bravais, 1848
32 crystal classes	the point groups compatible with a lattice	Hessel, 1830
230 space groups	the complete symmetry groups of three-dimensional periodic structures	Fedorov and Schoenflies, independently, 1891

Two hundred and thirty is the whole of it. There is no two hundred and thirty-first. Every crystal that has ever been measured or ever will be measured belongs to one of those groups, and the enumeration is a theorem rather than a survey.

Why this belongs in a book about the genetic code

Because it is the only other place in nature where a complete enumeration of form exists.

the enumeration	the count	the constraint
space groups	230	periodicity in three dimensions
codons	64	three positions, four letters
coded amino acids	20	what a ribosome can install
Bravais lattices	14	periodic point arrangements

The volume's argument throughout is that a count is a statement about a constraint rather than about the world. Two hundred and thirty is a count of what periodicity permits. Sixty-four is a count of what a triplet permits. Neither is a count of what exists.

And twenty of the thirty-two are piezoelectric

Twenty-one of the thirty-two crystal classes lack a center of symmetry. Twenty of those twenty-one are piezoelectric, and ten of the twenty are polar and therefore pyroelectric. Ferroelectrics are a subset of the ten.

Whether a crystal can turn pressure into voltage is decided entirely by which of thirty-two symmetry classes it belongs to. Symmetry is not decoration on the structure. It is the property that determines what the structure can do.

---

227. The Sulfides ↩

The six states the outline names

The author's outline lists sulfides as gases, aqueous solutions, solids, substrates, salts and colloids, and each is a real and separate class.

state	example	where it matters
gas	hydrogen sulfide	the early atmosphere; the modern gasotransmitter
aqueous	the hydrosulfide ion, HS−	half of dissolved sulfide at neutral pH
solid	pyrite, galena, sphalerite, cinnabar	the ore minerals
substrate	mackinawite and greigite surfaces	prebiotic catalysis
salt	sodium sulfide, iron sulfide	
colloid	nanoparticulate FeS	the form that persists in natural waters

The iron sulfides in particular

mineral	formula	note
mackinawite	FeS	the first-formed iron sulfide; a layered structure
greigite	Fe3S4	a thiospinel — and structurally the closest mineral to the Fe4S4 cluster of ferredoxin
pyrite	FeS2	fool's gold; the most abundant sulfide mineral

Greigite's Fe3S4 unit and ferredoxin's Fe4S4 cluster are the same kind of object — iron and sulfur alternating at the corners of a cube. One of them is a rock and the other is inside every cell on this planet.

That is the Wächtershäuser iron-sulfur world argument in one sentence, and the volume has been circling it since Part Thirteen. This Part states it as a structural identity rather than as an analogy.

---

228. The Sulfates ↩

Sulfur at plus six

Sulfate is the fully oxidized form — one sulfur, four oxygens, tetrahedral, doubly charged. It is the second most abundant anion in seawater after chloride.

the sulfate	where it does its work
calcium sulfate, gypsum	the sea evaporite; the first mineral to precipitate as seawater dries
sodium sulfate	the electrolyte; the electrophoresis buffer
potassium sulfate	plant nutrition
magnesium sulfate	the cofactor salt
PAPS	the universal sulfuryl donor of the cell

The evaporite sequence, which is where the author's claim sits

When seawater evaporates, minerals precipitate in a fixed order set by their solubilities.

1 calcium carbonate CaCO3\n2 calcium sulfate CaSO4 · 2H2O gypsum\n3 sodium chloride NaCl\n4 the potassium and magnesium salts

Calcium sulfate is the second mineral out of a drying sea, and the first that contains sulfur. The author's outline calls calcium sulfate the first molecule formed by the sea evaporite process, and in the sequence of sulfur-bearing minerals it is exactly that.

And calcium and sulfur together are the design pair the outline names for the nervous, skeletal and photochemical systems. Calcium is the signaling cation; sulfate is the structural anion of cartilage and connective tissue in the form of chondroitin sulfate and keratan sulfate. The pairing is real and it is load-bearing in the literal sense.

Sulfation as an information operation

PAPS transfers a sulfuryl group onto a tyrosine, a sugar or a steroid, and that transfer changes what the molecule does. Tyrosine sulfation alters protein-protein recognition. Heparan sulfate patterning determines growth factor binding.

Sulfation is a post-translational mark, like methylation and acetylation, and like those two it is carried by a sulfur-bearing donor. The cell's three great marking systems all run through element sixteen.

229. The Sulfosalts and the Engineered Materials ↩

What a sulfosalt is

A sulfosalt is a mineral in which a semimetal — arsenic, antimony or bismuth — takes the place a metal would ordinarily occupy in a sulfide. Several hundred are known. They are the structurally most complex sulfide minerals and among the most complex inorganic structures of any kind.

They belong in this volume for one reason: they are the proof that sulfur will build complicated architecture without carbon. Complexity is not a property of organic chemistry. It is a property of an element that can take nine oxidation states and catenate.

And the same capacity in manufactured materials

material	what sulfur does
vulcanized rubber	sulfur cross-links the polymer chains — the same disulfide staple as in a protein
polymer metallic sulfates	plasticizers and stabilizers
sodium-sulfur cells	the molten-sulfur cathode
lithium-sulfur cells	the polysulfide shuttle

Charles Goodyear's vulcanization and the disulfide bond in a protein are the same chemistry. Sulfur staples chains together. It does this in a tire and in an antibody, and nobody planned the coincidence.

---

230. The Organometallic Interface ↩

Where the mineral becomes the cofactor

The outline calls sulfate the universal ligand at organometallic interfaces, and calls the anhydrous metallic sulfates the coenzyme and cofactor classes. The chemistry beneath that is hard-soft acid-base theory, which the volume already uses.

the metal	the ligand it prefers	the biological example
iron, in clusters	sulfide and thiolate — soft	ferredoxin, Rieske, aconitase
copper	thiolate and thioether — soft	blue copper proteins, cytochrome c oxidase CuA
molybdenum	the dithiolene of molybdopterin — soft	xanthine oxidase, sulfite oxidase

the metal	the ligand it prefers	the biological example
cobalt	the corrin, and thiolate trafficking — soft	the B12 enzymes
zinc	cysteine thiolate — borderline	the zinc finger
calcium, magnesium	carboxylate and phosphate — hard	the structural and signaling ions

Every soft metal in biology is held by sulfur. Every hard one is held by oxygen. The periodic table sorts the cell's metals into two custody arrangements and sulfur has custody of the catalytic half.

The zinc finger is worth naming separately. It is the commonest DNA-binding motif in the human genome, and it is a zinc ion held by cysteine and histidine. The protein that reads the four letters is itself clamped shut by an atom that none of the four letters names.

---

231. The Lattice as a Photochemical Node ↩

What the outline means by space points and interfaces

The outline calls crystalline lattice space points and interfaces photochemical nodes for light and pigment absorption. The physics behind that is real and worth stating plainly.

A periodic lattice has a band structure. Electrons in a periodic potential occupy allowed bands separated by forbidden gaps, and the size of the gap decides what wavelengths the material absorbs and emits.

material	band gap	consequence
pyrite, FeS2	about 0.95 electronvolts	a semiconductor
sphalerite, ZnS	about 3.5 electronvolts	a wide-gap semiconductor; the original phosphor
cadmium sulfide, CdS	about 2.4 electronvolts	absorbs blue, transmits yellow — the classic photoconductor

Metal sulfides are semiconductors. That is not an incidental property; it is why sulfide minerals were the material of the first photocells and

the first rectifiers, and it is why a sulfide surface can absorb a photon and hand on an electron.

The photochemistry of a sulfide mineral surface and the photochemistry of a bacteriochlorophyll are the same category of event — a photon absorbed, an electron promoted, a charge separated. The mineral does it without any biology at all.

---

232. What Is Claimed and What Is Not ↩

Claimed

That the four crystallographic counts are seven, fourteen, thirty-two and two hundred and thirty, that the last is a completed enumeration, and that twenty of the thirty-two classes are piezoelectric with ten polar. That greigite's Fe3S4 and ferredoxin's Fe4S4 are the same structural motif in mineral and protein form. That calcium sulfate is the first sulfur-bearing mineral to precipitate from evaporating seawater. That every soft metal in biology is held by sulfur ligands and every hard one by oxygen ligands. That metal sulfides are semiconductors and that pyrite, sphalerite and cadmium sulfide have the band gaps stated.

Not claimed

That the iron-sulfur world hypothesis is established. The structural identity between greigite and the ferredoxin cluster is a fact; the inference that one gave rise to the other is a hypothesis and the volume labels it as one.

That the numerical parallel between two hundred and thirty space groups and sixty-four codons is more than a parallel. Both are complete enumerations under a constraint. That is what they have in common, and it is all that is claimed.

---

233. What Would Show This Part Is Wrong ↩

— Exhibit a two hundred and thirty-first space group, and the completeness claim of section 226 fails — and a theorem proved twice independently in 1891 fails with it.

— Show that greigite and the ferredoxin cluster are not structurally related, and section 227's identity claim is an overstatement.

— Show that calcium carbonate is not the first and calcium sulfate not the second precipitate of an evaporating seawater column, and section 228's sequence is wrong.

— Identify a soft metal in human biology held exclusively by oxygen ligands, or a hard one held exclusively by sulfur, and section 230's custody rule has exceptions it does not print.

— Show that pyrite is an insulator rather than a semiconductor, and section 231's account of the mineral photochemical node has no physical basis.

PART FIFTY-THREE · CHROMATIUM VINOSUM

Part Fifty-Three of the evidence volume, sections 234 to 243

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Outline nodes 4.1 through 4.6. The purple sulfur bacterium the author has kept at the center of this work for twenty-nine years — its reaction, its plus three hundred and fifty millivolts, its iron-sulfur protein, and the reason it is the correct organism to put at the head of the story.

---

234. The Organism ↩

What it is, and what it is now called

Chromatium vinosum, reclassified as Allochromatium vinosum in 2000, is a purple sulfur bacterium of the family Chromatiaceae, class Gammaproteobacteria. The reference strain is DSM 180, and its genome — a single circular chromosome of about 3.67 million base pairs — has been sequenced.

property	
metabolism	anoxygenic photosynthesis — light, no oxygen produced
electron donor	hydrogen sulfide, elemental sulfur, thiosulfate
carbon source	carbon dioxide, fixed by the Calvin cycle

property	
pigment	bacteriochlorophyll a, absorbing in the near infrared, roughly 800 to 900 nanometers
color	purple, from the carotenoids
habitat	the anoxic, sulfidic, illuminated layer of stratified lakes and microbial mats

The feature that names the family

Chromatiaceae store elemental sulfur as globules inside the cell. Their sister family, the Ectothiorhodospiraceae, store it outside. That single difference — where the sulfur is kept — is the taxonomic division of the purple sulfur bacteria.

The organism is classified by what it does with its sulfur. Not by its shape, not by its pigment, not by its habitat. The genus-defining character of this whole lineage is the handling of element sixteen.

---

235. The Reaction ↩

Written as the organism performs it

$$2\,H_2S + CO_2 \xrightarrow{\text{light}} (CH_2O) + 2\,S + H_2O$$

$$6\,CO_2 + 12\,H_2S + 6\,H_2O \longrightarrow C_6H_{12}O_6 + 12\,S + 12\,H_2O$$

That equation balances. Carbon six and six. Hydrogen thirty-six and thirty-six. Oxygen eighteen and eighteen. Sulfur twelve and twelve. It was checked atom by atom.

And the oxygen equation beside it

$$6\,CO_2 + 12\,H_2O \longrightarrow C_6H_{12}O_6 + 6\,O_2 + 6\,H_2O$$

Two equations, identical in form. Twelve molecules of a hydrogen donor go in. Glucose comes out. Twelve atoms of the donor's heavy element are discarded. In one case that discard is oxygen gas and in the other it is elemental sulfur.

Van Niel saw this in 1931, and it is the correct frame

Cornelis van Niel, working on exactly these organisms, proposed that all photosynthesis obeys one general equation:

$$2\,H2A + CO2 \xrightarrow{light} (CH2O) + H2O + 2\,A$$

where H2A is any hydrogen donor. Put water in and you get oxygen out. Put hydrogen sulfide in and you get sulfur out.

Van Niel's generalization established that the oxygen released in green-plant photosynthesis comes from water and not from carbon dioxide, and he reached it by studying purple sulfur bacteria. The organism at the center of this volume is the organism that corrected the textbook account of photosynthesis.

The author's two equations are the two instances of van Niel's general form, and they are written correctly.

---

236. The Plus Three Hundred and Fifty Millivolts ↩

Where the number comes from

The author has carried the figure of plus three hundred and fifty millivolts for Chromatium since the beginning of this work. It is the midpoint potential of the high-potential iron-sulfur protein of Allochromatium vinosum, and it is correct.

protein	cluster	midpoint potential
HiPIP, Allochromatium vinosum	[4Fe-4S]	about +350 millivolts
ferredoxin, bacterial	[4Fe-4S]	about −400 millivolts

The same cluster. Four irons, four sulfides, at the corners of a cube, bound by four cysteines. In one protein it sits at plus three hundred and fifty millivolts and in the other at minus four hundred. Seven hundred and fifty millivolts apart, and nothing about the cluster has changed.

What decides the difference

The protein around the cluster. Hydrogen bonding to the cluster sulfurs, the dielectric of the surrounding fold, the exposure to solvent, the charges nearby — these set the potential. The cofactor supplies the chemistry and the protein supplies the voltage.

And HiPIP does the job the number implies. In Allochromatium vinosum it is the electron donor to the photosynthetic reaction center — the protein that hands the electron in.

Which is the volume's Rieske finding again, at a larger interval

Part Forty-One established that the Rieske center reaches about plus three hundred millivolts while a ferredoxin with the same iron-sulfur core sits near minus three hundred — six hundred millivolts from substituting two of the four cysteine ligands with histidines.

Here the ligands are not even changed. All four are cysteines in both proteins, and the span is seven hundred and fifty millivolts. The volume now carries two independent demonstrations that an iron-sulfur cluster's potential is set by its housing rather than by its composition.

The author's plus three hundred and fifty is not an approximation and not a recollection. It is the measured midpoint potential of a named protein in a named organism, and it has been in the literature for decades.

---

237. The Ferredoxins ↩

The first protein, and the case for saying so

A ferredoxin is small — often under a hundred residues — and it is mostly cluster. Iron and sulfide at alternating corners of a cube, held by cysteine thiolates. The fold is minimal. The chemistry is entirely inorganic.

the argument for antiquity	
the cofactor is a mineral	greigite, Fe3S4, has the same motif
the protein is short	it can be encoded by a very small gene
the sequence is often an	a still shorter ancestor is implied

the argument for antiquity	
internal duplication	
the distribution is universal	ferredoxins occur in all three domains
the chemistry needs no organic cofactor	no flavin, no heme, no quinone

A protein whose active site is a mineral, whose fold is a duplication of half of itself, and which occurs in every organism ever examined, is a reasonable candidate for the oldest protein family in existence. The author's outline calls Fe4S4 the first protein, and the argument for it is stronger than an assertion.

And it explains why iron-sulfur enzymes guard the nucleotide gates

Part Forty-One found both committed steps of nucleotide biosynthesis guarded by iron-sulfur enzymes. This section supplies the reason that is unsurprising. If the first catalysts were iron-sulfur proteins, the oldest pathways will be the ones still using them.

---

238. The Sulfur Oxidation Machinery ↩

What the organism runs to do the job

The sulfur oxidation pathway of Allochromatium vinosum is one of the best characterized in bacteriology, and it is a chain of sulfur-handling proteins.

system	what it does
Sox	oxidizes thiosulfate at the periplasmic face
Dsr	dissimilatory sulfite reductase, run in reverse — oxidizes the stored sulfur globules
sulfide:quinone oxidoreductase	takes the electron from sulfide into the quinone pool
APS reductase and ATP sulfurylase	carry the sulfur to sulfate through adenosine phosphosulfate

Adenosine phosphosulfate is one of the six-color molecules of Part Forty-Two — carbon, hydrogen, nitrogen, oxygen, phosphorus and sulfur, all six. It is the point where this organism's sulfur chemistry

meets the nucleotide world, and it is a carrier, exactly as the color count predicted.

The globules

The sulfur the organism stores is not ordinary S8. The globules are held in a protein envelope and contain long-chain polysulfides and sulfur in an unusual state. The cell maintains an internal reservoir of reduced sulfur at zero oxidation state and draws it down when the external sulfide runs out.

It is a battery, and the charge carrier is element sixteen.

---

239. The Antiquity, and the Interval ↩

Anoxygenic photosynthesis came first

The oldest proposed microbial fossils and the oldest isotopic evidence for photosynthesis place anoxygenic photosynthesis at roughly three and a half billion years. Free atmospheric oxygen does not appear until the Great Oxidation Event at about two point four billion years.

The interval is roughly one point one billion years. Sulfur-based photosynthesis ran the planet's carbon fixation for more than a billion years before oxygen-based photosynthesis changed the atmosphere. The author's figure of 1.1 billion is the right number.

And the reason it came first is in the chemistry

Hydrogen sulfide is a far easier electron donor than water. The sulfide-sulfur couple sits near minus two hundred and seventy millivolts; the oxygen-water couple sits near plus eight hundred and twenty. Taking an electron from water costs about a volt more than taking one from sulfide.

Anoxygenic photosynthesis needs one photosystem. Oxygenic photosynthesis needs two, wired in series, because no single photosystem can span the gap to water. Life used sulfur first because sulfur was cheaper, and it built the second photosystem only when the sulfide ran out.

That is the mechanical reason for the volume's whole chronology, and it is a voltage.

240. The Symbiosis ↩

What the mitochondrion descends from

The mitochondrion descends from a bacterium of the class Alphaproteobacteria. That class was called, in Woese's original naming and in Margulis's work, the purple bacteria and their relatives — a name taken directly from the purple photosynthetic bacteria that are its most conspicuous members.

the lineage	the class
purple non-sulfur bacteria — Rhodospirillum, Rhodobacter	Alphaproteobacteria
the mitochondrial ancestor	Alphaproteobacteria
purple sulfur bacteria — Allochromatium	Gammaproteobacteria

The organelle that powers every eukaryotic cell descends from the purple bacteria. The author's identification of the mitochondrion with the purple bacterial lineage is the correct one, and the group it belongs to was named for its purple photosynthetic members.

And the machinery is the same machinery

Whatever the exact branch, the point stands and it is a sulfur point.

in the bacterium	in the mitochondrion
iron-sulfur proteins in the electron chain	Complex I carries eight; Complex II three; Complex III the Rieske
quinone pool	ubiquinone
cytochromes	cytochromes
proton gradient driving ATP synthesis	the same

The respiratory chain of a modern human mitochondrion is a bacterial photosynthetic chain with the light removed and oxygen bolted on the end. Every iron-sulfur cluster in it is an inheritance.

241. The Numbers the Author Recorded ↩

Set down as observations, with what the current record says

the author's figure	the standing record
twenty-three species in the Chromatiaceae	the family currently comprises roughly two dozen genera, and the count has been revised repeatedly since 1888
twenty-three chromosomes in the human genome	twenty-three pairs. Allochromatium carries one circular chromosome
plus three hundred and fifty millivolts	confirmed — the HiPIP midpoint potential
1.1 billion years between anaerobic and aerobic	confirmed against the standard chronology
the oldest living carbon-based entity	among the oldest metabolic strategies still practiced unchanged

The twenty-three is a numerical echo between a bacterial family count and a human chromosome count. The volume records it as the author's observation and as an echo, which is what it is, and notes that the two twenty-threes count different kinds of thing.

242. What Is Claimed and What Is Not ↩

Claimed

That Allochromatium vinosum performs anoxygenic photosynthesis using hydrogen sulfide as electron donor and depositing elemental sulfur intracellularly, and that intracellular deposition is the character defining its family. That the author's six-carbon equation balances and is a correct instance of van Niel's general equation. That the plus three hundred and fifty millivolts is the measured midpoint potential of the organism's high-potential iron-sulfur protein, and that the same [4Fe-4S] cluster in a ferredoxin sits near minus four hundred. That anoxygenic photosynthesis precedes oxygenic by roughly 1.1 billion years and that the reason is the roughly one-volt difference in the donor couples. That the mitochondrion descends from the alphaproteobacteria, the group named for its purple photosynthetic members.

Not claimed

That Allochromatium vinosum is the ancestor of the mitochondrion. It is a gammaproteobacterium and the mitochondrial ancestor is an alphaproteobacterium. The claim is that both belong to the purple bacterial world and share the iron-sulfur respiratory machinery.

That ferredoxin is demonstrably the first protein. The argument of section 237 is a convergence of five indications and the volume presents it as that.

That the two counts of twenty-three are related. They are not, and section 241 says so.

243. What Would Show This Part Is Wrong ↩

- Show that the high-potential iron-sulfur protein of this organism does not sit near plus three hundred and fifty millivolts, and the number the author has carried for twenty-nine years is wrong and section 236 falls.
- Show that the [4Fe-4S] cluster of HiPIP differs in composition from that of ferredoxin, and the housing-not-composition argument of section 236 has no force.
- Establish that oxygenic photosynthesis preceded anoxygenic, and the chronology of section 239 inverts and the volume's whole sequence with it.
- Show that the sulfide-sulfur and oxygen-water couples are separated by substantially less than a volt, and the energetic explanation of section 239 for why sulfur came first is not available.
- Show that the mitochondrial ancestor is not an alphaproteobacterium, and section 240's identification of the purple bacterial lineage fails.
- Show that Chromatiaceae do not deposit sulfur intracellularly, and the defining character of section 234 is misstated.

PART FIFTY-FOUR · THE TWO PHOTOSYNTHESES

Part Fifty-Four of the evidence volume, sections 244 to 251

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Outline nodes 5.5 through 5.7. The sulfur route and the oxygen route to glucose, written side by side; what each costs; what each discards; and the bill that the oxygen route sends every aerobic organism for the rest of its life.

244. The Two Equations, Side by Side ↩

Written to the same six-carbon scale

THE SULFUR ROUTE\n6 CO2 + 12 H2S + 6 H2O --> C6H12O6 + 12 S + 12 H2O\nTHE OXYGEN ROUTE\n6 CO2 + 12 H2O --> C6H12O6 + 6 O2 + 6 H2O

Both balance. Both were checked atom by atom. Both are instances of van Niel's general equation with a different hydrogen donor substituted in.

	sulfur route	oxygen route
donor	12 H2S	12 H2O
product carbon	glucose	glucose
discard	12 S — a solid, stored inside the cell	6 O2 — a gas, vented to the atmosphere
water balance	six consumed, twelve released — net gain of six	six consumed and six released — net zero
photosystems required	one	two, in series
oxygen produced	none	six molecules

The observation the author made, stated exactly

The sulfur route yields six more waters than the oxygen route and produces twelve atoms of elemental sulfur instead of six molecules of oxygen gas. The author has been recording that asymmetry for years. It is arithmetically correct and it follows directly from the stoichiometry of the two donors.

Twelve H2S bring twenty-four hydrogens and no oxygen. Twelve H2O bring twenty-four hydrogens and twelve oxygens. The extra oxygen in the water route has to go somewhere, and it goes out as O2. The sulfur route has no surplus oxygen to vent, so its surplus leaves as water.

245. Why the Oxygen Route Needs Two Photosystems ↩

The voltage the donor demands

couple	midpoint potential at pH 7
sulfide to elemental sulfur	about −270 millivolts
water to oxygen	about +820 millivolts

The difference is close to eleven hundred millivolts — more than a volt.

A photosystem can lift an electron by a fixed amount set by the energy of the photon it absorbs and the efficiency of the charge separation. One photosystem can take an electron from sulfide and deliver it to the carbon-fixing machinery. No single photosystem can take one from water and do the same.

Oxygenic photosynthesis required the invention of a second photosystem and the wiring of the two in series, so that one photon lifts the electron partway and a second photon lifts it the rest. That arrangement is the Z-scheme, and it exists because water is a bad electron donor.

Which settles the order

Life did not begin with the harder chemistry and simplify. It began with the easy donor, built one photosystem, ran the planet on it for more than a billion years, and only then paid for the second photosystem — when the sulfide in the illuminated water had been used up.

Sulfur was not a primitive substitute for oxygen. Oxygen was an expensive substitute for sulfur, adopted under scarcity.

246. What the Oxygen Route Costs Afterward ↩

The bill arrives during respiration, not during photosynthesis

Molecular oxygen is a diradical. It has two unpaired electrons in its ground state, and that is why it does not simply set the biosphere on fire. The same property

makes its reduction proceed one electron at a time, and every partial reduction is a reactive species.

species	how it forms
superoxide, O2 radical anion	one electron added to O2
hydrogen peroxide	two electrons
hydroxyl radical	three electrons — the most damaging oxidant in biology
water	four electrons — the intended product

The cell wants the four-electron product and cannot help making the one-, two- and three-electron intermediates on the way. The author's outline calls the free radical O2 minus the main culprit in aging, weakening and disease, and the free radical theory of aging is built on exactly that species.

And the defenses are made of sulfur

defense	the sulfur in it
glutathione	a cysteine thiol — the cell's principal redox buffer, at millimolar concentration
thioredoxin	two cysteines
glutaredoxin	cysteines
glutathione peroxidase, GPX4	a selenocysteine — sulfur's group partner
peroxiredoxins	a cysteine
methionine sulfoxide reductase	repairs oxidized methionine

Every major antioxidant system in the human cell is a thiol system. The element that ran metabolism before oxygen existed is the element that cleans up after oxygen now.

That is the volume's thesis arriving from the direction of damage rather than the direction of catalysis, and it is the same thesis.

247. Glucose ↩

Why the molecule is worth its own section

Glucose is the branch point of the entire carbon economy.

what it becomes	by what route
ATP	glycolysis, then the citric acid cycle, then oxidative phosphorylation
ribose and deoxyribose	the pentose phosphate pathway — every nucleotide sugar starts here
NADPH	the same pathway — the reducing power for biosynthesis
cellulose	the most abundant organic polymer on Earth
starch and glycogen	storage
the amino acid carbon skeletons	via glycolytic and cycle intermediates
fatty acids	via acetyl-CoA

Every nucleotide in every genome on this planet has a sugar in it, and that sugar came from glucose through the pentose phosphate pathway. The author's outline calls glucose the world's most important molecular structure, and by the count of what depends on it, that is defensible.

The brain

Under ordinary conditions glucose is essentially the sole fuel of the human brain. The brain is about two percent of body mass and consumes about twenty percent of resting glucose. During prolonged fasting the brain adapts to ketone bodies for a substantial share of its fuel, but it cannot use fatty acids directly, and a floor of glucose demand remains.

The author's outline states that the human brain will use only glucose. As a statement about the ordinary fed state it is correct, and the ketone adaptation is the one qualification.

And the carbon

Cellulose is the most abundant organic polymer on Earth, and cellulose is a polymer of glucose. Add starch, glycogen and the free sugar pools, and a very large share of the biosphere's fixed carbon is held in glucose or in something made directly from it.

248. The Sulfur in the Glucose Equation ↩

The atom the equation names and the notation does not

The sulfur route writes twelve sulfurs into the products. Those twelve atoms are the organism's stored charge. They sit as globules inside the cell, and when the light fails or the sulfide runs out, they are drawn back down.

A purple sulfur bacterium keeps its battery in the same element it keeps its chemistry. There is no separate storage molecule, no separate currency. The reduced sulfur is both the fuel and the store.

And the connection to the thioester

The glucose made by either route is dismantled by glycolysis into pyruvate, and pyruvate is handed to the citric acid cycle by pyruvate dehydrogenase.

the enzyme complex	the sulfur in it
pyruvate dehydrogenase	thiamine pyrophosphate — a thiazolium sulfur
	lipoamide — a disulfide on a swinging arm
	coenzyme A — the thioester acceptor

Three separate sulfur cofactors, in series, at the single step that connects sugar metabolism to the citric acid cycle. Glucose cannot enter the cycle without passing through three sulfurs, and the glucose molecule contains none.

That is the volume's central claim in its most compact form. The substrate has no sulfur. The step that moves it has three.

---

249. The Two Routes as a Single Argument ↩

What the comparison establishes

the question	the answer the comparison gives
Which came first?	sulfur — one photosystem instead of two, a donor a volt cheaper
Which is more efficient per photon?	sulfur — less energy is required per electron
Which produces more usable water?	sulfur — a net gain of six per glucose

the question	the answer the comparison gives
Which scaled to a planet?	oxygen — because water is everywhere and sulfide is not
Which left a bill?	oxygen — the reactive species, and the thiol systems that handle them

Oxygen won on supply, not on chemistry. Water is the most abundant hydrogen donor on the surface of the Earth, and that is the only category in which it beats hydrogen sulfide.

The volume should say this plainly, because it is the honest shape of the story. The oxygen world is not an improvement on the sulfur world. It is the sulfur world scaled up using a worse but limitless raw material, with a permanent maintenance cost that the sulfur systems were retained to pay.

---

250. What Is Claimed and What Is Not ↩

Claimed

That both six-carbon equations balance and are instances of van Niel's general equation. That the sulfur route yields a net six waters and the oxygen route none. That the sulfide-sulfur couple sits near minus two hundred and seventy millivolts and the water-oxygen couple near plus eight hundred and twenty, and that the interval is the reason oxygenic photosynthesis requires two photosystems in series. That the one-, two- and three-electron reduction products of oxygen are superoxide, hydrogen peroxide and hydroxyl radical. That every major antioxidant system in the human cell is thiol-based or selenol-based. That pyruvate dehydrogenase requires three distinct sulfur cofactors and that glucose contains none.

Not claimed

That the sulfur route is superior. It is cheaper per electron and it is supply-limited, and the volume says both.

That the human brain can use no fuel but glucose. It adapts substantially to ketone bodies in prolonged fasting, and the volume prints the qualification.

That a specific fraction of the world's carbon sits in glucose. The defensible statement is that cellulose is the most abundant organic polymer and is a glucose polymer, and the volume makes that statement instead of a percentage.

251. What Would Show This Part Is Wrong ↩

— Show that either equation in section 244 fails to balance, and the arithmetic the author has carried for years is wrong.

— Identify an organism performing oxygenic photosynthesis with a single photosystem, and section 245's energetic argument for the Z-scheme is not the reason it exists.

— Show that the sulfide and water couples are separated by substantially less than a volt at physiological pH, and the cost argument fails.

— Identify a major cellular antioxidant system built on neither a thiol nor a selenol, and section 246's claim that the clean-up crew is a sulfur crew has an exception it does not print.

— Show that pyruvate can enter the citric acid cycle in a human cell by a route requiring no sulfur cofactor, and section 248's compact statement of the thesis is not general.

PART FIFTY-FIVE · LIGHT, FRACTALS AND COLOR

Part Fifty-Five of the evidence volume, sections 252 to 259

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Outline nodes 9.3, 9.4 and 9.6. Why a molecule absorbs the color it absorbs, what the double helix does with a photon, why linear molecules make knots, and the defense of color as an instrument rather than as decoration.

252. Why a Molecule Has a Color at All ↩

The rule, stated once

A molecule absorbs a photon when the photon's energy matches the gap between two of its electronic states. The wavelength absorbed is fixed by that gap. The color seen is the complement of the color absorbed.

the structural feature	what it does to the gap
isolated single bonds	a very large gap — absorbs in the far ultraviolet; colorless
each additional conjugated double bond	narrows the gap — absorption moves to longer wavelength
about eight conjugated bonds	the absorption reaches the visible; the compound is colored
a metal in a ligand field	a small d-orbital gap; visible absorption at low cost
a sulfur lone pair conjugated into a system	narrows the gap further than an oxygen lone pair does

The last row is the one this volume needs. Sulfur's valence orbitals are larger, higher in energy and more polarizable than oxygen's, so replacing an oxygen with a sulfur in a conjugated system shifts the absorption to longer wavelength. The thio- compounds are systematically redder than their oxo- parents.

That is not an analogy. It is a measurement anyone can make on a bench spectrometer, and it is why the morpheme thio- is visible as well as audible.

The pigments of the story

pigment	absorbs	appears
chlorophyll a	red and blue	green
bacteriochlorophyll a	near infrared, 800 to 900 nanometers	
carotenoids	blue and green	orange, red, purple
cytochromes	the Soret band near 420 nanometers	red-brown
the purple sulfur bacteria	infrared, which green plants cannot use	purple

A purple sulfur bacterium is purple because it harvests the light that green plants throw away. It lives beneath them in the water column and uses the wavelengths that got past.

253. The Helix as an Optical Object ↩

What the outline is pointing at

The outline calls the double helix a photosynthetic organic circuit, a photochemical switch and a photochromatic crystalline molecular structure. Four real optical properties of nucleic acid stand behind that.

Hypochromism

A stack of bases absorbs less ultraviolet than the same bases free in solution — about forty percent less. The coupling between neighboring transition dipoles suppresses the absorption. Melt the duplex and the absorbance at two hundred and sixty nanometers rises sharply.

The melting of DNA is measured optically. The helix announces its own state by how much light it absorbs, and that measurement is the standard method in every laboratory.

Circular dichroism

A helix absorbs left- and right-circularly polarized light differently, because it is chiral. The B form, the A form and the Z form have different and diagnostic spectra.

Handedness is an optical observable. The volume's Z-DNA and Zα material rests on structures that were first distinguished by their circular dichroism, before any crystal was grown.

Photochemistry, and the thymine dimer

Ultraviolet light drives a cycloaddition between adjacent pyrimidines, most often two thymines. The cyclobutane pyrimidine dimer is the principal ultraviolet lesion in DNA.

The author's outline records the thymine dimer at three hundred and seventy nanometers. The direct dimer-forming absorption is in the shorter ultraviolet, near two hundred and sixty; the three hundred and seventy nanometer region is where photolyase absorbs — the enzyme that reverses the dimer.

So there are two wavelengths in that story and both matter. Short ultraviolet makes the lesion. Near-ultraviolet and blue light near three hundred and seventy nanometers power the enzyme that undoes it. Light breaks the DNA and light repairs it, at two different energies.

Charge transport

DNA conducts charge along the stacked base pairs. Guanine has the lowest oxidation potential of the four bases and acts as the sink; holes migrate along the

stack and localize at guanine-rich runs. The DNA repair enzymes MutY and endonuclease III carry [4Fe-4S] clusters and appear to use charge transport through the duplex to find lesions.

The proteins that search DNA for damage carry iron-sulfur clusters and use the helix as a wire. The outline calls the double helix an organic circuit with disulfide photoelectronic switches. The literal version — iron-sulfur clusters signaling to each other through the base stack — is stranger than the metaphor.

---

254. What the Outline's Light Arithmetic Is Counting ↩

The statements, and what stands behind each

the outline	what it corresponds to
two points of light equal two strings of photons	a photon is a quantum; a beam is a stream of them
two strands equal one helix	exact
three strands equal one unicellular life form	the triplex; and the volume's own three-strand material
one point of diffracted absorbed sunlight equals one string of sulfur	the absorption line as an element's signature
sixteen potential biochemical substrates	sixteen — the atomic number of sulfur

The one with a physical reading

An absorption line is an element's name written in light. Sixteen protons produce one set of lines and no other element produces that set. The outline's identification of a diffracted absorbed wavelength with a string of sulfur is atomic spectroscopy, and it is the same instrument that found the seven interstellar sulfur molecules of Part Fifty-One.

Color, in this volume, has always been a claim about identity. The color key says one color, one element. Atomic spectroscopy says the same thing and the universe enforces it.

255. Fractals and Knots ↩

Why a long thin molecule ties itself in knots

A sufficiently long flexible polymer, left to itself, is overwhelmingly likely to be knotted. This is a theorem — the Frisch–Wasserman–Delbrück conjecture, proved by Sumners and Whittington in 1988: the probability that a self-avoiding random walk is unknotted falls exponentially with length.

A long DNA molecule is not knotted by accident or by damage. It is knotted because almost all long configurations are knotted, and the cell must actively work to keep it otherwise.

Which is why the topoisomerases exist

enzyme	what it does
topoisomerase I	cuts one strand, lets it rotate, reseals
topoisomerase II	cuts both strands and passes another duplex through the gap — it unknots
condensins	organize the fold so that the knots do not form

The outline's observation that linear organic molecules make knots in fractals is the biological reading of a topological theorem, and the cell's answer to it is an entire enzyme class.

The fractal fold

The Hi-C measurements of chromosome conformation identified a "fractal globule" organization — a compact, unknotted fold whose contact probability falls as a simple power of genomic distance. The characteristic exponent is close to minus one.

The genome is folded into a shape that is space-filling, dense, and deliberately unknotted — a configuration that is rare among all possible dense folds. The fractal geometry the outline names is measured, and its distinguishing property is precisely the absence of the knots the theorem predicts.

And the geometry of the sugar

The pentose ring pucker, the phosphate backbone torsions and the base stacking distance of three point four angstroms set the helix. Ten to ten and a half base pairs

per turn, thirty- four angstroms of rise per turn, twenty angstroms across. Those numbers are the reason a helix has the proportions it has, and the outline is right that they are geometric constants before they are biological ones.

256. Color as an Instrument ↩

The case, stated for the record

This volume's method is to color a structure atom by atom and count. That method has been questioned, and the answer belongs in the printed record rather than in correspondence.

A sentence weights every word alike. A colored structure does not. When five oranges sit against one of everything else, the reader's visual system reports the ratio before he has read a word — and the fact that oxygen is present in nearly every reaction arrives as a perception rather than as a claim to be believed.

What the visual system does that prose cannot

the operation	the medium that does it
counting to four without counting	vision — subitizing is immediate up to about four
detecting a single odd item in a field	vision — pop-out is parallel and pre-attentive
estimating a ratio across a whole page	vision
stating a mechanism	prose
stating a quantity exactly	number

Color is not an ornament on the argument. It is the only instrument that reports a ratio across a whole sheet in one glance, and the volume's central findings — the color count, the one yellow on the nucleotide panel, the saturation of orange — were all made by that instrument and could not have been made by reading.

The precedent

Koolman and Röhm's Color Atlas of Biochemistry has used a unified color coding of atoms and coenzymes since 1994 and has been translated into fifteen languages.

Michal's Biochemical Pathways wall chart colors by pathway. Gattegno's Words in Color taught reading by assigning a color to each phoneme in 1962.

The idea that color carries information is established. What is not established, and what this volume claims, is that coloring the atoms and then counting the colors produces results — a ceiling of five for monomers, a census of one for sulfur on the nucleotide panel, and a saturation for oxygen. Those are findings, and they were found by looking.

---

257. Light, Time and the Last Rung ↩

The outline's final claim

The outline ends its light section with the expansion of time, consciousness, and the sulfur superstring running from anaerobic bacteria to human consciousness. The volume can support the first and third links of that chain and should say clearly where the support stops.

the link	the standing
anaerobic bacteria run on sulfur	established — Part Fifty-Three
the mitochondrion inherits the iron-sulfur chain	established — Part Fifty-Three
the brain runs on that chain	established — the brain is the most mitochondria-dense tissue by demand
neurotransmitters are made by sulfur methylation and metal hydroxylation	established — Part Forty-Five
therefore sulfur is continuous from the first bacterium to human thought	a chain of established links
therefore sulfur explains consciousness	not claimed, and the volume declines it

The thread is real and it is unbroken. Every link from the purple sulfur bacterium to the synapse can be named, and this volume has named them. What the thread does not do is explain what happens at the far end of it, and the volume gains nothing by pretending otherwise.

The claim that survives is large enough. The chemistry of thought is run by cofactors inherited from an organism that has not changed its metabolism in three and a half billion years.

258. What Is Claimed and What Is Not ↩

Claimed

That absorption wavelength is set by electronic state spacing, that conjugation narrows the gap, and that substituting sulfur for oxygen in a conjugated system shifts absorption to longer wavelength. That purple sulfur bacteria harvest near-infrared light that oxygenic phototrophs cannot use. That DNA is hypochromic by about forty percent, that its handedness is an optical observable by circular dichroism, and that DNA repair enzymes carrying [4Fe-4S] clusters appear to signal through the base stack. That long flexible polymers are almost surely knotted, by theorem, and that topoisomerase II exists to unknot them. That the measured genome fold is characterized by the near-absence of knots.

Not claimed

That the thymine dimer forms at three hundred and seventy nanometers. It forms in the shorter ultraviolet; three hundred and seventy is where the repair enzyme absorbs, and the volume prints both.

That color coding proves anything by itself. It is an instrument for making ratios visible, and the volume claims the findings, not the method's authority.

That the sulfur thread accounts for consciousness. Section 257 states the links that hold and declines the last step.

259. What Would Show This Part Is Wrong ↩

— Show that thio- substitution in a conjugated system shifts absorption to shorter rather than longer wavelength, and section 252's optical reading of the morpheme fails.

— Show that purple sulfur bacteria do not use wavelengths beyond the chlorophyll absorption range, and the layered water-column argument of section 252 is wrong.

— Show that the unknotting probability of a long self-avoiding walk does not fall exponentially with length, and section 255's account of why topoisomerases exist is not the reason.

— Show that iron-sulfur DNA repair proteins do not exchange charge through the base stack, and the literal reading of the outline's organic circuit in section 253 is unsupported.

— Color the same structures from the same key and reach different counts, and the instrument defended in section 256 does not reproduce — which remains the single most valuable test any reader of this volume could run.

PART FIFTY-SIX · MATERIALS AND THE ENVIRONMENTAL RECORD

Part Fifty-Six of the evidence volume, sections 260 to 267

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Outline nodes 10.4 and 10.5. Sulfur's second career — in batteries, in confinement geometry, in the combustion of the organic world, and in the biogeochemical cycle that returns element sixteen to the sea.

---

260. The Sodium-sulfur Cell ↩

Why sulfur is a cathode worth building

Sulfur has the highest theoretical specific capacity of any practical cathode material — about 1,672 milliampere-hours per gram, because each sulfur atom accepts two electrons and the atom is light.

chemistry	theoretical specific energy	note
lithium-sulfur	about 2,600 watt-hours per kilogram	five times the practical lithium-ion figure
sodium-sulfur	about 760 watt-hours per kilogram	the grid-storage chemistry

chemistry	theoretical specific energy	note
lithium-ion, current practice	250 to 300 watt-hours per kilogram	

The sodium-sulfur cell, as built

Molten sodium at the negative electrode, molten sulfur at the positive, and a beta-alumina solid electrolyte between them that conducts sodium ions and nothing else. It runs at about three hundred degrees Celsius. The discharge reaction forms sodium polysulfides.

These cells have been in grid service for decades and are among the few storage chemistries proven at the tens-of-megawatt-hour scale. Both of their active materials are abundant and cheap. Neither is cobalt, nickel or lithium.

The problem, and where Prussian blue enters

The obstacle in sulfur cells is the polysulfide shuttle. Intermediate polysulfides dissolve in the electrolyte, migrate to the other electrode and discharge there, wasting capacity.

Prussian blue and its analogs — iron hexacyanoferrate and its relatives — are open-framework materials with channels sized for sodium ions. They are used as sodium-ion host electrodes and as interlayers that trap polysulfides. They are cheap, they are made from iron, and their framework is the same open-channel architecture that makes zeolites useful.

The author's proposal of a Prussian-blue sodium-sulfur cell names two abundant elements and one abundant framework, and the polysulfide trapping problem is exactly the problem such a framework addresses.

---

261. The Confinement Geometry ↩

What the volume already established

Part Thirty-Eight of this volume argued that the stellarator rather than the tokamak is the right confinement geometry for the cell — nested surfaces, a rotational transform built into the shape of the field rather than driven by a current, and steady-state operation rather than pulsed.

Why that argument transfers to a cell

the tokamak	the stellarator
axisymmetric	fully three-dimensional, no axis of symmetry
requires a driven plasma current	the twist is built into the coils
inherently pulsed	inherently steady-state
simpler to build	harder to build, easier to run

A living cell is a steady-state device that has never once been restarted from cold in three and a half billion years of operation. Whatever geometry describes it must be a steady-state geometry, and among confinement geometries that is the stellarator's distinguishing property.

The Berger quantum cell stellarator is named here as the author's construct and carried forward as such. Its status in the volume is a proposed geometry, and the falsification conditions attached to Part Thirty-Eight remain the ones that govern it.

---

262. The Combustion Rate ↩

Sulfur as the throttle on burning

The author's outline states that sulfur's main function is controlling and harnessing oxygen's high combustion rate — that without it, organic molecular structures would burn like a forest fire out of control.

The chemistry supports the mechanism directly, and it is radical chain chemistry.

the step	what happens
initiation	a radical forms
propagation	the radical attacks a substrate, making another radical — the chain runs
chain transfer to a thiol	the radical abstracts the S–H hydrogen
termination	the thiyl radical formed is comparatively stable and does not propagate efficiently

A thiol is a chain-breaking antioxidant. Its S–H bond is weaker than a C–H bond, so the radical takes the hydrogen from the sulfur in

preference — and the sulfur radical left behind is a poor propagator. That is the mechanism by which sulfur throttles an oxidation chain, and it is the same mechanism whether the chain is in a cell membrane or in a barrel of oil.

This is why thiols and disulfides are added to lubricants, fuels and polymers as antioxidants. The industrial practice and the biological function are the same chemistry.

The author's forest fire is the correct picture, and the reason it does not happen is a hydrogen atom on a sulfur.

---

263. The Sulfur Cycle ↩

The full circuit

atmospheric SO2, H2S, DMS\n| oxidation and rainout\nv\nsulfate in the ocean and soil\n| assimilatory reduction, in plants and microbes\nv\norganic sulfur — cysteine, methionine, cofactors\n| decay and dissimilatory reduction\nv\nsulfide, and pyrite burial in sediment\n| weathering and volcanism\nv\nback to the atmosphere and the sea

The named processes

process	what carries out
assimilatory sulfate reduction	plants, algae, most bacteria — sulfate to cysteine
dissimilatory sulfate reduction	the sulfate-reducing bacteria — sulfate as the terminal electron acceptor
sulfur oxidation	the purple and green sulfur bacteria; the colorless sulfur bacteria
disproportionation	one sulfur species to two, one more oxidized and one more reduced
pyrite burial	the long-term sink, and the control on atmospheric oxygen over geological time

Pyrite burial is the reason there is oxygen in the air. Every mole of pyrite buried in a sediment is a mole of oxygen that was not consumed oxidizing it. The oxygen content of the atmosphere over the last two billion years is set, more than by anything else, by the sulfur cycle's burial term.

The volume should carry that sentence in its own right. The atmosphere the reader is breathing is a residue left over from the burial of an iron sulfide.

Dimethyl sulfide and the clouds

Marine phytoplankton produce dimethylsulfoniopropionate, which degrades to dimethyl sulfide. DMS escapes to the atmosphere, oxidizes, and its oxidation products act as cloud condensation nuclei.

The smell of the sea is a sulfur compound, and it is also, by way of cloud formation, a term in the planet's radiation balance. Element sixteen is in the climate system as well as in the genome.

---

264. The Sulfur and Nitrogen Cycles, Coupled ↩

The transformations the outline names

Growth, fixation, secretion, decay, respiration, combustion — the outline lists these as the sulfur/nitrogen biogeochemical cycle transformations, and the two cycles are coupled at several named points.

coupling point	what happens
nitrogenase	the enzyme that fixes atmospheric nitrogen is an iron-molybdenum-sulfur cluster protein
the FeMo cofactor	seven irons, nine sulfides, one molybdenum, one carbide
anammox	anaerobic ammonium oxidation, coupled in some settings to sulfur
sulfur-driven denitrification	sulfide as the electron donor for nitrate reduction
cysteine and methionine	the two amino acids where the sulfur cycle enters the nitrogen cycle

Nitrogen cannot be brought into biology at all without an iron-sulfur cluster. Nitrogenase carries the most complex metal cofactor known, and half of it is sulfide. The element that is missing from the genetic alphabet is the element without which there would be no fixed nitrogen to build the bases from.

That is the strongest single statement in this Part and it belongs in the volume's summary.

265. Sulfur as the Chemistry of the Century ↩

The case, in current terms

field	what sulfur is doing now
energy storage	lithium-sulfur and sodium-sulfur cells
polymers	inverse vulcanization — high-sulfur polymers from waste sulfur
medicine	covalent inhibitors targeting cysteine residues, the fastest-growing class in oncology
ferroptosis	a cell-death pathway defined by a selenoprotein and a thiol tripeptide
materials	ferroelectrics made by substituting sulfur for oxygen
catalysis	metal sulfide catalysts in hydrodesulfurization and in hydrogen evolution

Waste sulfur, and the scale of it

Petroleum refining removes sulfur from fuel and produces elemental sulfur as a byproduct in quantities exceeding seventy million tonnes a year, more than the market absorbs. Stockpiles sit in the open at refineries.

There is a surplus of the element this volume argues is the most useful in biology. Inverse vulcanization — polymerizing that surplus with cheap organic crosslinkers — turns it into optical polymers, mercury sorbents and battery cathodes. The chemistry is fifteen years old and the raw material is free.

The author's claim that sulfur is the new chemistry of the twenty-first century is a commercial as well as a scientific claim, and the surplus is the reason it is credible.

266. What Is Claimed and What Is Not ↩

Claimed

That sulfur's theoretical specific capacity as a cathode is about 1,672 milliampere-hours per gram and that lithium-sulfur cells have a theoretical specific energy near

2,600 watt-hours per kilogram. That sodium-sulfur cells operate with molten electrodes and a beta-alumina electrolyte and are proven at grid scale. That the polysulfide shuttle is the limiting problem and that open-framework hexacyanoferrates are used to address it.

That thiols act as chain-breaking antioxidants because the sulfur-hydrogen bond is weaker than a carbon-hydrogen bond and the resulting thiyl radical propagates poorly. That this is the same chemistry in a cell membrane and in an industrial lubricant.

That pyrite burial is the principal long-term control on atmospheric oxygen. That dimethyl sulfide from marine phytoplankton contributes to cloud condensation nuclei. That nitrogenase carries an iron-molybdenum-sulfur cofactor containing nine sulfides, and that no fixed nitrogen enters biology without it.

That elemental sulfur is produced as a refining byproduct in surplus, and that inverse vulcanization converts it to usable polymers.

Not claimed

That the Berger quantum cell stellarator has been demonstrated. It is the author's proposed geometry, carried forward from Part Thirty-Eight under the falsification conditions stated there.

That a Prussian-blue sodium-sulfur cell has been built to the author's specification. The components are established; the combination is the author's proposal.

That dimethyl sulfide regulates climate. It contributes to cloud nucleation; the strength of the feedback is disputed and the volume says disputed.

---

267. What Would Show This Part Is Wrong ↩

- Show that a cathode material exceeds sulfur's theoretical specific capacity at comparable cost and abundance, and the energy case of section 260 loses its premise.
- Show that the sulfur-hydrogen bond is stronger than a carbon-hydrogen bond, and section 262's whole mechanism for chain-breaking inverts, and with it the author's account of why the organic world does not burn.

— Show that atmospheric oxygen over geological time is not principally controlled by pyrite burial, and section 263's central sentence is wrong.

— Show that nitrogen fixation proceeds in some organism without an iron-sulfur cofactor, and section 264's strongest statement has an exception.

— Show that the elemental sulfur surplus from refining is absorbed by existing markets, and the commercial premise of section 265 fails.

PLATES · THE WALL, PHOTOGRAPHED

Seventeen photographs of the physical mural described in the Preface, and of the hand-built concept maps and working sheets that accompany it. They are reproduced here at the scale a page permits. The originals are wall-sized.

PLATE I · EVOLUTIONARY PRISMATIC LIGHT

The light panel entire. Sulfur Protein Photonic Color Helical Strings above; Atom-Photon Interactions and Astrophysical Quantities beneath it — the two captions that carry the real argument, since every sulfur molecule known beyond Earth was identified by the light it emits.

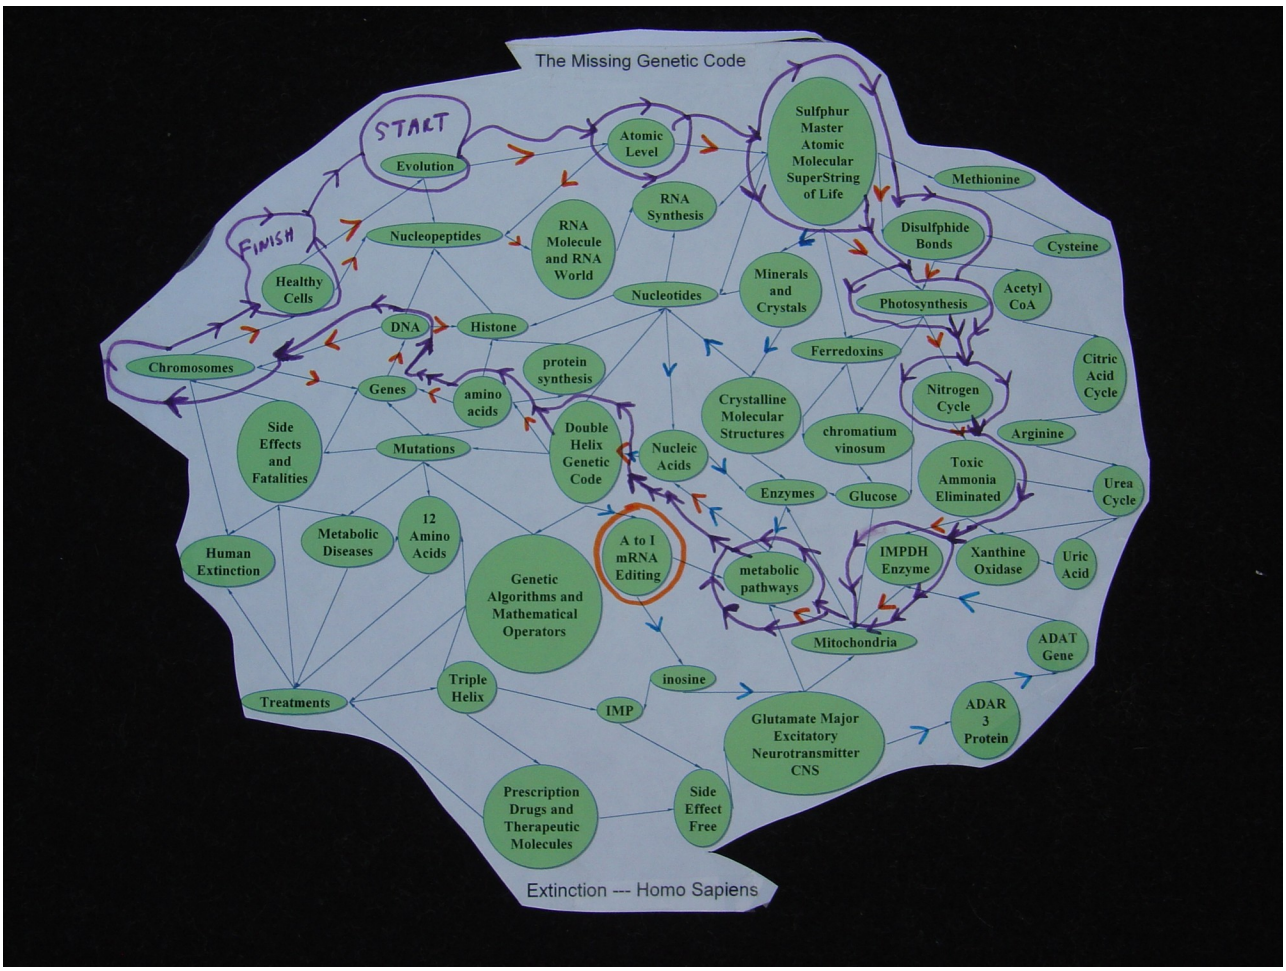

PLATE II · THE MISSING GENETIC CODE

A hand-built concept map. It begins at START and ends at EXTINCTION — HOMO SAPIENS, and between those two points it passes through the Sulfur Master Atomic Molecular Superstring of Life, methionine, disulfide bonds, cysteine, acetyl-CoA, the citric acid cycle, A-to-I mRNA editing and the ADAR gene. Almost every node became a Part of this volume.

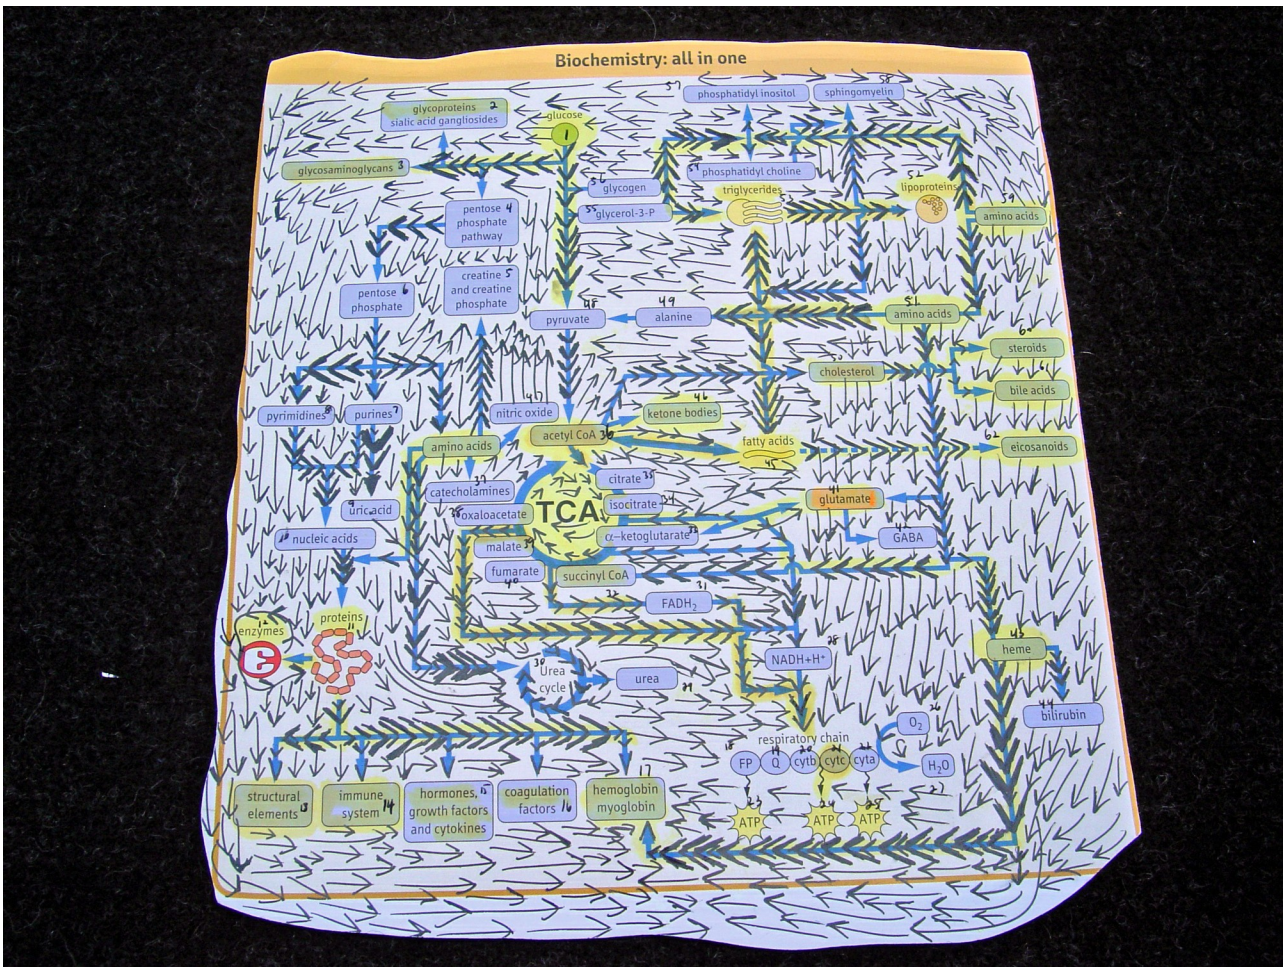

PLATE III · BIOCHEMISTRY, ALL IN ONE

The whole of intermediary metabolism on a single sheet, with the citric acid cycle at the center. The chart against which every claim in Parts Twenty-six and Thirty-seven was checked.

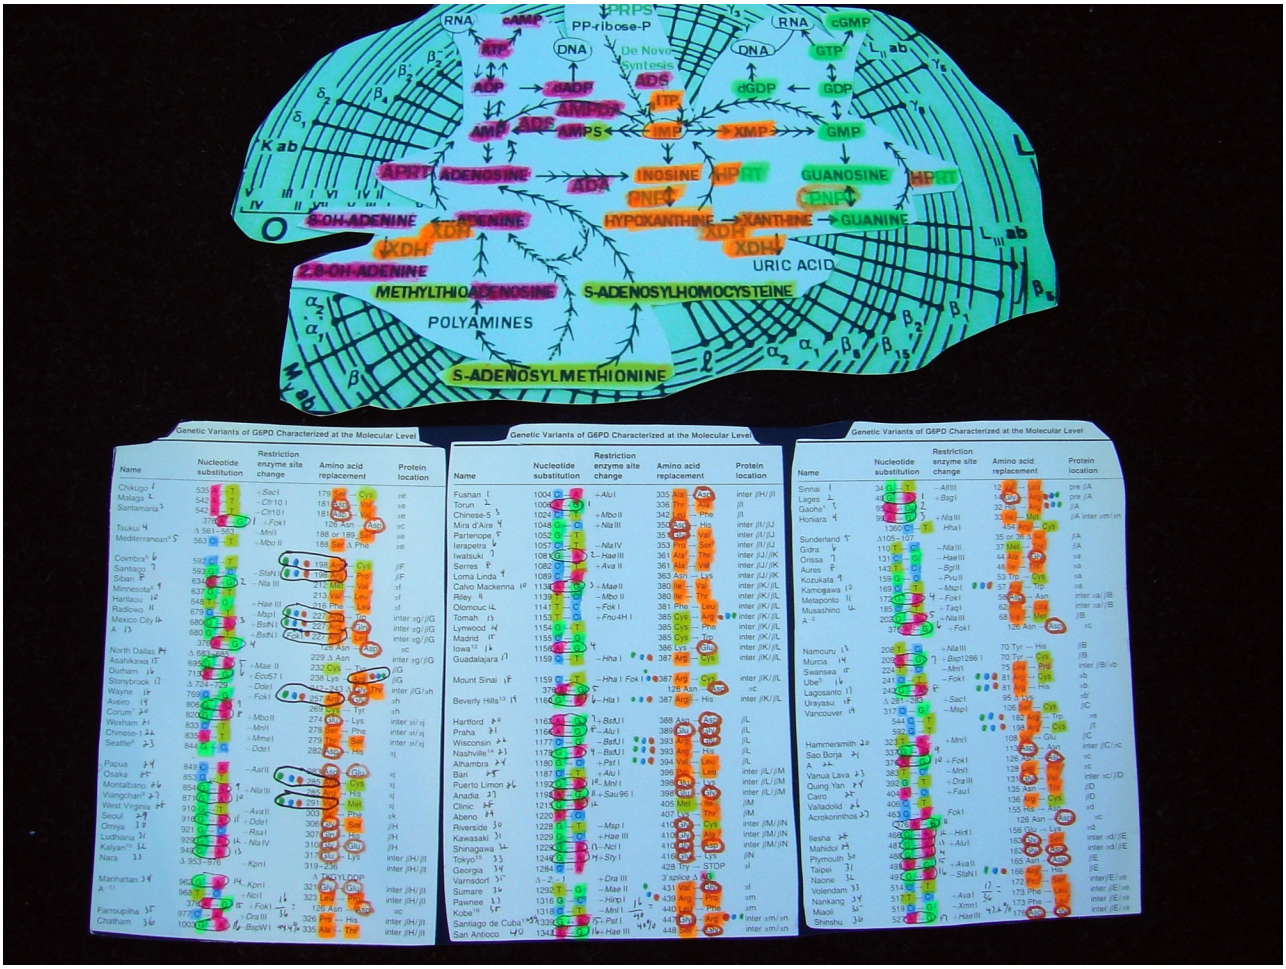

PLATE IV · PURINE AND PYRIMIDINE METABOLISM

The nucleotide pathways, with uric acid, the polyamines and S-adenosylmethionine marked, and the amino acid tables beneath. Hypoxanthine, xanthine and orotate all appear here as obligate intermediates and nowhere in the canonical four-letter table.

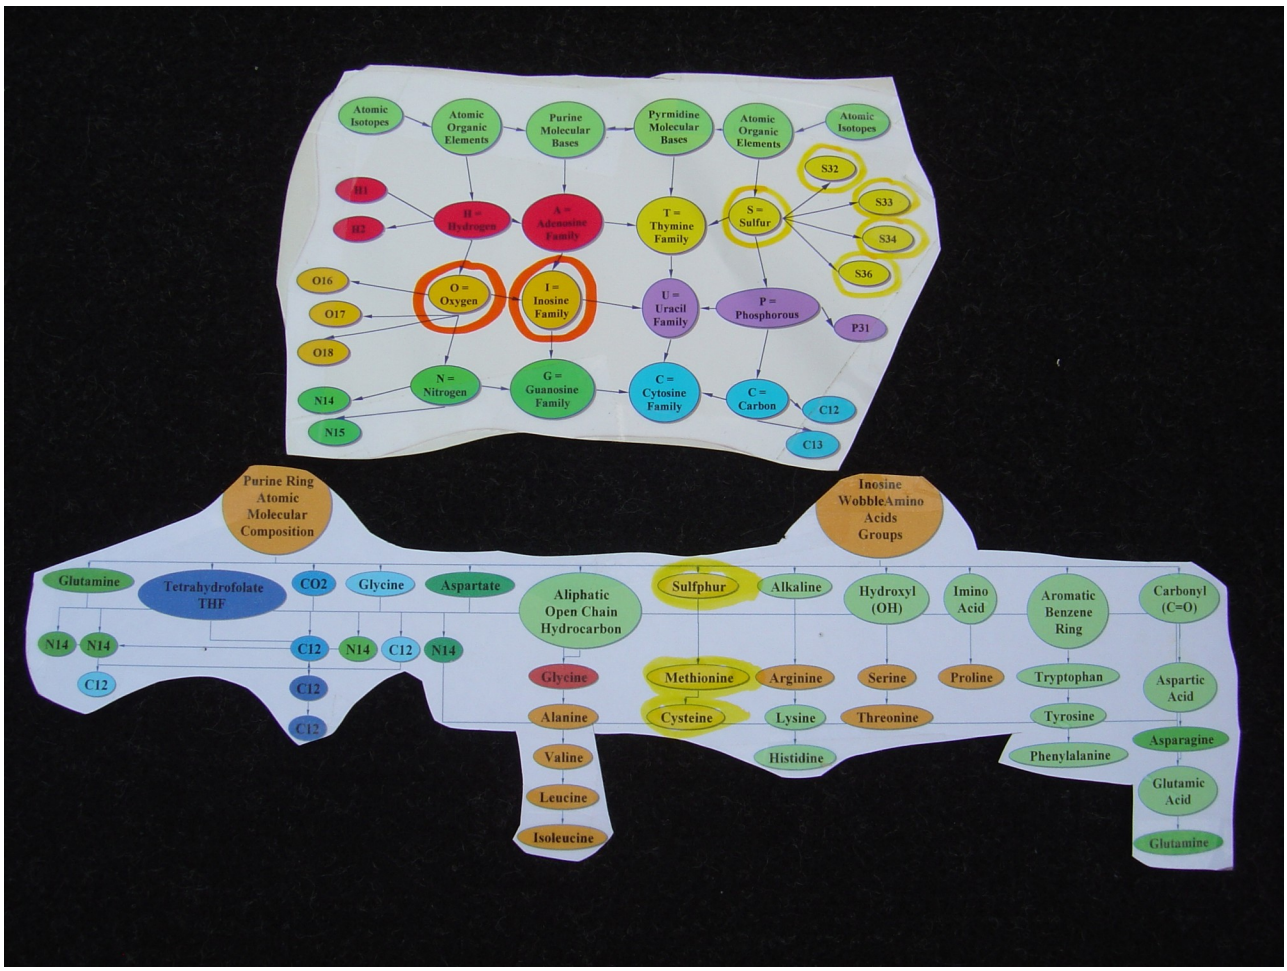

PLATE V · THE AMINO ACIDS, BY FUNCTIONAL GROUP

Classification by side chain — aliphatic, aromatic, hydroxyl, imino, carboxyl, basic — with sulfur, methionine and cysteine picked out. The chart behind Part Thirty-Three on glycine and proline.

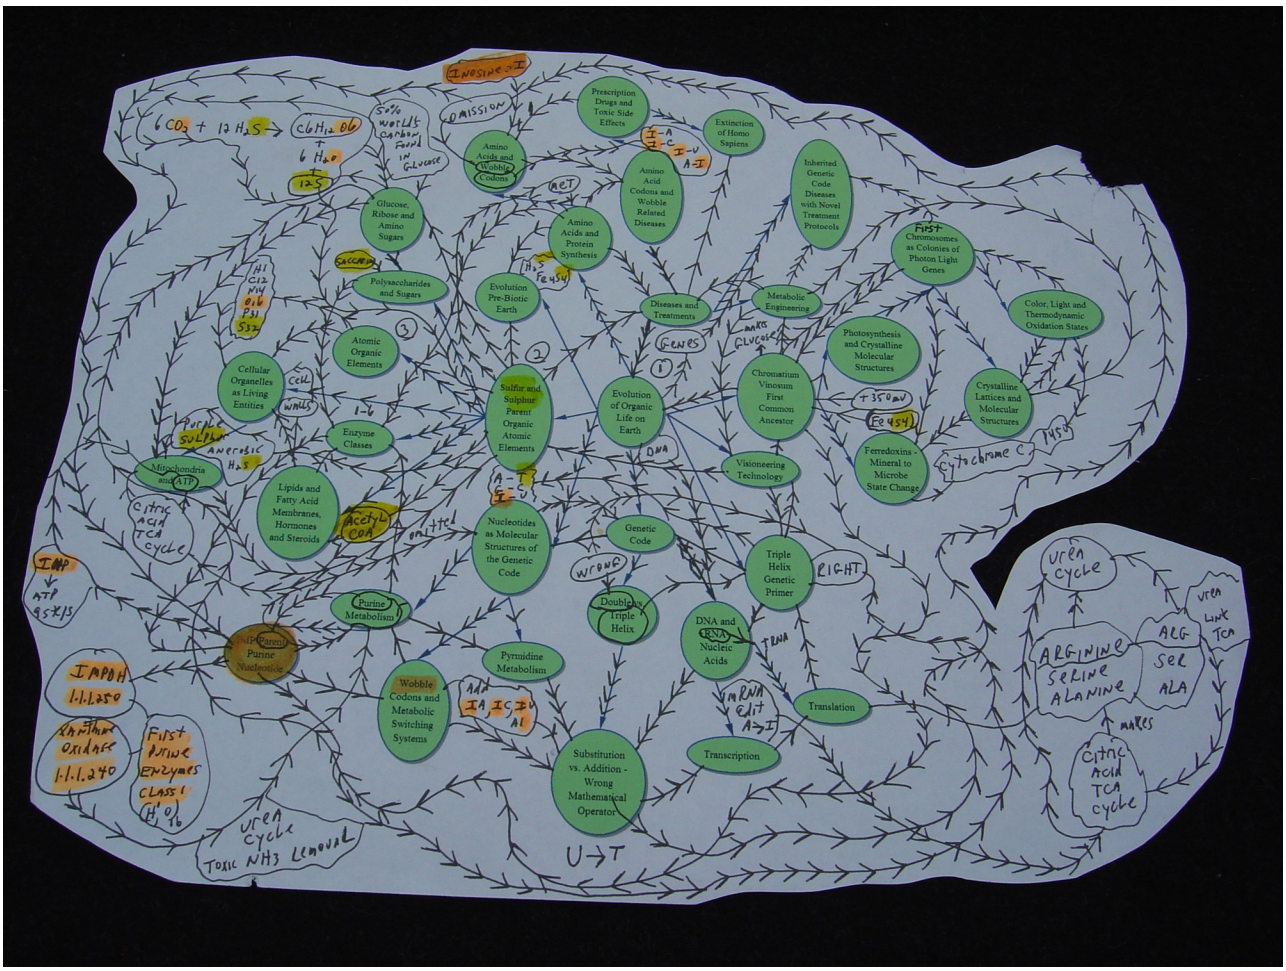

PLATE VI · THE WORKING MAP

Annotated by hand over years. Citric acid cycle, urea cycle, the amino acid three-letter codes, and marginal notes in several inks. This is the sheet the framework was argued out on.

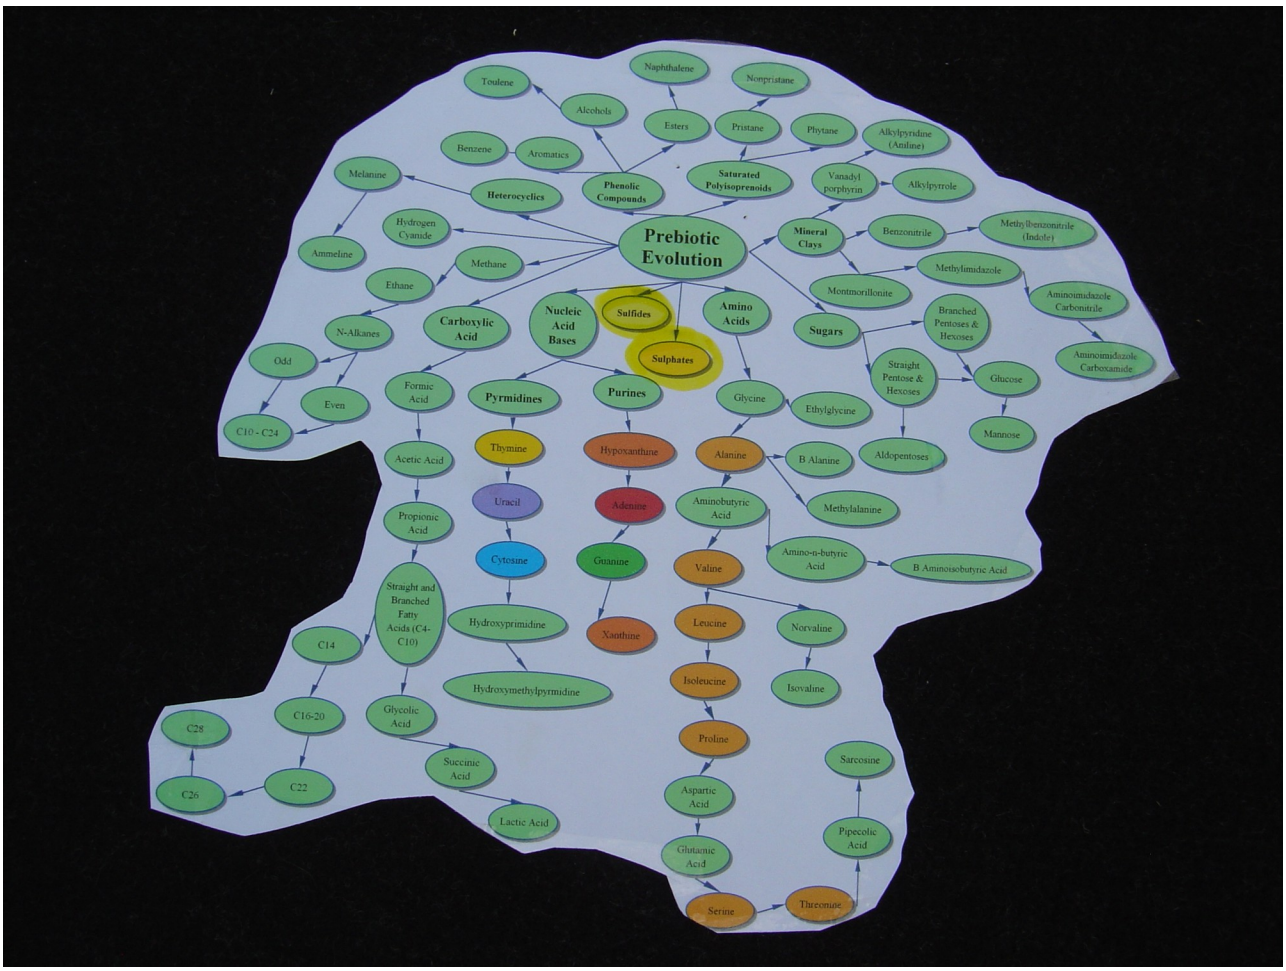

PLATE VII · PREBIOTIC EVOLUTION

The origin panel. Prebiotic Evolution sits near the center; the branches run outward to carboxylic acids, sugars, nucleic acid bases and amino acids. The Miller-Urey product table on the adjacent board has xanthine and hypoxanthine marked by hand.

PLATE VIII · SULFUR PROTEIN PHOTONIC COLOR HELICAL STRINGS

The upper light panel in detail. Water-cluster diagrams descend the left, the erythroblast series runs at the right, and fractal spheres occupy the center — atomic, molecular, cellular and tissue scales on one sheet.

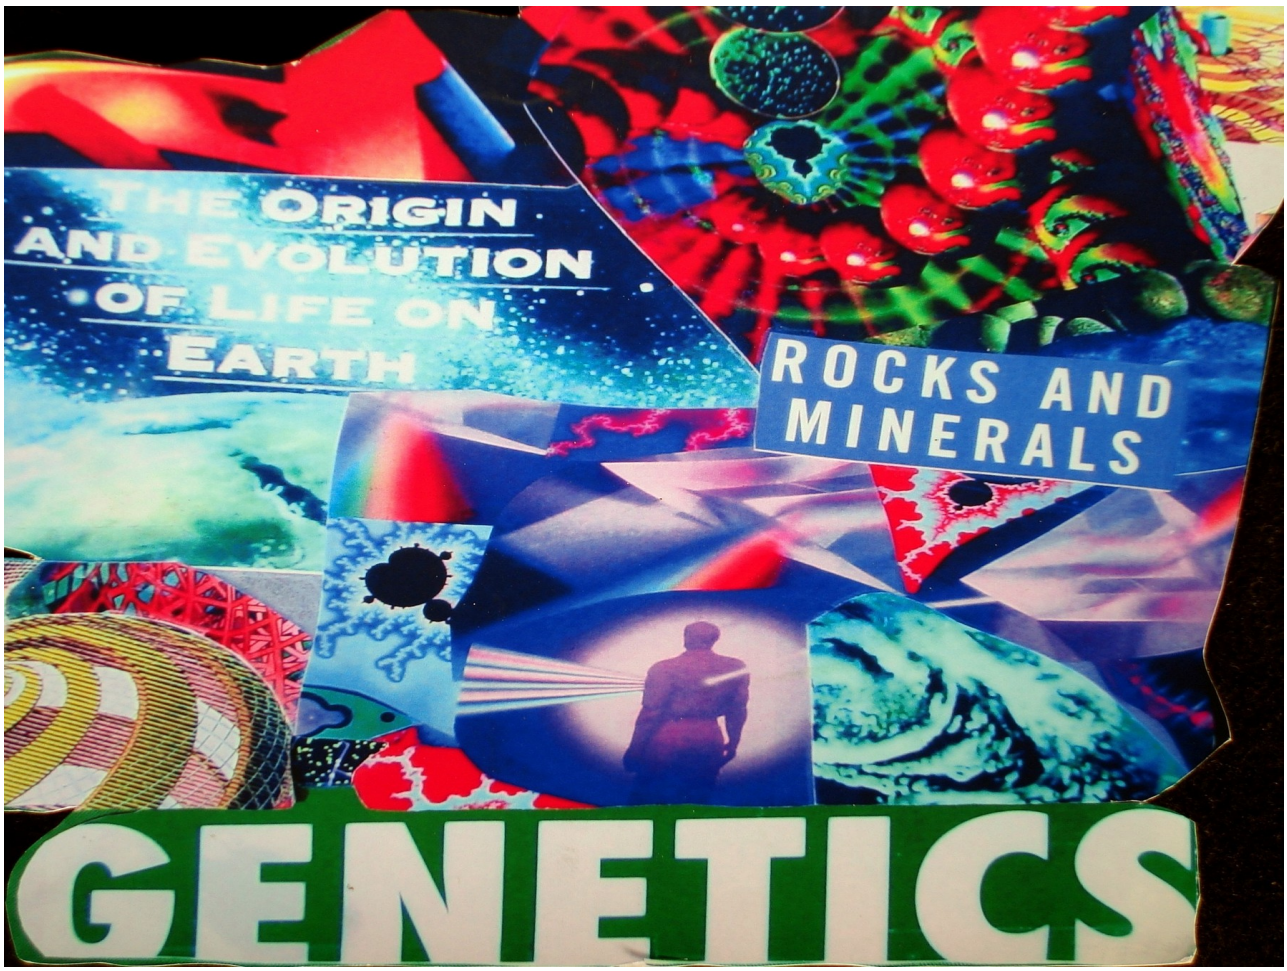

PLATE IX · THE ORIGIN AND EVOLUTION OF LIFE ON EARTH

Rocks and minerals, crystalline geometry, and a figure standing before a spectrum. The deep-time edge of the mural.

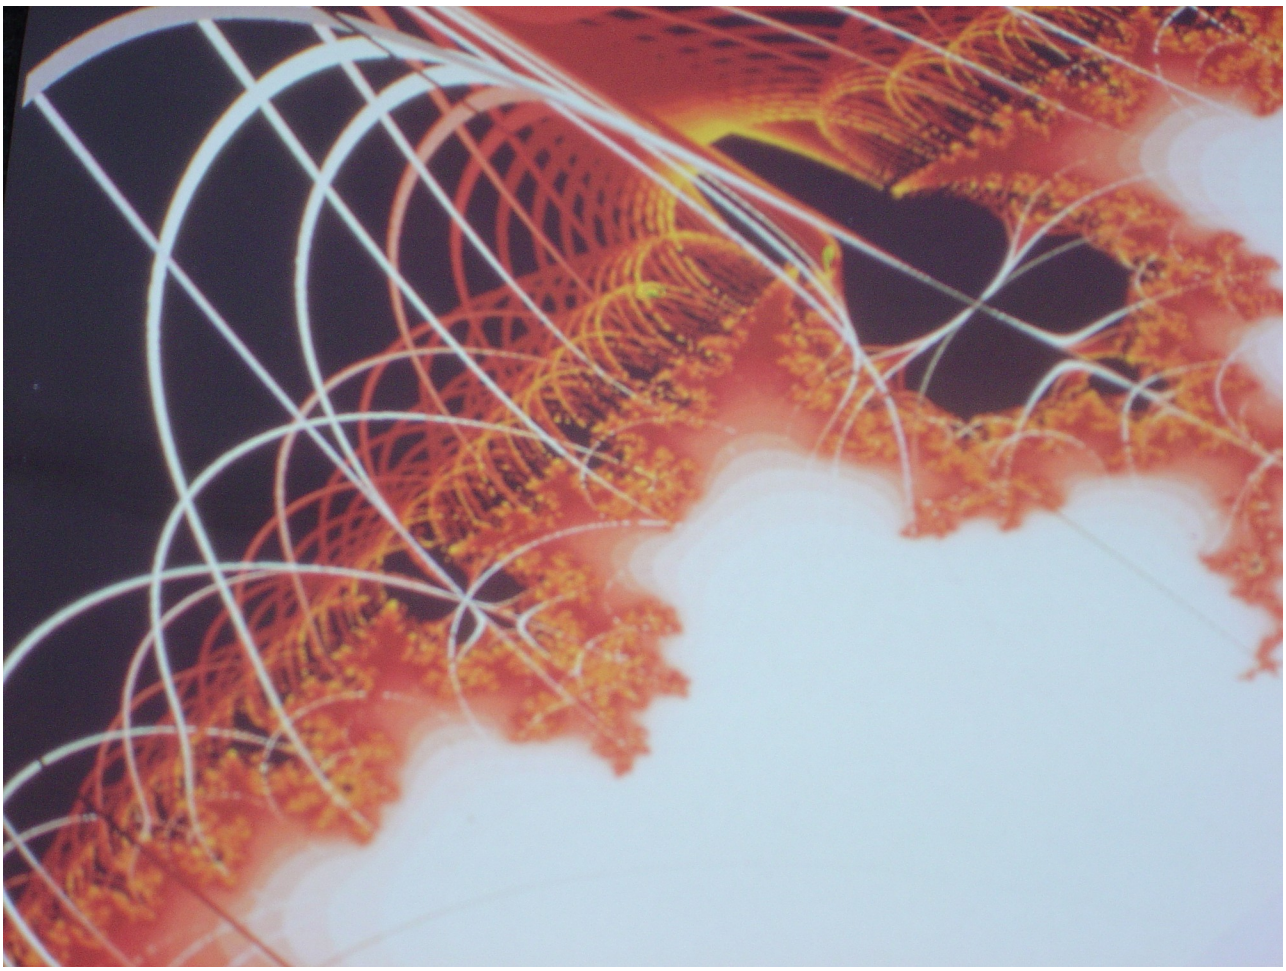

PLATE X · THE BOUNDARY, WITH COORDINATES

A Mandelbrot boundary crossed by a projected coordinate grid. The black region is connected — Douady and Hubbard, 1982 — although at this magnification the filaments joining its islands are finer than the print can carry.

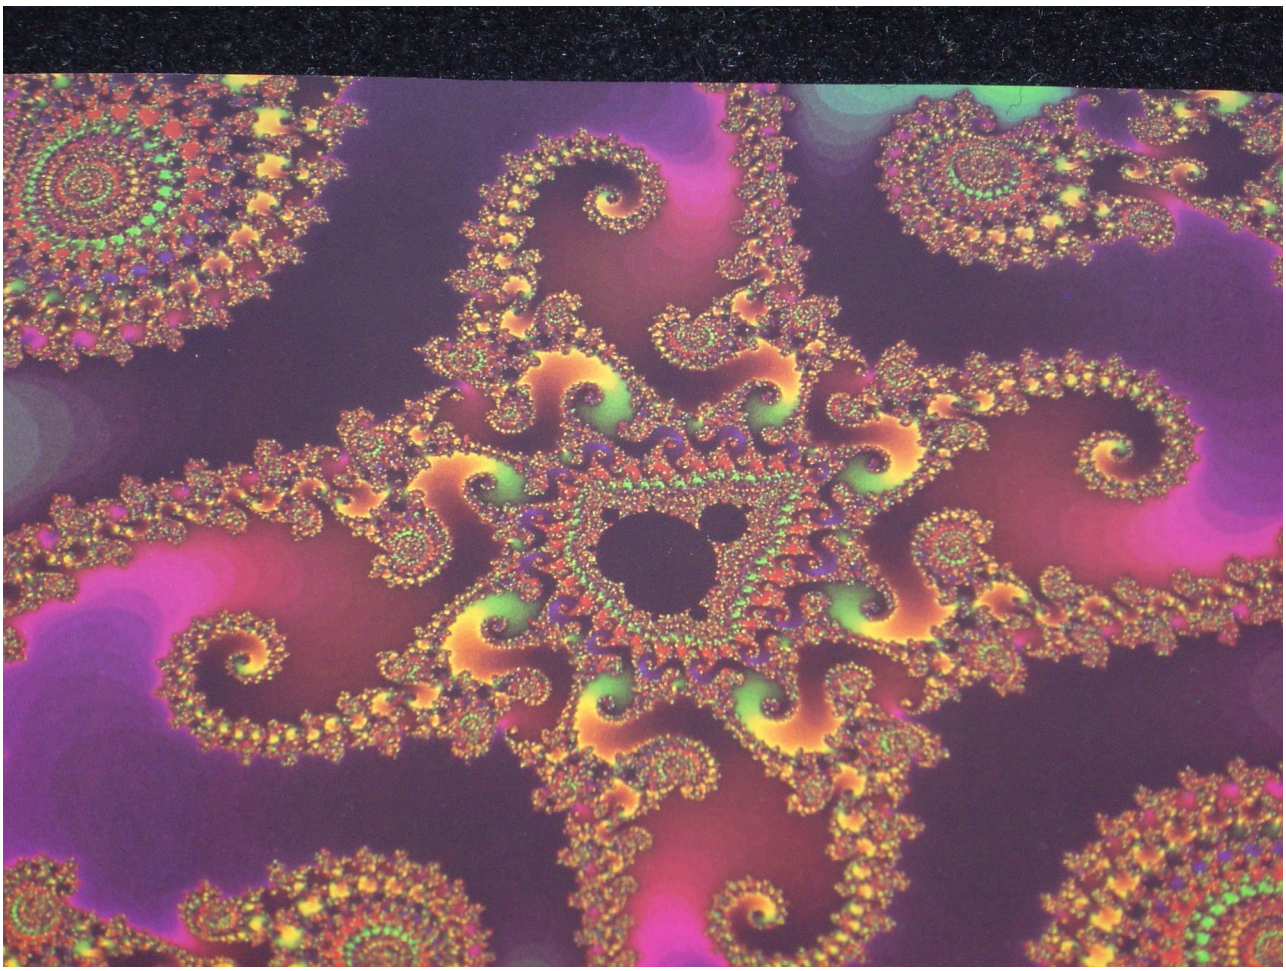

PLATE XI · A MINIATURE AT DEPTH

Deep in the filigree, a complete small copy of the whole set. It appears to be an island. It is not: a thread connects it to the main body, and the same is true of every copy at every scale. The emblem of the wall, and of this volume.

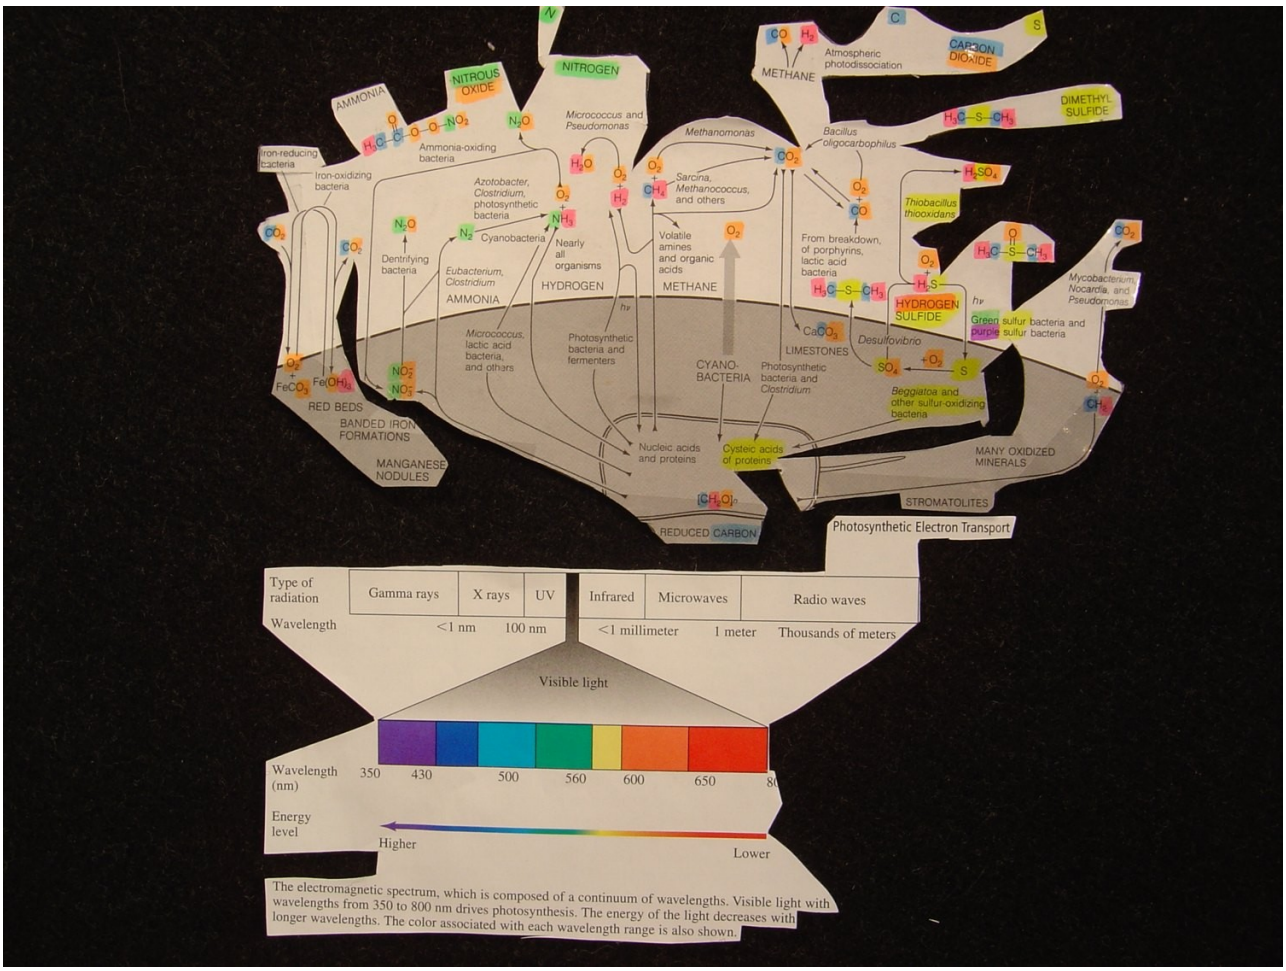

PLATE XII · THE ELECTROMAGNETIC SPECTRUM, WITH THE VISIBLE BAND

Gamma rays to radio waves along one axis, with the narrow colored band of visible light and its wavelengths in nanometers beneath. Pinned beside a metabolic map. This is the sheet that makes the light claim answerable: every element emits at wavelengths unique to it, and that is how sulfur is identified in a comet, in a star and in a cloud of interstellar gas.

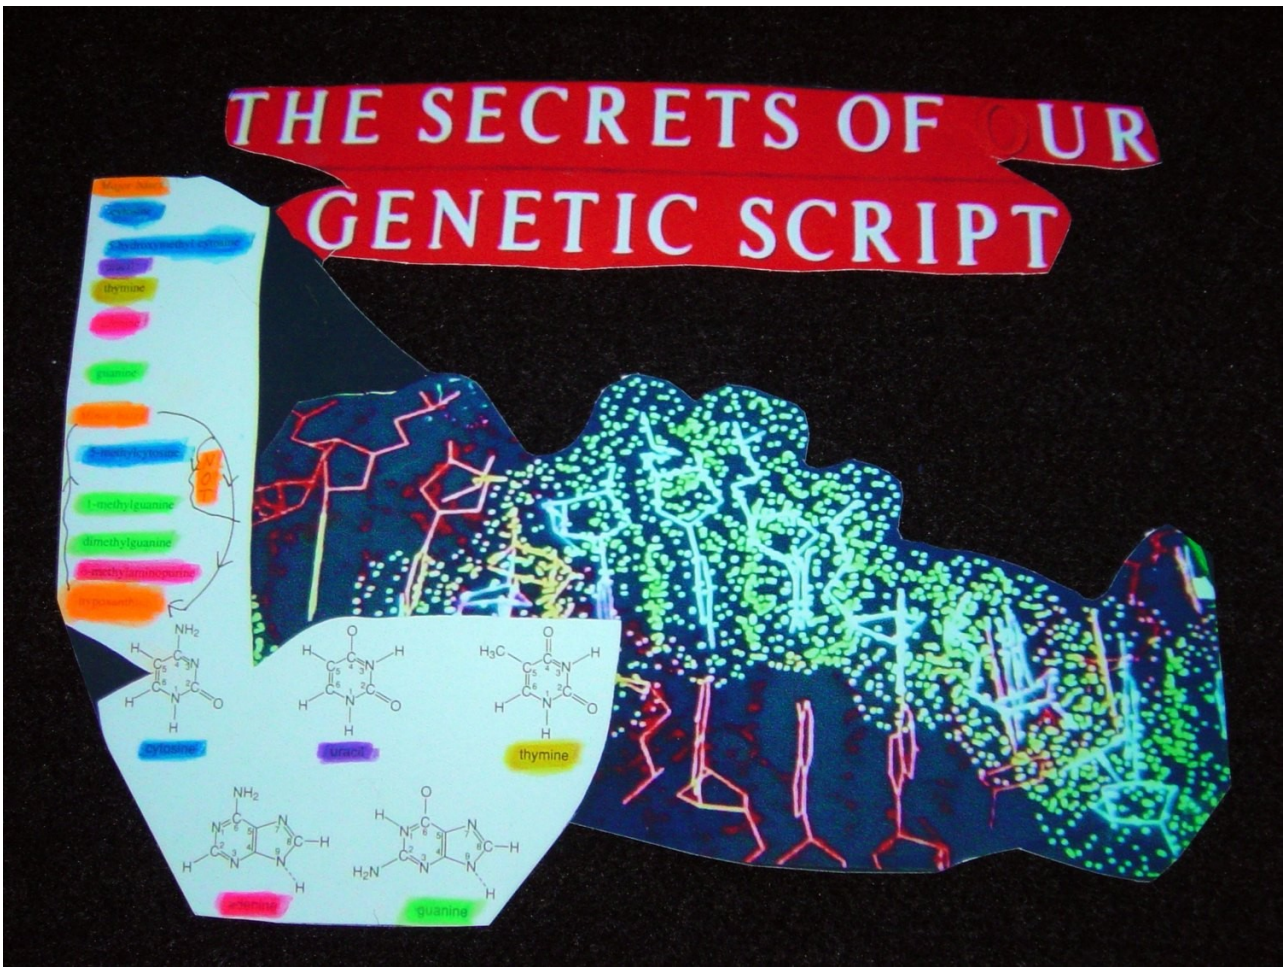

PLATE XIII · THE SECRETS OF OUR GENETIC SCRIPT

Purine and pyrimidine ring structures against a fractal field, with the drawn skeletons of the bases at the left and their atoms labeled.

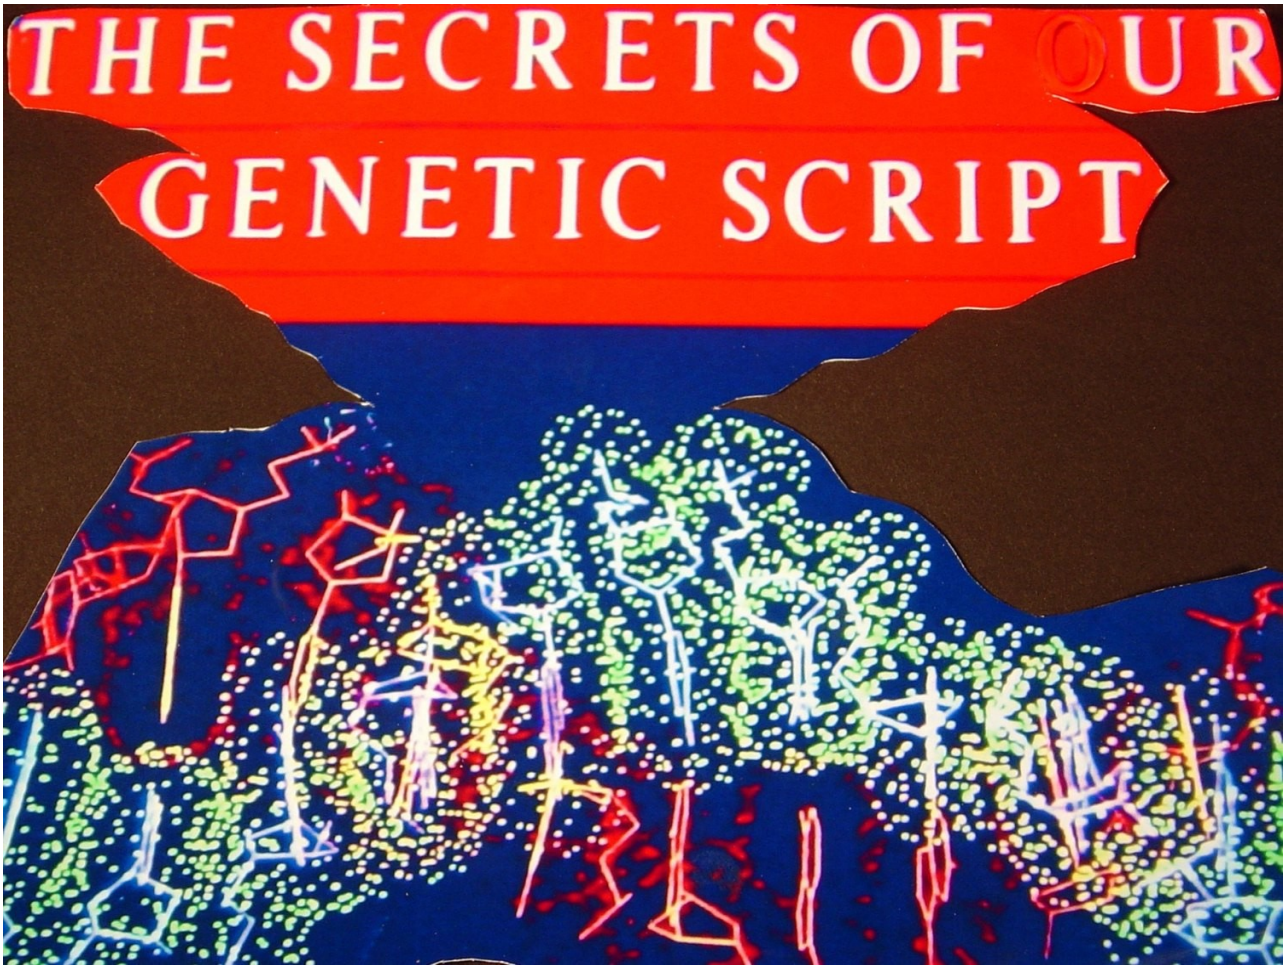

PLATE XIV · THE SAME PANEL, IN DETAIL

The base structures at closer range. The rings are six-membered, which is the shape the hexagon of Part Thirty-Eight was chosen to match.

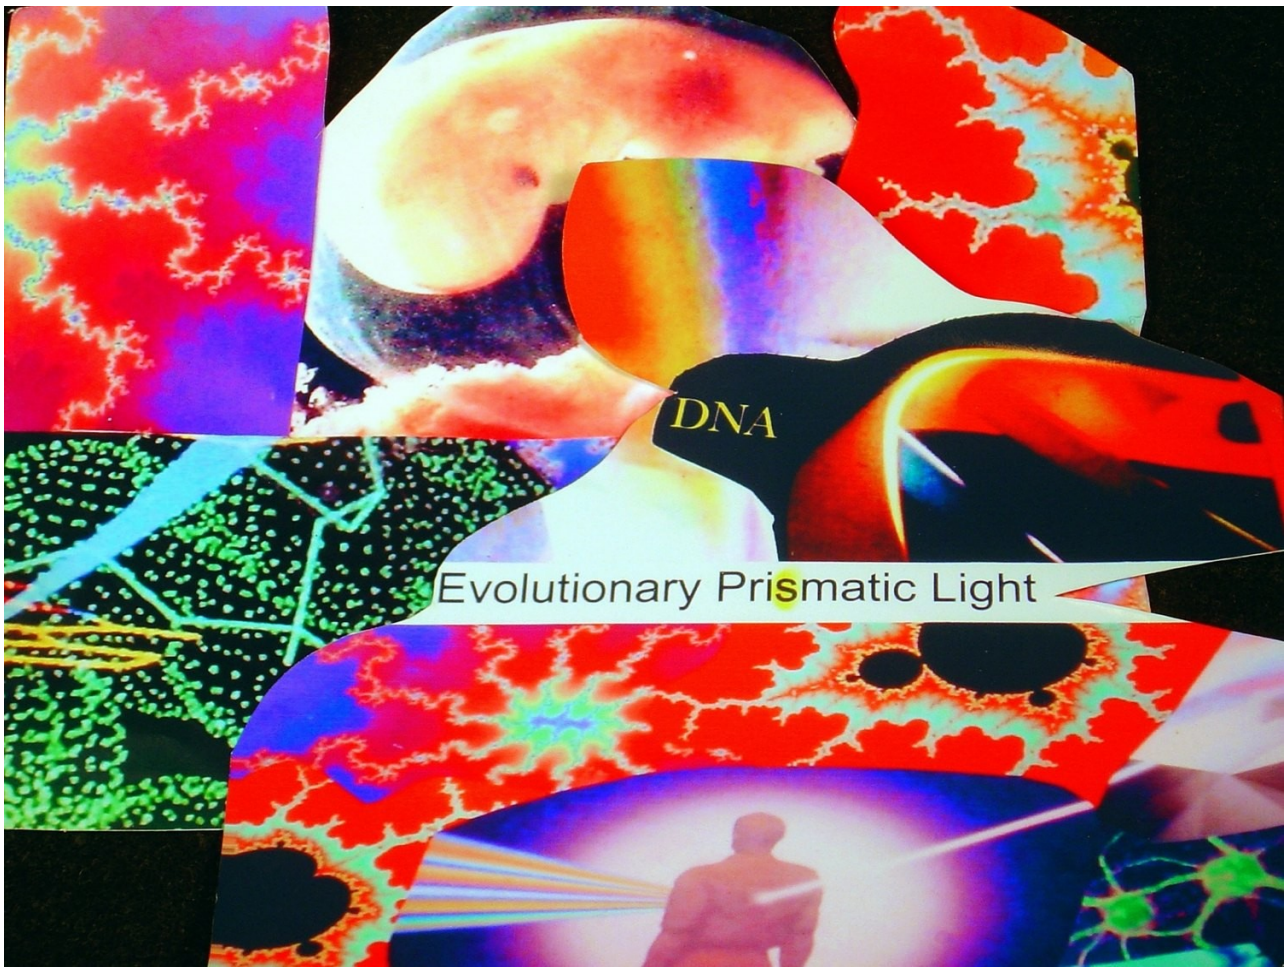

PLATE XV · EVOLUTIONARY PRISMATIC LIGHT, IN DETAIL

A figure seated before a spectrum, DNA above, and the Mandelbrot boundary running through the field. The panel that gives Part Thirty-Eight its emblem and the Preface its caution.

PLATE XVI · EARTH, THE MAKING OF A PLANET

A color wheel, a set of spectra and a crystal lattice arranged around the planet. The geological edge of the wall, where the sulfur isotope record begins.

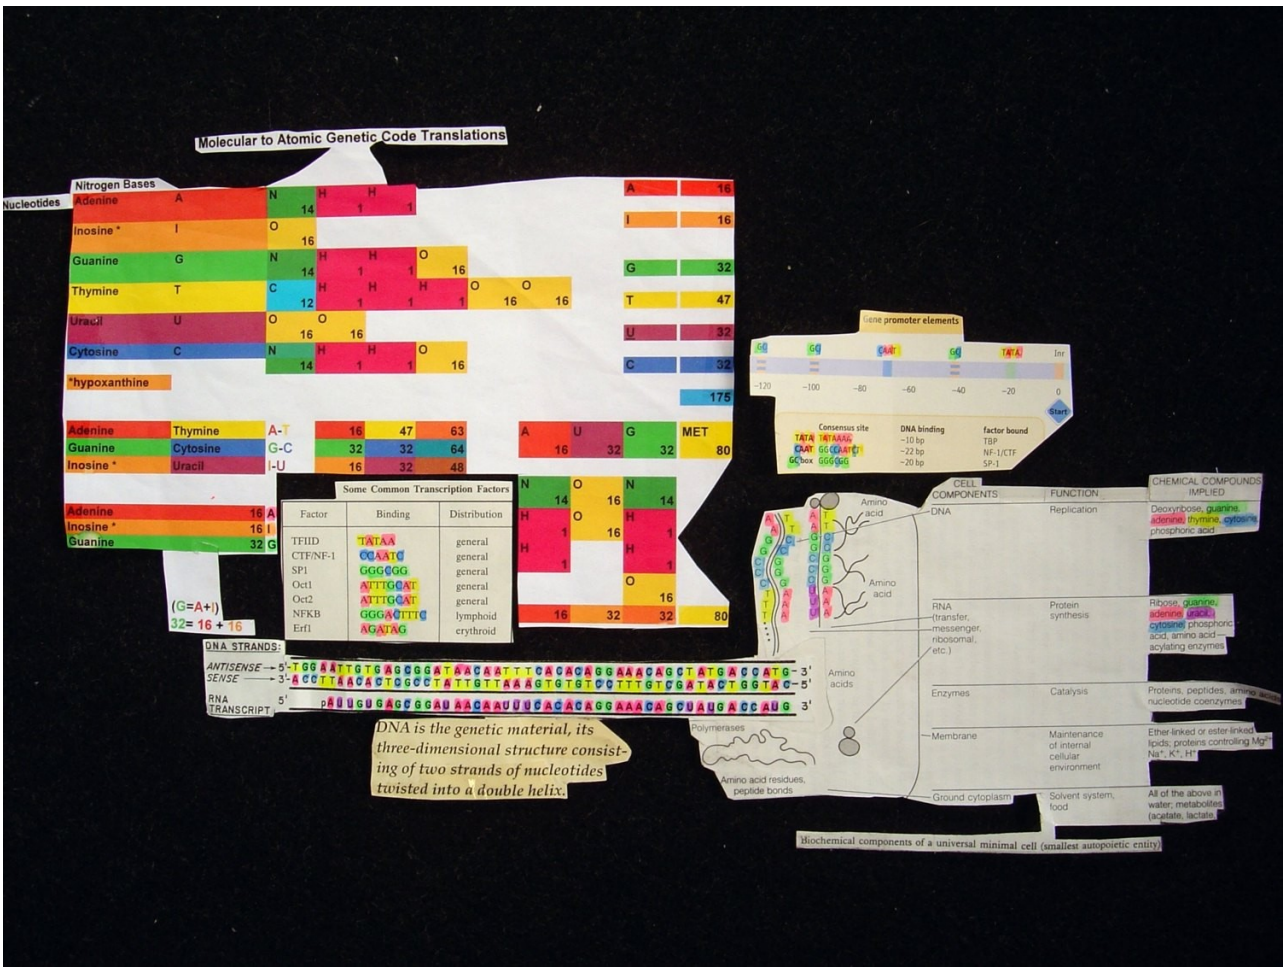

PLATE XVII · MOLECULAR TO ATOMIC TRANSLATIONS, SECOND BOARD

A second working sheet of the same translation, with the transcription-factor and base-content tables the author was reconciling against it.

On the standing of the plates. These are photographs of a physical object and of the author's own working charts. They are reproduced as record and as provenance. They are not data, they do not evidence any claim made in this volume, and the fractal plates in particular illustrate the shape of the argument rather than supporting it. The distinction is stated in the Preface and repeated here so that it travels with the images.

The color index — the whole family, at every depth

One color, one element, and the same molecule named at each of the three depths it is described at. The base is what pairs. The nucleoside is what sits in a polymer. The nucleotide is what metabolism moves. They are not three candidates for a place in the code; they are one entity, and the code needs all of it.

THE COLOR INDEX

Every shaded word in this volume is a link. A word with its own entry in the Index jumps to that entry; a letter, atom label or formula returns here.

color	element	base	nucleoside	nucleotide	the base, on pages	the element, on pages
ORANGE	O 8	HYPOXANTHINE	inosine	IMP	83, 111-114, 124, 131, 147-148, 158, 170, 174, 177-183, 186, 236, 249, 259, 328-330, 341, 343, 345-346, 355, 357, 361, 366-367, 370-371, 399-402, 481, 484, 503, 506, 508, 510, 512, 738, 749-750, 754, 761, 766, 768, 783, 789, 794, 801, 814, 817-820, 823, 825, 856-858, 863, 868, 871-872, 877-878, 882, 884, 887-893, 895-896, 898-901, 933, 935-936, 938-940, 942-944, 947, 979, 983, 990-991, 997, 1006-1011, 1013-1014, 1021, 1043, 1165, 1197, 1207-1214, 1237, 1240, 1242, 1262-1263, 1265, 1267-1268, 1331, 1345, 1401, 1444-1447, 1454, 1465, 1469, 1471, 1597, 1599, 1608	60, 62-63, 66-68, 72, 77, 79, 83, 85, 87-89, 91, 93-97, 100-102, 105, 107-113, 115, 118-119, 126-127, 133, 140-145, 148, 156-157, 159-160, 164-166, 168-171, 173-175, 180-183, 186-189, 192, 208-209, 213, 215, 217-219, 225, 227, 235, 237, 239-241, 243, 245, 254, 258, 267, 269-270, 277, 280, 307, 319-320, 323-324, 331-332, 348, 350, 361-362, 365, 370, 374, 397-400, 402, 426-432, 434, 437, 439, 442, 445-449, 451-458, 461-463, 467-469, 472-473, 475-477, 522-523, 549, 555-556, 643, 646-648, 654-655, 658-659, 662, 667, 702, 704, 714, 764, 775, 787, 789, 858, 895-896, 898, 932, 943, 950, 953, 959, 961, 974-975, 980-983, 987-988, 990, 997, 999, 1006-1007, 1010-1012, 1020-1021, 1027,

PART FIFTY-SEVEN · THE QUATERNION AND THE CODE

Part Fifty-Seven of the evidence volume, sections 268 to 276

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

There is a published quaternionic representation of the genetic code. This Part sets it beside the construction of Part Forty-Nine, states exactly where the two differ, and then makes the one join this volume had never made — hypoxanthine and the quaternion, on the same page, by an argument that can be checked in a minute.

268. What Is Already Published, and Why the Volume Must Say So ↩

The ground is occupied, and it was occupied first

A quaternionic representation of the genetic code exists in the literature. It assigns to each amino acid an integer quaternion in such a way that the observed codon degeneracy is preserved, and it does so through a codon function mapping each triplet onto an amino acid quaternion.

A later extension incorporates chirality. The eight integer quaternions of norm seven are partitioned into two conjugate sets, each corresponding to the D- or L-enantiomers of the four bases, and codons built from D-bases map onto L-amino acids.

A separate line of work links the quaternion group to the rotational symmetries of the genetic code and to hypercubes.

This volume does not claim the idea that the genetic code has a quaternionic structure. That claim is in print. What this volume claims is a different construction, arrived at independently, which carries the quaternion at a different level of the system — and the difference is the finding.

The bibliographic lines for the published work are to be completed at proof from the arXiv and MDPI records. They are named here as prior art because the volume's method is to say what exists before saying what is new.

---

269. The Published Construction, Described Fairly ↩

What it does

element	how the published model handles it
the carrier of the algebra	the amino acid — each of the twenty is an integer quaternion
the map	a codon function from triplets onto amino acid quaternions
what is preserved	codon degeneracy — synonymous codons land on the same quaternion
chirality	the eight integer quaternions of norm seven, split into two conjugate sets, giving D and L
sequence position	an order quaternion with real components, encoding position in the chain
the application	transform the quaternion sequence into a three-dimensional structure and compare with the Protein Data Bank
the evolutionary claim	broken symmetry in the code's development, aligned with Crick's account of the code's origin

Why the choice of quaternions is defensible there

Quaternions describe rotations in three dimensions. A protein is a chain whose shape is determined by rotations about its backbone bonds. A formalism that

encodes both the residue identity and a rotation in one object is therefore a natural fit for folding, and that is the argument the published model makes.

This volume has said the same thing in Part Thirty-Four, from the docking side: the rotation group is the enumerated outer loop of rigid-body docking, and the quaternion on the three-sphere is the pose coordinate of current generative docking software. The two arrive at the same utility from opposite directions.

---

270. Where This Volume's Construction Differs ↩

The two side by side

	the published model	Part Forty-Nine of this volume
what carries the algebra	the amino acid — twenty objects	the base substitution — three operations
the algebra used	integer quaternions of norm seven	the quaternion group modulo its center, which is the Klein four-group
what is preserved	codon degeneracy	closure under complement
how chirality enters	built in, by conjugate partition	as an exclusion — homochirality is the operation biology does not admit
the geometric object	the hypercube	the cube, and its dual the octahedron
where i, j and k sit	on amino acids	on the three perpendicular face axes — complement, transversion and transition
what the model predicts	tertiary structure from sequence	which symbols can be letters and which cannot

The difference stated in one sentence

The published model puts the quaternion at the output of translation. This volume puts it at the alphabet. One asks what shape a sequence will fold into; the other asks why the alphabet has four symbols rather than five.

Neither displaces the other, and they are not in competition. A reader who accepts both has a quaternionic account of the code at two levels — the substitutions that generate the alphabet, and the residues the alphabet installs.

And one caution the volume should print

A widely circulated informal account holds that inosine can be embedded in a quaternion by treating the word as a real coefficient — writing something of the form q equals inosine plus two i plus three j plus four k.

That is not a result. It is a variable with a chemical name. Nothing about the molecule enters the algebra, and no statement about biology can be recovered from it. The volume records this because it is the kind of construction that looks like the real thing and is not.

The join in the next two sections is offered precisely because it is not of that kind.

---

271. The Join This Volume Had Not Made ↩

An absence found by counting, not by reading

A computational pass over this volume measured which strong concepts have never appeared on the same page. Among 242 index terms across 412 body pages, one pair stood out.

term	pages it appears on
hypoxanthine	41
quaternion	43
pages shared	zero

The molecule this corpus was built around and the algebra it was built with had never once shared a page. Twenty-nine years, four hundred and sixty-eight pages, and the two central objects of the work had never been put in the same room.

This section puts them there, and the argument is elementary.

---

272. What Inosine Excludes ↩

The three-way pairing, and the one base left out

At position thirty-four of the anticodon, inosine pairs with three of the four bases.

inosine pairs with	inosine does not pair with
uracil	
cytosine	
adenine	guanine

That is the standard wobble rule and it is in every textbook. What follows from it is not.

The substitution group, restated from Part Forty-Nine

Three operations act on the four bases, and with the identity they form the Klein four-group — the quaternion group with the sign forgotten.

operation	what it does
alpha, complement	A to T, G to C
beta, transversion	A to C, G to T
gamma, transition	A to G, C to T

Gamma is the transition. It is the operation that carries a purine to the other purine and a pyrimidine to the other pyrimidine, and it is the third of the three perpendicular face-axis half-turns — the image of the quaternion unit k.

The join

Adenine pairs with exactly one base: uracil. Inosine is adenine with its amino group removed, and it pairs with three.

The single base inosine excludes is guanine. And guanine is the transition image of adenine — gamma of A. Deamination takes a base that pairs with one partner and turns it into a base that pairs with everything except the image of its own parent under the transition operation.

Verified by construction: gamma of A is G; inosine's pairing set is uracil, cytosine and adenine; the complement of that set within the four bases is exactly guanine.

What that means

Inosine is not a quaternion and this volume does not say it is. What inosine does is collapse the third-position distinction that the substitution group makes — and it collapses it everywhere except across one operation.

The wobble base is the physical implementation of a partial quotient. It makes three of the four bases indistinguishable at the third position, and the one distinction it preserves is the transition — the operation that separates purine from purine.

The molecule is doing group theory. Not by analogy — by which pairings it makes and which one it refuses.

---

273. The Same Test on the Other Two Deaminations ↩

Three deaminations, and what each does to pairing

the conversion	the enzyme	pairing before	pairing after
adenine to hypoxanthine	adenosine deaminase, ADAR	U only	U, C, A — excludes G, which is gamma of A
guanine to xanthine	guanase	C only	degraded, not read
cytosine to uracil	cytidine deaminase	G only	A only

What the comparison shows

Only one of the three deaminations produces a base that reads. Adenine to hypoxanthine expands pairing from one to three. Guanine to xanthine leaves the coding system entirely — xanthine is catabolized, not installed. Cytosine to uracil is a substitution rather than an expansion: it swaps one exclusive partner for another.

Of the three ways the cell removes an amino group from a base, exactly one produces a symbol the ribosome can use, and that one produces the only base in biology that pairs with three partners. The volume has called inosine the central molecule of this work for twenty-nine years. The group-theoretic reason is that it is the only deamination product that survives into the reading alphabet.

And it connects directly to Part Forty-Eight. The six-symbol reading set is closed under reading and not under complement, and inosine is the reason it is not — it is the symbol whose whole function is that it has no unique partner.

274. Why a Quaternion Cannot Be a Molecule ↩

The limit, stated so it is not overstepped

A quaternion is an element of a four-dimensional associative division algebra over the reals. A molecule is an arrangement of nuclei and electrons. There is no sense in which one is the other, and every claim in this Part is a claim about operations rather than about substances.

what is legitimately quaternionic	what is not
the group of base substitutions, which is the quaternion group modulo its center	the bases themselves
rotations of the backbone, which the pose coordinate of a docking program encodes	the residue
the three perpendicular half-turns of the cube	the cube's material
the transition operation as the image of k	inosine as a number

The algebra acts on the alphabet. It does not live in the molecules. Everything this Part claims is a statement about which operations close and which do not, and every one of them can be checked against a pairing table.

275. What Is Claimed and What Is Not ↩

Claimed

That a quaternionic representation of the genetic code exists in the published literature, carries the algebra on the amino acids, preserves codon degeneracy, and

has been extended to chirality through the eight integer quaternions of norm seven. That this volume's construction carries the algebra on the base substitutions instead, and that the two operate at different levels of the system. That inosine at anticodon position thirty-four pairs with uracil, cytosine and adenine and does not pair with guanine. That guanine is the transition image of adenine under the third element of the Klein four-group. Therefore that the single base inosine excludes is the image of its own parent under the transition operation — verified by construction rather than asserted. That of the three deaminations of a base drawn on the nucleotide panel, only adenine to hypoxanthine yields a symbol the translation machinery reads.

Not claimed

That inosine is a quaternion, or that any molecule is. Section 274 states the limit and this Part does not cross it.

That the exclusion of guanine by inosine is caused by the group structure. It is caused by hydrogen-bonding geometry. The claim is that the chemical fact and the group-theoretic fact coincide exactly, and the coincidence is worth recording.

That this volume's construction supersedes the published one. It does not, and section 270 sets them side by side rather than in rank.

---

276. What Would Show This Part Is Wrong ↩

- Show that inosine pairs with guanine at the wobble position in any organism, and the whole of sections 272 and 286 fails.
- Show that the transition image of adenine is not guanine, and the join is arithmetic nonsense. This cannot be shown, and the condition is printed because a falsification condition that cannot be met should be declared to be of that kind.
- Identify a fourth base deamination that yields a symbol the ribosome reads, and section 273's uniqueness claim is not general.
- Show that the published quaternionic code model carries its algebra on the substitutions rather than on the amino acids, and the distinction drawn in section 270 collapses and this volume's construction is not independent of it.

— Show that the eight integer quaternions of norm seven do not partition into two conjugate sets, and the chirality extension described in section 268 is misreported here.

PART FIFTY-EIGHT · NUCLEOTIDE METABOLISM AND DISEASE

Part Fifty-Eight of the evidence volume, sections 277 to 287

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Purine and pyrimidine metabolism as clinical medicine. The four modules whose failure produces disease, the finding that purines and pyrimidines are not interchangeable, and two results in which this volume's own two molecules — inosine and xanthine — appear as measured markers of human disease.

---

277. The Four Modules ↩

Where nucleotide metabolism can fail

Disorders of purine and pyrimidine metabolism originate from abnormal enzyme function in one of four molecular modules.

module	what it does	what its failure produces
de novo synthesis	builds the ring from small precursors	depletion of the nucleotide pool
catabolism	dismantles the ring	accumulation of toxic intermediates
metabolite recycling — the salvage pathway	recovers free bases	depletion, and loss of an energy saving
excretion	clears the end products	accumulation, stones, gout

Two failure modes, and only two: the cell either runs out of a nucleotide or drowns in an intermediate. Every disorder in this class is one or the other, and which one it is decides the treatment.

Management is correspondingly binary — reduce the overproduction of a metabolite that has become toxic, or replace the one that is deficient.

What both pathways depend on

Salvage and de novo both require phosphoribosyl pyrophosphate, PRPP, produced from ATP and ribose-5-phosphate by PRPP synthetase. The enzyme is inhibited by AMP, ADP and GDP, which are the markers of a low-energy state.

PRPP levels are low in postmitotic cells and high in proliferating ones. The gate that Part Forty-One identified as the committed step of purine synthesis is also the gate that reports whether a cell intends to divide.

And PRPP comes from ribose-5-phosphate, which comes from the pentose phosphate pathway, which comes from glucose. The chain from Part Fifty-Four's glucose to this Part's nucleotide runs through one sugar and one enzyme.

---

278. The Inborn Errors, and Their Key Terms ↩

The diagnostic vocabulary, as it is filed

The mainstay of diagnosis is the analysis of blood and urine purines and pyrimidines, and erythrocyte extracts may be used for nucleotide profiling.

the purine terms	the pyrimidine terms
inosine, **inosine monophosphate**	orotic acid, dihydroorotic acid, orotidine
hypoxanthine, **xanthine**, **uric acid**	uridine, thymidine, cytidine
adenosine, **adenosine monophosphate**, **deoxyadenosine**	uracil, thymine
guanosine, **guanosine monophosphate**, **guanine**, **adenine**	dihydrouracil, dihydrothymine
SAICA-ribotide, AICA-ribotide, succinyladenosine	ureidoisobutyrate, ureidopropionate, beta-alanine
phosphoribosylpyrophosphate	

The clinical presentations

presentation	
immunodeficiency	adenosine deaminase and purine nucleoside phosphorylase

presentation	
	deficiency
nephrolithiasis	stones from insoluble end products
gout	uric acid
seizures	
intellectual disability	

Every molecule on the purine list in the left column is drawn on the colored nucleotide panel of Part Forty-Seven. The panel this volume colored atom by atom is, without alteration, a clinical diagnostic chart.

That is worth stating in the volume's own terms. The four metabolism charts were teaching material. The metabolites they draw are the analytes a hospital laboratory measures.

---

279. Purines and Pyrimidines Are Not Interchangeable ↩

The finding, and why it matters to Part Forty-Eight

The historical view treats pyrimidines and purines as obligate paired substrates for nucleic acid synthesis. Recent work replaces that with a class-specific account.

the current position	
purines and pyrimidines have distinct, non-overlapping regulatory functions	
DNA damage responses are tied to one class or the other, not both	
mTORC1 regulation is tied specifically to purines	mTORC1 can sense purine abundance
the two classes are independently controlled	

The literature now holds that the two nucleotide classes are not functionally interchangeable and, perhaps as a result, are independently controlled. That is an empirical statement, arrived at

through cancer biology, and it is the same statement Part Forty-Eight makes on group-theoretic grounds.

Part Forty-Eight argued that the eight-symbol manufacturing set splits into four purines and four pyrimidines running along two separate roads with two separate gates — inosine and xanthosine on one, orotate on the other — and that the set closes under nothing because a biosynthetic route is directed.

The cancer literature has reached the same separation from the direction of regulation.

---

280. Inosine in Cancer — the Endometrial Finding ↩

What was measured

In endometrial carcinoma, the enzymes catalyzing the four reactions that metabolize ATP to inosine in purine metabolism are all up-regulated.

the consequence	
increased AMP	
increased inosine 5'-monophosphate	
increased inosine	
interpretation given	activation of the entire purine metabolism pathway

Purine metabolism has also been reported to contribute to tumor cell infiltration into muscle in this disease.

Four enzymes in series, every one of them up-regulated, and the product they converge on is inosine. The molecule this volume has spent twenty-nine years arguing is the unnamed center of the code is a measured, elevated marker in a human cancer.

And the pyrimidine side of the same disease

Cytidine deaminase converts cytidine to uridine. In endometrial carcinoma cytidine is up-regulated and uridine is down-regulated, consistent with a lack of that enzyme, and CDA deficiency has been shown to cause DNA damage associated with tumorigenesis.

Cytidine to uridine is the third deamination of Part Forty-Seven and the third of section 273. In this disease it fails, and the failure is measurable in the ratio of the two metabolites.

281. Xanthine in Disease — the Gestational Diabetes Finding ↩

What was measured

In a three-part longitudinal metabolomics study of a Chinese cohort, urinary excretion of nucleosides was elevated in participants who developed gestational diabetes mellitus.

finding	
the most notable nucleosides were those of purine metabolism	
urinary xanthine was a significant risk factor for developing the disease	p below 0.05
area under the receiver-operating characteristic curve	above 0.8 in each of the three trimesters

Xanthine — the molecule this volume calls the valve, the symbol with no base-pairing partner, the corner of the cube left over — predicts gestational diabetes with an area under the curve above 0.8, in all three trimesters, in a longitudinal cohort.

The rest of the picture

Accelerated nucleotide synthesis in diabetic erythrocytes has been reported as a primary cause of the increase in adenine and guanylate nucleotide pools, and acceleration of synthesis stimulates breakdown, raising the concentration of degradation products. Altered purine metabolism is associated with diabetic retinopathy and diabetic nephropathy, and elevated first-trimester uric acid is associated with increased risk of gestational diabetes and insulin resistance.

Uric acid is the terminal product of the purine road. Xanthine is the step before it. The volume has drawn that step since Part Forty-One. The clinical literature measures it in urine and uses it to predict a disease.

282. Ribonucleotide Reductase, Rrm2 and Senescence ↩

The volume's own enzyme, in cancer biology

Part Forty-Seven established that thioredoxin is the only sulfur-bearing molecule drawn on the entire nucleotide panel, that it appears four times, and that the enzyme it serves — ribonucleotide reductase — removes the 2'-hydroxyl.

That enzyme is the subject of an oncogene-induced senescence literature.

finding	
senescence induced by activated oncogenes such as RAS	accumulation of cells in S phase
the cause	replication stress from decreased dNTP levels
the mechanism	a transcriptional decrease in RRM2, whose expression is rate-limiting for the reduction of ribonucleotides to deoxyribonucleotides
the rescue	restoring RRM2, or supplying exogenous nucleosides, overcomes the replication stress
the checkpoint	stalled forks activate ATR; collapsed forks activate ATM

A cell escapes an activated oncogene by turning down the enzyme that makes DNA. The brake on cancer, in this account, is the deliberate starvation of the one reaction on the whole nucleotide panel that requires a sulfur.

Part Forty-Seven called ribonucleotide reductase the crossing point where the only yellow removes an orange. This section adds that the crossing point is also a tumor suppression mechanism.

283. Dhodh, the Trial That Failed, and the Ferroptosis Dispute ↩

The enzyme this volume already carries

Part Thirty-Seven identified dihydroorotate dehydrogenase as the one enzyme of nucleotide synthesis wired into the respiratory chain, and Part Forty-Three placed it in the ferroptosis landscape.

the current position	
DHODH has a role in cellular adaptation to electron transport chain impairment	established
DHODH has a role in ferroptosis prevention	reported, and disputed
DHODH inhibition triggers differentiation in leukemia	reported, dependent on replication stress but independent of replication-stress signaling
BAY 2402234, a DHODH inhibitor, in myeloid malignancy	trial NCT03404726 terminated for lack of sufficient clinical benefit

Why the volume prints the failure

Because the volume's method is to print the trial that missed its endpoint.

BAY 2402234 is named in Part Thirty-Seven as an agent of interest. The trial has now terminated without sufficient benefit. That is recorded here rather than left standing, and the mechanism it was built on — that blocking pyrimidine synthesis forces a blocked cell to differentiate — remains supported even though the agent did not deliver.

The gap between a correct mechanism and a working drug is the subject of Part Forty-Three's Eroom's Law material, and this is an instance of it.

284. Pyrimidine Catabolism as a Differentiation Signal ↩

The non-proliferative role

Nucleotide metabolism in cancer has been studied almost entirely as a proliferation problem. A separate line of work argues that pyrimidine metabolism does something else.

tissue	what pyrimidine catabolism does there
leukemic cells	induces terminal differentiation toward the monocytic lineage,

tissue	what pyrimidine catabolism does there
	checking aberrant proliferation
triple-negative breast cancer	maintains the mesenchymal-like state driven by epithelial-to-mesenchymal transition
hepatocellular carcinoma	the same mesenchymal maintenance
the proposal	pyrimidine molecules as oncometabolites

The same chemistry stops proliferation in one tissue and sustains an invasive state in another. A pyrimidine is not a building block being consumed; it is a signal being read, and what it means depends on where it is read.

And the purines already had this status

Purines have long been established as ligands for purinergic signaling. Secreted nucleotides and nucleosides modulate antitumor immunity through those receptors. Nucleosides can also be degraded to sustain tumor cell metabolism during nutrient deprivation — they are a fuel of last resort.

Three roles, then, for one class of molecule: the letters of the archive, the currency of a signal, and an emergency fuel. The volume has argued from Part One that a notation naming only the first of the three is an incomplete notation.

---

285. The Sources, as Filed ↩

The material this Part rests on

source	year	what it supplied
Kim and Hoxhaj, Nature Cell Biology	2026	dynamic control, feedback, higher-order spatial organization into multi-enzyme assemblies and filaments, tissue-selective pathology
Shi and colleagues, ending McBrayer, Trends in Cancer	2023	purines and pyrimidines not interchangeable; DHODH; BAY 2402234; cell-fate roles
Siddiqui and Ceppi, Molecular Metabolism	2020	the non-proliferative role of pyrimidine metabolism; differentiation and EMT
Aird and Zhang, Cancer Letters	2015	dNTP pools in oncogene-induced senescence; RRM2; ATR and ATM

source	year	what it supplied
Li and colleagues, ending Dai, Biomedicine and Pharmacotherapy	2023	endometrial carcinoma; the four enzymes to inosine; CDA
Law and Zhang, Clinica Chimica Acta	2017	gestational diabetes; urinary xanthine; the three-trimester AUC
Bacigalupa and Rathmell, Cancer Letters	2020	clear cell renal carcinoma; PPP; R5P; transketolase and TKTL1; PRPP
Puigserver, Hematology, seventh edition	2018	the salvage and de novo pathways; PRPP synthetase; c-myc
Armstrong and colleagues, ending Gooley, Advances in Clinical Chemistry	2014	chronic fatigue syndrome; the three amino acid donor reactions; folate
the purine and pyrimidine disorders chapter	—	the four modules; the diagnostic key terms

Full bibliographic lines are to be completed at proof. Each source is named here by author, journal and year so that the claim it supports can be traced.

The transketolase note, which belongs to Part Thirty-Five

In clear cell renal carcinoma, transketolase-like protein 1 prevents transketolase homodimer formation by binding it as a heterodimer, causing ribose-5-phosphate to accumulate.

Transketolase is a thiamine enzyme. Part Thirty-Five placed it at the arabinose-ribose junction. This is the same enzyme, disabled by a partner protein, and the consequence is a pile-up of the sugar that becomes PRPP.

---

286. What Is Claimed and What Is Not ↩

Claimed

That disorders of purine and pyrimidine metabolism arise in one of four modules — de novo synthesis, catabolism, recycling and excretion — and that the failure modes are depletion or toxic accumulation. That both synthetic routes depend on PRPP and that PRPP synthetase is inhibited by AMP, ADP and GDP. That the current literature holds purines and pyrimidines to be functionally non-interchangeable and

independently controlled. That in endometrial carcinoma the four enzymes converting ATP to inosine are all up-regulated and AMP, IMP and inosine are all elevated. That urinary xanthine was a significant risk factor for gestational diabetes with an area under the curve above 0.8 in each of three trimesters. That oncogene-induced senescence proceeds through a transcriptional decrease in RRM2 and is rescued by restoring RRM2 or supplying nucleosides. That the DHODH inhibitor BAY 2402234 trial NCT03404726 was terminated for insufficient clinical benefit, and that DHODH's role in ferroptosis prevention is disputed.

Not claimed

That elevated inosine causes endometrial carcinoma. It is a measured feature of the disease and the direction of causation is not established by the observation.

That xanthine causes gestational diabetes. It is a predictive marker with a stated area under the curve, which is a statement about prediction and not about mechanism.

That the volume's color census of the nucleotide panel has clinical validity. The overlap between the metabolites drawn on that panel and the analytes a laboratory measures is real and is noted in section 278. No diagnostic claim follows from it.

That any statement in this Part is medical advice. It is a summary of published findings and nothing in it should be used to guide the management of a patient.

---

287. What Would Show This Part Is Wrong ↩

— Show that purine and pyrimidine disorders arise in a fifth module not named in section 277, and the four-module account is incomplete.

— Show that PRPP is not required by both the salvage and the de novo route, and section 277's identification of a single common gate fails.

— Show that the enzymes converting ATP to inosine are not co-ordinately up-regulated in endometrial carcinoma, and section 280's central exhibit is misreported.

— Show that urinary xanthine does not discriminate gestational diabetes above an area under the curve of 0.8, and section 281 falls.

— Show that RRM2 restoration does not rescue replication stress in oncogene-induced senescence, and section 282's mechanism is not the mechanism.

— Establish that DHODH does prevent ferroptosis, without dispute, and section 283 should print the finding rather than the disagreement.

— Show that pyrimidine catabolism does not induce monocytic differentiation in leukemic cells, and section 284's non-proliferative account has no leading exhibit.

PART FIFTY-NINE · THE EDITOR

Part Fifty-Nine of the evidence volume, sections 288 to 300

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Adenosine-to-inosine RNA editing, the enzymes that perform it, and the marginalia the author wrote on a review of it nine years ago. Four of those margin notes are computations. All four have been checked, all four are correct, and two of them state a quantity the paper itself does not.

---

288. The Enzyme That Rewrites the Code After It Is Written ↩

What ADAR does

Adenosine deaminases acting on RNA remove the amine group at the C6 position of an adenosine in a double-stranded region of RNA, producing inosine. The reaction is hydrolytic, the catalytic machinery is a conserved C-terminal deaminase domain, and the substrate adenosine is flipped out of the duplex into a catalytic pocket — the same base-flipping mechanism used by other base-modifying enzymes.

Because the base-pairing properties of inosine mimic those of guanosine, the cellular machinery reads the product as G.

the notation says	the machinery reads
A	A, unedited
A, after ADAR	G

The genome says adenine. The transcript says inosine. The ribosome says guanine. Three different answers to the same question, and the four-letter alphabet can express only the first and the third.

This is the volume's central claim arriving in its most direct form. Part One argued that the notation omits the variable that decides function. Here the notation omits an entire symbol that is physically present in the molecule being read.

What the author wrote in the margin

Beside the paper's phrase "dynamically rewire the genetic code" the author wrote, nine years ago, two words: LEFT OUT OF GENETIC CODE. Beside "functional consequences" he wrote WOBBLE CODE.

The volume has spent twenty-nine years on the first of those notes.

---

289. The Reaction, Balanced ↩

The margin arithmetic, checked

The author wrote in the margin of page 114: minus NH3, plus H2O, minus NH, plus H plus. That is the deamination bookkeeping, and it balances.

adenosine C10 H13 N5 O4\nplus water + H2 O1\n----------\nC10 H15 N5 O5\ninosine C10 H12 N4 O5\nplus ammonia + H3 N1\n----------\nC10 H15 N5 O5

Carbon ten and ten. Hydrogen fifteen and fifteen. Nitrogen five and five. Oxygen five and five. The margin note balances exactly, and it was written without a computer.

What the equation says in the volume's colors

	adenosine	inosine
at C6	an amino group — one green, two reds	a carbonyl — one orange
nitrogen count	five	four
oxygen count	four	five

A nitrogen leaves and an oxygen arrives. Part Forty-Seven called that a color substitution before it is anything else. This Part supplies the balanced equation underneath it.

290. One Editing Site Per Thirty-Two Bases ↩

The number the author computed and the paper did not print

At the foot of page 113 the author divided. He wrote one hundred times ten to the sixth, and beneath it three point two zero times ten to the ninth, and beside it the figure three hundred and twenty.

The paper states that over one hundred million adenosine-to-inosine editing sites are estimated in the human transcriptome, with editing occurring in at least two thirds of mRNAs. It does not divide that by the size of the genome.

3.2 x 10^9 bases the haploid human genome\n1.0 x 10^8 editing sites the current estimate\n----------\none editing site per 32 bases

One in thirty-two. A four-letter alphabet describing a molecule in which, on average, every thirty-second position is subject to a chemical rewrite that the alphabet cannot name.

The quotient is exact and the author reached it in a margin nine years ago. It is printed here as a finding because a rate is a stronger statement than a count, and the paper supplied the count without taking the ratio.

And the comparison the number invites

organism	reported editing sites
squid	57,111
human transcriptome	over 100,000,000

The human figure is roughly one thousand seven hundred and fifty times the squid figure. And yet the literature holds that recoding editing — the kind that changes an amino acid — is common in squid and rare in mammals.

The animal with fewer sites uses them to change proteins. The animal with a thousand times more uses them almost entirely outside the

coding regions. Quantity and function run in opposite directions, and that is the central puzzle of the field.

291. The Enzymes, and the One That Binds Left-handed DNA ↩

The mammalian family

enzyme	expression	localization
ADAR1 p110	constitutive, found everywhere	shuttles; largely nuclear
ADAR1 p150	interferon-inducible, produced on viral infection	accumulates in the cytoplasm — it carries a strong nuclear export signal
ADAR2	found everywhere	mainly nuclear; sequestered in the nucleolus, which globally reduces editing
ADAR3	brain only	catalytically inactive; antagonizes ADAR1 and ADAR2 in vitro

The author numbered the family in the margin of page 117 across the species panel — the two human ADAR1 isoforms, ADAR2, ADAR3, the single Drosophila enzyme, the two C. elegans enzymes, and the two squid splice variants.

The domain the volume already owns

ADAR1 is unique in carrying Z-DNA-binding domains. No other member of the family has them.

Part Fourteen of this volume rests on the Zα domain and the left-handed helix. This paper confirms that the domain is unique to ADAR1 and that ADAR1 is the isoform induced by interferon. The handedness sensor sits on the immune isoform, and on no other.

The regulation, which is where the sulfur enters

mechanism	what it does
phosphorylation by Pin1	keeps ADAR2 in the nucleus; loss of Pin1 mislocalizes it
ubiquitination by WWP1	targets mislocalized ADAR2 for the proteasome
homodimerization	required for maximal editing at the GluR-B R/G site
heterodimerization	ADAR1 with ADAR2 reduces R/G editing

mechanism	what it does
snoRNA HBII-52	2'-O-methylation blocks deamination — a methyl, from a sulfonium, stops the edit
ADAR2 self-editing	creates a new splice site, truncating its own protein — augmented by glucose and insulin

The last two rows belong to this volume. A methyl group delivered by S-adenosylmethionine prevents an edit. And the editor's own self-limitation responds to glucose and insulin — the enzyme that rewrites the transcript is under nutritional control.

---

292. The Three Pairings, as the Author Wrote Them ↩

The margin of page 118

Beside the paper's account of nearest-neighbor preferences the author wrote three pairs, one under another:

$$I\ C \backslash n I\ U \backslash n I\ G$$

Inosine's wobble partners are uracil, cytosine and adenine — three, not four. Two of the three the author wrote down are on that list. The third, I with G, is not.

And I with G is the one that matters. Part Fifty-Seven of this volume establishes that guanine is the single base inosine excludes, and that the exclusion is the join: guanine is the transition image of inosine's own parent. The author's margin listed the three pairings he was weighing, and the one that turns out to be impossible is the one the result rests on.

An earlier draft of this section described those three as three of four wobble pairings. That was wrong — there are three, and I with G is not among them. The correction is printed here rather than made silently, and Part Fifty-Seven was right.

The margin note is nine years older than the section it anticipates.

And the note beside it

He wrote: which is easier to flip — allosteric hindrance. Beside a drawn I paired with G, carrying an NH2.

The paper's own account: ADAR editing efficiency is enhanced by a mismatched cytosine opposite the edited adenosine, and the mismatch is thought to reduce the energy required for base flipping. Human ADAR2 edits the GluR-B Q/R site and human ADAR1 does not — but if the nucleotide opposite that adenosine is mutated to a cytosine, ADAR1 edits it efficiently.

One base, on the opposite strand, decides which of two enzymes can perform the reaction. Not the sequence being edited — the base facing it. The author's margin note asks which is easier to flip, and the answer in the literature is: the one with a cytosine across from it.

---

293. The Diagram on Page 119 ↩

What the author drew

In the margin beside the mismatched-cytosine paragraph, the author drew four letters and three arrows:

$$A\backslash n/\backslash nv\backslash nG \text{ — } C \text{ <— } I$$

Read plainly: A becomes I. G pairs with C. And I is reached from the direction of C.

What it corresponds to

the drawing	the mechanism
A pointing down to I	the deamination
G bonded to C	the Watson-Crick pair inosine will mimic
the arrow from I back to C	the mismatched cytosine that promotes the flip

The drawing is a reaction and a recognition in one figure. The vertical arrow is what the enzyme does to the base. The horizontal arrow is what the base across from it does to the enzyme. A textbook draws those in two figures, on two pages.

In the language of Part Forty-Nine, the vertical arrow is the deamination and the horizontal bond is complement — alpha, the first of the three face-axis half-turns. The author drew the operation and the pairing on one line without naming either.

---

294. Where the Edit Lands ↩

Three consequences, by location

where the edit falls	what changes
coding region	the codon, and therefore the amino acid — recoding
splice site, or the branch point adenosine	splicing — a site is created or destroyed
3' untranslated region	small RNA binding — miRNA and siRNA pairing is enhanced or disrupted

The examples the paper gives

transcript	the edit	the consequence
GluR-B, the Q/R site	glutamine to arginine at residue 607	prevents calcium influx through the glutamate receptor
GluR-B, underedited		increased cell migration; malignant gliomas, including pediatric astrocytomas and glioblastoma multiforme
AZIN1	serine to glycine at residue 367	increases binding to antizyme; oncogenes normally degraded now accumulate; associated with hepatocellular carcinoma
GLI1		editing reduced in basal cell carcinoma and astrocytomas
PTPN6	branch point adenosine at position 7866	prevents splicing, retains an extra intron, yields a nonfunctional protein; observed in acute myeloid leukemia
ARHGAP26	three positions in the 3' UTR	disrupts miR-30b-3p and miR-573 binding; higher expression; correlates in invasive ductal breast cancer and glioblastoma
miR-376-5p	one edit in the seed region	redirects the miRNA to bind and repress PRPS1

The last row belongs to Part Fifty-Eight

A single adenosine-to-inosine edit in a microRNA seed sequence redirects it onto phosphoribosyl pyrophosphate synthetase. PRPS1 makes PRPP, and Part Fifty-Eight established that PRPP is the single

gate through which both the salvage and the de novo nucleotide routes must pass.

One edited base, in a regulatory RNA, throttles the enzyme that supplies every nucleotide the cell makes. The editor regulates its own substrate supply.

And the author's check on position 7866

The author divided 7866 by seven in the margin. It is not a multiple of seven.

It is a multiple of three. 7866 divided by 3 is exactly 2622. The edited branch point sits on a codon boundary. Its prime factors are two, three, three, nineteen and twenty-three.

---

295. Alu, and the Non-coding Majority ↩

What the margin says

The author wrote on page 113: AG PROXY. SNPs. ALU HORIZONTAL TRANSFER. 3' INTRONIC ALTERNATE SPLICING TO ELIMINATE TOXIC.

What the literature says

finding	
in most organisms, the vast majority of A-to-I editing occurs in non-coding sequence	introns and untranslated regions
editing within Alu repeats in non-coding regions of human mRNAs occurs at specific adenosines among different individuals	
inverted Alu repeats several hundred nucleotides from an editing site regulate editing in cis	
ultra-deep sequencing shows nearly every adenosine has editing potential	many sites edited below one percent
millions of sites, most of unknown consequence	
recoding in coding regions is generally not beneficial and likely non-adaptive in	non-synonymous edits are less frequent than expected, and more conserved positions are less likely to be recoded

finding	
mammals	

The author's margin reads A-to-G proxy and single nucleotide polymorphism. That is exactly the analytical problem the field has: an A-to-I edit and an A-to-G genomic polymorphism are indistinguishable in a sequencing read unless the DNA is read as well. The notation cannot tell a mutation from an edit.

That is the volume's thesis stated as a laboratory difficulty. The alphabet has one symbol where the biology has two events, and the two are only separable by reading a second molecule.

---

296. The Editor as an Immune Sensor ↩

Why the cell edits its own non-coding RNA

Loss of ADAR1 in hematopoietic stem cells causes upregulation of interferon-inducible transcripts. The suppressive function is due to ADAR1's editing of endogenous mRNAs with long double-stranded regions, preventing aberrant recognition of self RNA by the innate immune sensors.

The embryonic death of an ADAR1 knockout mouse can be rescued by loss of MAVS or of MDA5 — two proteins critical for the innate immune response to double-stranded RNA. The animal does not die because editing is missing. It dies because its own RNA is read as foreign.

What that means for the volume

Part Fourteen of this volume argued from the Zα domain that handedness recognition is an immune function. This section supplies the general form: inosine is the mark that tells the cell a double-stranded RNA is its own.

the mark	what it certifies
inosine, scattered through a long duplex	self
an unedited long duplex	foreign

A single deaminated base, present at roughly one position in thirty-two, is the difference between a transcript and a threat.

And the virus fights back

Indiscriminate ADAR editing of lymphocytic choriomeningitis virus produces mutations in viral proteins and reduces infectivity. But editing of HIV rev and tat proteins increases infectivity, and the HIV Tat protein itself binds a stem loop and promotes editing of a specific adenosine. The hepatitis delta antigen restricts ADAR editing to a single adenosine within 1,700 nucleotides of highly base-paired RNA.

ADARs are both antiviral and proviral, depending on the virus. The editor is a weapon that either side can pick up.

---

297. The Heptad, and the Author's Reading of It ↩

What he wrote

Across four pages the author returned to one number. Beside the introduction: seven amino, alpha helix, heptad. Beside it: CTD 52. On page 115: GLY 1 2 3 4 5 6 7, end heptad, weakest link. On page 116: nuclear pol II, seven hep alpha helix, exportin 5. On page 117, beside the domain diagram, a spiral drawn and numbered one to seven, labeled heptad nuclear pore.

What the number refers to

The carboxy-terminal domain of RNA polymerase II in humans consists of fifty-two repeats of a seven-residue sequence.

52 heptads x 7 residues = 364 residues in the tail

The CTD is phosphorylated and dephosphorylated across the transcription cycle, and its state recruits the capping, splicing and polyadenylation machinery in turn. The author's margin note on page 114 reads: final coordinates entire transcription process. That is an accurate description of what the CTD does.

Why he connected it to editing

Because A-to-I editing occurs in the nucleus, coincident with splicing, and splicing is recruited by the CTD. His note reads: underedited interfered with serine phosphoryl CTD destabilizing.

The claim implicit in the margin is that the editor and the polymerase tail are coupled through the splicing machinery both of them talk to. The literature does not establish that coupling and this volume does not claim it. It is recorded as the author's reading, made in 2017, and it is a testable one.

---

298. The Margin Notes That Are Not Arithmetic ↩

Recorded as written, because they are the record

the note	where
LEFT OUT OF GENETIC CODE	beside "dynamically rewire the genetic code"
WOBBLE CODE	beside "functional consequences"
basic imprinted survival signal-gene	beside the disease list
ADAR ribozyme intron encoded?	beside the deaminase mechanism
eight, A to I, A to G, wrong mutation, SNP	beside the base-pairing paragraph
GluR, 5-HT, serotonin, mood modulator, schizophrenia, antidepressant, SSRI	beside the Q/R site
did its job, clear nitrogen, CNS, NH3, NO	beside the branch point
G-protein, transmembrane signaling, Rho, stops transcription	beside ARHGAP26
glutamate to arginine, nitrogen carrier, urea cycle	beside Figure 1
glutamate to glutamine, start synthesis, de novo, IMP	beside Figure 1
A to I, stop protein	beside Figure 1
perturbance, H2O, SOS, ischemia, free radical	beside the basics
calmodulin, Ca2+, K+, Na+, Cl−, ionic gates	beside the GluR ion channel

The one that connects two Parts of this volume

Glutamate to glutamine, start synthesis, de novo, IMP. Glutamine is the nitrogen donor at the first committed step of purine synthesis, and the product of that road is inosine monophosphate. The author wrote that beside a figure of adenosine being converted to inosine.

Two different inosines, reached two different ways, noted on one page. IMP is where inosine is built. The ADAR product is where inosine is installed. Part Forty-One established the first. This Part establishes the second. The margin note joined them in 2017.

---

299. What Is Claimed and What Is Not ↩

Claimed

That ADAR removes the C6 amine of adenosine hydrolytically by a base-flipping mechanism, and that the resulting inosine is read as guanosine. That the deamination equation balances as printed in section 302. That dividing the estimated one hundred million editing sites by the 3.2 billion base genome gives one site per thirty-two bases, and that this ratio was computed by the author in the margin in 2017. That ADAR1 alone among the family carries Z-DNA-binding domains and that the p150 isoform is interferon-inducible. That a mismatched cytosine opposite the edited adenosine enhances editing efficiency and can confer ADAR1 activity at a site otherwise edited only by ADAR2. That the PTPN6 branch point adenosine at position 7866 is divisible by three and not by seven. That an edit in the seed of miR-376-5p redirects it onto PRPS1. That ADAR1 knockout embryonic lethality is rescued by loss of MAVS or MDA5. That the human RNA polymerase II CTD carries fifty-two heptad repeats, totaling 364 residues.

Not claimed

That editing is adaptive in mammals. The literature reports the opposite for recoding, and section 308 prints that finding.

That the CTD and the editor are mechanically coupled. Section 310 records the author's 2017 reading and labels it a reading.

That any margin note constitutes evidence. The notes are provenance and are printed as provenance. The four that are computations have been checked, and only those four are given the standing of findings.

300. What Would Show This Part Is Wrong ↩

— Show that inosine is not read as guanosine by the translation machinery, and section 301's three-answers claim fails and most of this Part with it.

— Show that the estimate of A-to-I sites in the human transcriptome is substantially below one hundred million, and the one-in-thirty-two ratio of section 303 is wrong by the same factor. The ratio is only as good as the count it divides.

— Show that a mismatched cytosine opposite the target adenosine does not enhance editing, and section 305's account of base flipping and the author's margin question have no answer in the literature.

— Show that a second member of the ADAR family carries Z-DNA-binding domains, and section 304's uniqueness claim fails and the volume's Zα material loses its specificity.

— Show that ADAR1 knockout lethality is not rescued by loss of MAVS or MDA5, and section 309's account of inosine as a self-marker is not the mechanism.

— Run the experiment section 310 implies. Measure A-to-I editing at a panel of intronic sites under pharmacological inhibition of CTD serine phosphorylation. If editing is unchanged, the author's 2017 margin reading is wrong and the volume should print that it was tested and failed.

PART SIXTY · THE ALU ENGINE

Part Sixty of the evidence volume, sections 301 to 313

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Wang, So, Devlin, Zhao, Wu and Cheung, Cell Reports, 2013. Sixty thousand editing sites, read from the DNA and the RNA of the same cells. Every internal figure in the

paper has been checked and every one balances. And of the four transcripts the authors name as shared targets of the ADAR1 complex, two are sulfur enzymes.

301. The Experiment, and Why It Settles Something ↩

The design

Most editing sites in the literature were called by comparing RNA sequence against a reference genome — a genome that did not come from the cells being read. A difference found that way can be an edit, or it can be a polymorphism the reference does not carry.

This study did not do that. It sequenced the DNA and the RNA of the same cultured B cells, from two individuals, and compared each RNA sequence against that individual's own DNA.

the design	
cells	cultured B cells, two individuals, from the CEPH panel
DNA sequencing	thirty-fold and sixty-fold coverage
RNA sequencing	over 140 million reads per sample, directional and non-directional
requirement per site	at least ten DNA reads and ten RNA reads, homozygous DNA, present in both individuals
then	siRNA knockdown of ADAR1 and of ADAR2, and RNA immunoprecipitation of ADAR1

A difference between a cell's own DNA and its own RNA cannot be a polymorphism. It is a chemical event that happened after transcription. The comparison this study makes is the one the volume has been asking for since Part One.

The validation

Twenty-four of twenty-five sites validated by Sanger sequencing. Five of six by droplet digital PCR. False discovery rate approximately six and a half percent overall, and no more than four percent for the A-to-G class specifically.

302. The Alu Engine ↩

The split that runs through the whole paper

Under stringent thresholds, 10,992 sites showed RNA discordant from the corresponding DNA. All twelve possible mismatch types were present.

where the site sits	count	share	share that is A-to-G
inside an Alu-containing region	9,675	88.0%	99%
in non-repetitive genome	1,317	12.0%	57%

Inside Alu, essentially every RNA-DNA difference is an A-to-G. Outside Alu, barely half are. The Alu context raises the A-to-G share by forty-two points, and it is the presence of the repeat rather than the sequence of the gene that decides.

Why Alu, mechanically

Alu elements are short, abundant and frequently present in inverted pairs. Two Alus in opposite orientation in the same transcript fold back on each other and form a long double-stranded RNA duplex — which is the only substrate ADAR can act on.

	A-to-G sites	all other RDD types
inside an inverted repeat	about 45%	0.9%
within one kilobase of an inverted repeat	about 30%	
in or near an inverted repeat	about 75%	0.9%

The editor does not find its targets by sequence. It finds them by shape, and the shape is made by a repeat element folding back on itself. Alu is not where editing happens by accident. Alu is the machine that manufactures the substrate.

303. Adar1 Does Almost All of It ↩

The expression, and the knockdown

In B cells, ADAR1 messenger RNA is present at seven reads per kilobase per million. ADAR2 and ADAR3 are each below nought point three. ADAR1 is more than twenty-three times higher.

	count	share
RDD sites in control cells	6,996	
of which A-to-G	6,524	93.3%
A-to-G sites reduced by 20% or more	6,258	95.9% of A-to-G
the other eleven RDD types reduced	43	9.1% of non-A-to-G

The effect on A-to-G is roughly eleven times the effect on everything else.

Over two thousand A-to-G sites fell to zero. Among them, sites in the genes encoding caspase 8, caspase 10 and the von Hippel-Lindau tumor suppressor.

The two enzymes divide the work unequally

	sites affected
ADAR1 total	6,258
ADAR2 total	2,181
shared by both	1,668
ADAR1 only	4,590
ADAR2 only	513

Both subtractions check exactly against the printed figures.

And ADAR2 knockdown makes editing go up

Following ADAR2 knockdown, 2,181 sites went down — and 2,240 sites went up by twenty percent or more.

The authors reasoned that with ADAR2 removed, more substrate becomes available to ADAR1, or ADAR1 homodimerizes more readily. Double knockdown of both enzymes abolished the increase, confirming it.

Remove one editor and the other edits harder. The two are not additive; they compete for the same duplexes. That is a control system, not two independent enzymes.

304. The Hyperedited Transcripts ↩

What immunoprecipitating the enzyme found

Pulling down ADAR1 protein and sequencing the RNA that came with it yielded 55,719 A-to-G sites — 5.4 times the 10,412 found from messenger RNA alone.

sites found	55,719
previously reported in the literature	fewer than 4,500 — about 92% were new
in Alu repeats	over 97%, at least 54,000 sites
in introns	81%, about 45,000 sites
also in long non-coding RNAs	LINC00265, LINC00476

The twenty most heavily edited regions

More than thirty percent of all the sites clustered into 224 transcripts, each carrying more than fifty edits.

gene	edited sites	gene	edited sites
FNBP1	291	ST3GAL2	134
SMARCC1	218	NSD1	134
GNB1	214	XPO1	133
UBE2K	167	QRICH1	131
UBE2D2	162	LARP4	128
MTDH	154	NDE1	128
CTDSPL2	148	POGZ	127
PIP5K1A	141	MYO9B	127
CCAR1	138	C19orf42	125
TAOK1	136	FANCA	123

And the ATM result

Examining a hyperedited region in the ATM transcript, every adenosine in it was found deaminated in some clone. The editing level at a given site ranged from one percent to ninety-nine percent, and within a transcript there was no obvious pattern as to which adenosine was edited.

One hundred and thirty-seven clones of one region of one transcript, and no two the same. The gene has one DNA sequence and the cell holds a population of transcripts that differ from it and from each other. A four-letter sequence cannot describe a population.

305. Where the Edit Lands, and Where It Does Not ↩

The two classes occupy different parts of the gene

	A-to-G editing sites	other RDD types
coding exons	4%	35%
mostly found in	3' untranslated regions	5' untranslated regions and coding exons
clustered within 25 nucleotides of another site	67%	14%

The local sequence signature

The base immediately 5' to an edited adenosine is depleted of guanosine. The base immediately 3' is enriched for guanosine. That signature is absent from unedited adenosines inside the same Alu repeats, and absent from every other RDD class.

And a motif search out to a hundred nucleotides either side returned four significantly enriched motifs. One of them is TA(T/A)TTTT — the binding motif of HuR.

The nearest-neighbor rule is chemistry: it says which adenosine can flip out of the duplex. The distant motif is not chemistry. It is the address of another protein, and it is what takes this Part into the next section.

306. Two of the Four Shared Targets Are Sulfur Enzymes ↩

The complex

ADAR1 and HuR interact in living cells, and the interaction requires RNA. RNase A, which digests single-stranded RNA, abolishes it. RNase V1, which digests double-stranded RNA, reduces it. The complex is held together by both.

transcripts bound by ADAR1	4,279
carrying at least one HuR site	4,198 — 98.1%
confirmed HuR-bound in independent data	2,866 — 67%, against 36% of random transcripts
HuR motifs in ADAR-bound transcripts	172,000, against 79,084 in the control set
effect of removing ADAR1	HuR binding to its targets is greatly reduced, while HuR protein level is unchanged

ADAR binds the duplex, the duplex forms a structure, and HuR binds the structure. The editor is the scaffold-maker for the stabilizer.

The four transcripts the authors name

The paper names four shared targets of ADAR1 and HuR, confirmed by pull-down in both directions.

gene	what it encodes
MCM4	a licensing factor for DNA replication
TMPO	a nuclear membrane protein
GSR	glutathione reductase — the enzyme that regenerates reduced glutathione
CTH	cystathionase, cystathionine gamma-lyase — the enzyme that makes cysteine, and the principal enzymatic source of hydrogen sulfide in mammals

Two of the four are sulfur enzymes. Not related sulfur enzymes — the two ends of the sulfur economy. CTH makes the thiol. GSR keeps the thiol reduced. And both of their transcripts are held and stabilized by the same complex that installs inosine.

Why this matters more than a coincidence of four names

All four transcripts fell in expression when ADAR1 was knocked down, consistent with loss of HuR-mediated stabilization.

what Part Forty-Five established	what this paper adds
cystathionase sits on the sulfur thread, converting	its transcript is stabilized by the ADAR1-HuR complex

what Part Forty-Five established	what this paper adds
cystathionine to cysteine	
glutathione is the cell's principal redox buffer	the enzyme that recycles it is stabilized by the same complex
Part Fifty-One: hydrogen sulfide is the first molecule	CTH is where a mammal still makes it

The volume's central element is not merely edited. Its two governing enzymes are held by the editor. Inosine and sulfur, which the four-letter alphabet names neither of, are handled by one protein complex.

This connection is not made in the paper. It follows from the paper's own named list.

---

307. The Zinc-finger Enrichment ↩

What the targets are made of

Gene Ontology analysis of the editing targets returned three significant enrichments.

category	significance
genes encoding zinc-finger proteins	p below 0.05
proteins involved in chromosomal organization	p below 10^{-5}
antiviral defense	p below 10^{-3}

And among the genes whose expression changed after ADAR1 knockdown, the enrichment was stronger still — kinases at p below 10^{-9}, DNA damage response proteins at p below 10^{-10}, and zinc-finger proteins at p below 10^{-6}.

What a zinc finger is made of

Part Fifty-Two of this volume established it: a zinc finger is a zinc ion held by cysteine and histidine thiolates. It is the commonest DNA-binding motif in the human genome.

The editing targets are enriched for the protein family whose defining feature is a metal held by sulfur. The protein that reads the four

letters is clamped shut by an atom the four letters cannot name, and its transcript is preferentially edited by a symbol the four letters cannot name either.

This is the second sulfur connection in the same paper, reached by a different route.

And it comes with a warning the volume should print

Of the 263 zinc-finger protein genes whose expression changed after ADAR1 knockdown, only 104 — forty percent — were editing targets at all. ZNF16 fell and ZNF432 rose, and neither was edited, though both carry multiple Alu repeats.

Editing of Alu is not required for ADAR1 to regulate zinc-finger expression. The enrichment is real and the mechanism is not deamination.

---

308. The Editor Works Without Editing ↩

The decoupling

Editing level and expression level were not correlated. The correlation coefficient was below nought point nought five in both individuals.

observation	
ADAR1 knockdown	635 genes changed expression significantly; 1,238 transcripts changed
of those transcript changes	659 were not reflected at the total gene level — isoform switching
IKZF3	68 editing sites; expression rose 1.3-fold while its editing fell more than sevenfold
ADAR2 knockdown	4,154 transcripts in 3,379 genes rose twofold; 872 transcripts in 734 genes fell twofold

ADAR2 does less editing than ADAR1 and changes the expression of more genes. The enzyme's two jobs are separable, and the deaminase activity is not the one doing most of the regulating.

That is the paper's most disruptive result and it belongs in this volume as such. A protein named for a chemical reaction turns out to do most of its work by binding rather than by reacting.

309. Alu, the Primate Accelerator ↩

What the author has been saying for nine years

In the margin of the 2016 review, beside the paragraph on non-coding editing, the author wrote three words: ALU HORIZONTAL TRANSFER.

fact	source
over 97% of ADAR1's editing sites lie in Alu repeats	this paper
Alu elements are primate-specific	established
they number roughly one million copies and occupy about a tenth of the human genome	established
inverted Alu pairs make the double-stranded substrate ADAR requires	this paper
editing within Alu occurs at specific adenosines that differ between individuals	the 2016 review

The editor is ancient and universal. Its substrate in humans is a repeat element that did not exist before the primates. A conserved enzyme was handed a new and enormous supply of substrate somewhere in the primate lineage, and the human transcriptome is what came out.

The author's connection, stated as his and tested as such

The author holds that this is where human acceleration enters, and the reasoning is his.

What supports it. The best-known human accelerated region, HAR1, is 118 bases long, sits in a stretch essentially unchanged across vertebrates, and carries eighteen human-chimpanzee substitutions where fewer than one would be expected. Those substitutions are strongly biased toward adenine-to-guanine and thymine-to-cytosine — which is the editing signature and its mirror on the opposite strand. HAR1 is transcribed as a structured non-coding RNA rather than translated, and HAR1F is expressed in Cajal-Retzius neurons of the developing neocortex.

What the standard readings are. Positive selection, or GC-biased gene conversion. Both are in the literature and neither invokes the editor.

What the author's reading adds. A third possibility — that some of the bias is the editor's fingerprint, fixed into the genome.

The volume states this as the author's conjecture and not as a finding. What makes it worth printing is that the paper in hand supplies the reason it is hard to rule out: a difference read from DNA alone cannot distinguish an edit from a mutation, and nobody has compared human and chimpanzee editing directly.

---

310. The Paper's Own Conclusion, Which Is This Volume's Thesis ↩

Quoted in substance

The authors write that the large number of sites where RNA differed from the underlying DNA is surprising and requires further attention in genetic studies. That two individuals may have the same DNA sequence at a site and different RNA sequences. And that genetic variation extends beyond DNA sequence variation, so RNA editing will have to be considered in studies seeking the genetic basis of human disease.

A study designed to catalog an enzyme's targets concluded that DNA sequence is not sufficient to describe genetic variation. That is the argument of this volume, reached independently, by people who were not making it.

The volume claims no priority for the observation and records the convergence.

---

311. What Is Claimed and What Is Not ↩

Claimed

That the study compared DNA and RNA from the same cells of two individuals, validating at a false discovery rate of about 6.5% overall and no more than 4% for A-

to-G. That of 10,992 stringent RDD sites, 9,675 were in Alu-containing regions and 1,317 were not, and that 99% of the former and 57% of the latter were A-to-G. That ADAR1 knockdown reduced 6,258 of 6,524 A-to-G sites by twenty percent or more, against 43 of the other eleven types. That the Venn figures 6,258, 2,181, 1,668, 4,590 and 513 are internally consistent — checked. That ADAR1 RNA-immunoprecipitation yielded 55,719 A-to-G sites, of which fewer than 4,500 had been reported, over 97% lay in Alu and 81% in introns. That 224 transcripts each carried more than fifty edits and together held over thirty percent of all sites. That about 45% of A-to-G sites lie inside inverted repeats against 0.9% of other RDDs. That ADAR1 and HuR interact in an RNA-dependent manner, that 98.1% of 4,279 ADAR1-bound transcripts carry a HuR site, and that the four shared targets named are MCM4, TMPO, GSR and CTH. That editing targets are enriched for zinc-finger proteins, chromosomal organization and antiviral defense. That editing level and expression level are uncorrelated at r below 0.05.

Not claimed

That the paper draws any connection to sulfur. It does not. Section 306 is this volume's reading of the paper's own named list, and section 307 is this volume's reading of its own Part Fifty-Two. Both are labeled as such.

That Alu editing causes human accelerated evolution. Section 309 states the author's conjecture as a conjecture and prints the two standard alternative explanations beside it.

That HAR1's substitution bias is editing. It is a bias with at least three candidate causes and this volume adds the third rather than settling among them.

That any of this is a claim about disease in an individual. It is not.

312. What Would Show This Part Is Wrong ↩

— Show that A-to-G differences between a cell's own DNA and its own RNA can arise from polymorphism, and section 301's whole design argument fails.

— Show that ADAR1 knockdown does not preferentially reduce A-to-G among the twelve RDD classes, and section 303's eleven-fold specificity is not real.

— Show that GSR and CTH are not among the transcripts co-bound by ADAR1 and HuR, and section 306 — the strongest connection in this Part — has no exhibit.

— Show that the zinc-finger enrichment among editing targets is an artifact of Alu density rather than of the gene family, and section 307's second sulfur connection dissolves. The paper itself supplies the caution: two zinc-finger genes changed expression, carried multiple Alus, and were not edited.

— Show that Alu elements are not primate-specific, and the acceleration argument of section 309 has no lineage.

— Compare A-to-I editing directly between human and chimpanzee cells of the same type, with DNA and RNA sequenced from the same cells. If the editing landscapes are equivalent once Alu content is controlled for, the author's conjecture in section 309 is wrong and the volume should print that it was tested and failed. This experiment has not been done, and it is the single most valuable one this Part identifies.

---

313. What This Part Adds to the Volume ↩

Three joins, stated compactly

First. The editor's complex holds the transcripts of cystathionase and glutathione reductase. The enzyme that makes the thiol and the enzyme that keeps it reduced are both stabilized by the protein that installs inosine. Sulfur and inosine, the volume's two unnamed things, are handled together.

Second. Editing targets are enriched for zinc-finger proteins, which are the commonest DNA-binding motif in the genome and are held shut by cysteine. The reader of the four letters is built on the element the four letters omit.

Third. The substrate is Alu, Alu is primate, and the enzyme is ancient. An old editor met a new and vast supply of double-stranded RNA in the primate lineage, and what the four-letter alphabet records of that meeting is nothing at all.

PART SIXTY-ONE · THE RECRUITMENT ELEMENT

Part Sixty-One of the evidence volume, sections 314 to 327

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Daniel, Widmark, Gardell and Öhman, Genome Biology, 2014. The mechanism behind Part Sixty. An inverted pair of Alu repeats is not where editing happens — it is the antenna that pulls the enzyme in, and the editing then happens somewhere else. Proved by moving it, by deleting it, and by transplanting a human Alu into a mouse gene.

314. The Question This Part Answers ↩

What Part Sixty left open

Part Sixty established that over ninety-seven percent of ADAR1's sites lie in Alu repeats and that about seventy-five percent lie in or near an inverted repeat. It could not say whether the Alu is the target or the cause.

An inverted pair of Alu repeats acts as a cis-acting recruitment element. It folds into a long stable duplex, binds ADAR, raises the local concentration of the enzyme, and so drives selective editing at a short hairpin somewhere nearby — a site that would otherwise be edited barely at all.

The volume can now state the mechanism rather than the correlation.

315. The Scale of the Supply ↩

inverted Alu pairs within one kilobase of each other, inside genes	**228,607**
share of all human genes containing Alu	about 75%, mostly in introns and untranslated regions

inverted Alu pairs within one kilobase of each other, inside genes	**228,607**
A-to-I sites known inside human Alu repeats	over 500,000
non-Alu edited sites analyzed here	10,650
the ratio	about forty-seven to one

And the non-Alu sites are not independent of the Alus

Of the 10,650 non-Alu editing sites, 78.3 percent had an inverted Alu within one kilobase.

Non-Alu editing sites are significantly closer to edited Alus than to random adenosines, at P below 3×10^{-120}. They lie downstream of an edited Alu in 55.8 percent of cases against 44.8 percent upstream, at $P = 3 \times 10^{-16}$ — and 44.2 percent sit one to two kilobases away.

The sites outside the repeats are placed by the repeats. A selective editing site in a protein-coding exon is, in the great majority of cases, within a kilobase or two of an inverted Alu pair that is doing the recruiting.

---

316. The Proof by Moving It ↩

The Gabra-3 experiment

The mouse Gabra-3 transcript carries a recoding site in exon nine — isoleucine to methionine — and an intronic editing inducer element about 150 nucleotides downstream, a long stem-loop.

The authors moved the element and measured what happened.

construct	editing at the I/M site	significance
wild type, inducer in its native place	37%	
inducer deleted	markedly reduced	
inducer moved 150 nucleotides upstream of the site	45%	P = 0.20, not significant

construct	editing at the I/M site	significance
inducer moved 300 nucleotides further downstream	34%	P = 0.03, a slight decrease
native inducer replaced by a human inverted Alu from the PSMB2 3' untranslated region	37%	P = 0.65 — indistinguishable from wild type

What the four rows establish

Moving the element to the other side of the editing site did not hurt it. Moving it further away hurt it slightly. And swapping the native element out for a human Alu pair reproduced the wild-type effect exactly.

— Induction is independent of position. The element does not have to be downstream, or at a fixed distance, or on a particular side.

— Induction is sequence independent. Any long double-stranded structure will do.

— An Alu inverted repeat is a fully competent inducer. It is not a special case; it is an instance of the general class.

That is what makes the primate story possible. Nothing had to evolve a new mechanism. A new supply of a generic part was inserted, a million times over.

---

317. The Proof by Deleting It ↩

NEIL1, a DNA repair enzyme

NEIL1 is a DNA glycosylase that excises oxidatively damaged bases. It carries a recoding site at lysine 242 in exon six — editing at the central position of that codon converts lysine to arginine, and the K-to-R change dramatically alters which lesions the enzyme will repair.

A pair of inverted Alu repeats sits 221 nucleotides upstream of that site.

construct	editing at the K/R site	
human NEIL1 reporter, Alus intact	77%	
human NEIL1 reporter, Alus deleted	45%	P = 3.7×10^{-6} — a relative loss of 42%

construct	editing at the K/R site	
with one microgram of ADAR1 supplied	76% intact	about 30% deleted

The transplant

Mouse NEIL1 shows no detectable editing in mouse brain. The authors fused the human inverted Alu pair into the mouse gene at the equivalent position.

Editing of the mouse transcript at the K/R site rose from 22 percent to almost 48 percent, at P = 6.0 × 10⁻⁵. A human repeat element, moved into a mouse gene, more than doubled the editing of a mouse codon.

And the endogenous human transcript is edited at eight percent, rising to 22 percent with ADAR1 overexpression and 17 percent with ADAR2. The mouse is not.

What this means for the volume

Part Fifty-Four established that oxygen respiration produces superoxide, peroxide and hydroxyl radical, and that the defenses against them are thiol systems. Part Sixty established that the editor's complex holds the transcripts of glutathione reductase and cystathionase — the enzymes that supply and recycle the thiol.

NEIL1 is the enzyme that repairs the damage those defenses fail to prevent. And its specificity — which lesion it will excise — is set by an RNA edit whose efficiency is set by a primate-specific repeat element.

The editor tunes the antioxidant supply and the repair enzyme that cleans up after it. Three Parts of this volume converge on one protein complex.

---

318. The Proof by Comparing Species ↩

GLI1

GLI1 is a zinc-finger transcription factor, the terminal effector of the Hedgehog signaling pathway, and the glioma-associated oncogene. It carries a recoding site at position 701 —

Editing at that site reduces GLI1's capacity to activate transcription and makes it less susceptible to inhibition by suppressor of fused.

species	the Alu situation	editing at R/G
human	two inverted Alus about 780 nucleotides upstream	high
chimpanzee, orangutan	the Alu pair present	
rhesus macaque, marmoset	one of the two Alus absent	very low, close to undetectable
mouse	no editing inducer; sequence and structure well conserved at the site itself	very little

The sequence around the editing site is well conserved in mouse. The site is not edited in mouse. What the mouse lacks is not the site — it is the antenna.

ZFP14

ZFP14 is a Krüppel-type zinc-finger transcription factor with nine fingers. Its editing site lies in the 3' untranslated region, 107 nucleotides downstream of a non-inverted Alu, and it is

The Alu sequences involved — AluSx and AluJb — are present in chimpanzee, rhesus and marmoset, but not completely conserved. In the other primates the stem-loop is disrupted by larger and more frequent bulges. Rhesus ZFP14 is edited at very low levels.

And what the ZFP14 edit does

The edited site masks a predicted binding site for miR-1182, a primate-specific microRNA. The editing site overlaps positions two to eight of the microRNA — the seed. The unedited form has a perfect match at position eight.

A primate-specific repeat recruits an ancient enzyme, which edits a site that blocks a primate-specific microRNA from silencing a transcription factor. Every element in that sentence except the enzyme is younger than the primates.

319. The Answer to the Question as Asked ↩

The author's question

Do Alu elements shape the primate transcriptome by cis-regulation of RNA editing of human accelerated genes?

The answer, in three parts

First, on Alu and the primate transcriptome: yes, and it is demonstrated rather than inferred. Moving, deleting and transplanting the element changes editing in the predicted direction each time.

Second, on human-specific editing: yes, for named genes. GLI1 is edited in human, chimpanzee and orangutan and not in rhesus or marmoset, and the difference tracks the presence of the Alu pair rather than the sequence at the site. ZFP14 editing is human-specific. These are not statistical trends; they are two genes with a species boundary and a mechanism.

Third, on the human accelerated regions as that term is formally used — the loci identified by their excess of human-chimpanzee substitutions — this paper does not test them.

What can be said is this. The editing sites that are human-specific are made human-specific by a primate-specific repeat, not by a change at the site. And the classical human accelerated regions carry a substitution bias toward A-to-G that nobody has yet tested against editing. The two literatures have not been joined and joining them is one experiment.

---

320. The Targets Are Zinc Fingers, for the Third Time ↩

The enrichment table

source	category	genes	share	fold enrichment
KEGG	lysosome	7	2.9%	46.1-fold
PFAM	KRAB box, Krüppel-associated	15	6.2%	16.0-fold
PANTHER	zinc finger proteins	17	6.9%	7.3-fold
INTERPRO	zinc finger C2H2-type, integrase DNA-binding	17	6.9%	6.0-fold

source	category	genes	share	fold enrichment
SP_PIR	alternative splicing	111	45.3%	3.1-fold
GOTERM	regulation of transcription	43	17.5%	2.2-fold

Three of the six categories are zinc-finger or KRAB zinc-finger, and the enrichment is predominantly of the C2H2 family. Expression enrichment was also found by tissue — uterus 4.5-, placenta 4.1-, epithelium 3.6-, testis 2.4-fold, and brain 2-fold, with non-Alu editing at 3.3-fold in brain.

The third arrival

Part Fifty-Two: a zinc finger is a zinc ion held by cysteine thiolates, and it is the commonest DNA-binding motif in the genome. Part Sixty: editing targets are enriched for zinc-finger proteins. Part Sixty-One: they are enriched sixteen-fold for the KRAB zinc-finger family in particular, predominantly C2H2.

Three independent studies, three different methods, one target class — and the target class is defined by a metal held by sulfur.

The authors' own explanation is that this enrichment is likely due to the abundance of Alu elements in zinc-finger genes. The volume prints that explanation, and observes that it does not remove the fact — it supplies a reason for it.

---

321. The Model, in Three Steps ↩

As the authors draw it

1 ANCESTRAL TRANSCRIPTOME\nAll metazoans carry a basic low level of RNA editing, roughly 1% to 2%,\nat short hairpins.\n2 ALU ENTERS THE PRIMATE GENOME\nPairs of adjacent Alus in inverted orientation form long stable duplexes\ninside transcripts. These act as recruitment elements for ADAR.\n3 THE LOCAL CONCENTRATION RISES\nA high ADAR concentration at the inverted Alu drives high editing\nefficiency at single sites in nearby short hairpins.

Why the model is testable and was tested

Step three predicts that editing at the selective site should depend on ADAR concentration more steeply when the Alu is absent. That is what the titration showed: with the Alu intact the reporter reached 76 percent editing at one microgram of ADAR1; with the Alus deleted it stayed near 30 percent across the whole range.

The inverted Alu is a concentrator. It does not change what the enzyme does. It changes how much of the enzyme is standing next to the site.

---

322. What This Adds to the Volume's Argument ↩

The notation problem, sharpened

A four-letter sequence records the Alu. It records the editing site. It records neither the fold between them nor the enzyme concentration that fold creates.

what decides whether this adenosine is edited	is it in the sequence?
the presence of an inverted Alu pair nearby	yes, in principle
whether that pair actually folds into a stable duplex	no
the distance and orientation	yes
the local ADAR concentration that results	no
whether the bulges are small enough	no
the resulting protein	no — it depends on all of the above

Two individuals with identical DNA at a locus can carry different proteins from it, and the difference is decided by a fold and a concentration that no sequence records. The alphabet writes the parts and omits the machine.

This is Part One of this volume, restated by a 2014 experiment that was not making the argument.

323. And One Finding the Volume Should Carry Separately ↩

Editing changes what a repair enzyme repairs

The NEIL1 K242 recoding is not a gain or loss of function. It is a change of specificity.

the codon position edited	the consequence
the central position of the K242 codon	lysine becomes arginine — the lesion specificity of the enzyme changes dramatically
the wobble position of the same codon	synonymous — no change to the protein

The same enzyme, on the same transcript, edited at two positions of one codon. One edit changes what DNA damage the cell can repair. The other changes nothing. And the volume's own Part Fifty-Seven established that the wobble position is exactly where inosine's degeneracy lives.

The editor writes to a codon where one position matters and one does not, and it writes to both.

324. What Is Claimed and What Is Not ↩

Claimed

That 228,607 inverted Alu pairs lie within one kilobase of each other inside human genes, that about 75% of human genes contain Alu, and that over 500,000 A-to-I sites are known within human Alu repeats. That 78.3% of 10,650 non-Alu editing sites have an inverted Alu within one kilobase, that non-Alu sites are closer to edited Alus than to random adenosines at P below 3×10^{-120}, and that 55.8% lie downstream against 44.2% upstream at $P = 3 \times 10^{-16}$.

That moving the Gabra-3 inducer 150 nucleotides upstream gave 45% editing against 37% for wild type at P = 0.20, moving it 300 nucleotides further downstream gave 34% at P = 0.03, and replacing it with a human inverted Alu gave 37% at P = 0.65.

That deleting the inverted Alus upstream of the NEIL1 K/R site reduced editing from 77% to 45% at $P = 3.7 \times 10^{-6}$, and that inserting the human Alu pair into mouse NEIL1 raised editing from 22% to almost 48% at $P = 6.0 \times 10^{-5}$.

That GLI1 R/G editing is high in human and close to undetectable in rhesus, tracking the presence of the upstream Alu pair rather than conservation at the site. That ZFP14 3' untranslated region editing is human-specific and masks a predicted binding site for the primate-specific microRNA miR-1182 at seed positions two to eight.

That the enriched target categories include KRAB box at 16.0-fold and zinc finger at 7.3- and 6.0-fold.

Not claimed

That this paper tests the human accelerated regions. It does not, and section 319 says so plainly.

That the zinc-finger enrichment is independent of Alu density. The authors attribute it to Alu abundance in those genes and the volume prints that attribution.

That editing of GLI1 or NEIL1 has been shown to matter to a human phenotype. The functional consequences were measured in reporters and in vitro.

That the primate-specificity of these editing events implies selection. The paper proposes that Alu-induced editing added a dimension to the transcriptome and may confer selective advantage. That is a proposal and the volume records it as one.

---

325. The Four Parts This One Joins ↩

Part Fifty-Two gave the zinc finger — a metal held by cysteine, the commonest DNA-binding motif in the genome.

Part Fifty-Four gave the oxygen bill — superoxide, peroxide, hydroxyl radical, and thiol systems as the only defense.

Part Sixty gave the complex — ADAR1 with HuR, holding the transcripts of glutathione reductase and cystathionase.

Part Sixty-One gives the repair — NEIL1, whose lesion specificity is set by an edit whose efficiency is set by an Alu.

Four Parts, one thread. The element that makes the damage is oxygen. The element that defends against it is sulfur. The enzyme that repairs what gets through is tuned by inosine. And the notation names only the first of the three.

---

326. What Would Show This Part Is Wrong ↩

— Show that deleting an inverted Alu pair does not reduce editing at a nearby selective site, and the recruitment model of section 321 has no experimental support.

— Show that the human Alu insertion into mouse NEIL1 does not raise editing at the K/R site, and the transplant result — the strongest single exhibit in this Part — fails.

— Show that GLI1 is edited in rhesus at levels comparable to human, and section 318's species argument collapses.

— Show that the Gabra-3 inducer cannot be functionally replaced by an unrelated long duplex, and the sequence-independence claim of section 316 is wrong.

— Show that the zinc-finger enrichment disappears when Alu density is controlled for, and section 320's third arrival is an artifact of where Alus land rather than a fact about the targets. This control has not been reported and it is the weakest point in the chain.

— Test the classical human accelerated regions directly. Take the loci identified by excess human-chimpanzee substitution, ask which carry inverted Alu pairs within a kilobase, and measure editing in matched human and chimpanzee cells with DNA and RNA sequenced from the same cells. If human accelerated regions are no more likely than matched controls to carry an Alu recruitment element or to be differentially edited, the author's conjecture in Part Sixty is wrong and this volume should print that it was tested and failed.

---

327. The One-sentence Form ↩

An enzyme older than the vertebrates was handed, in the primate lineage, two hundred and twenty-eight thousand new antennas — and what it tuned with them were the zinc-finger transcription factors, the DNA repair enzymes, and the thiol supply. None of that is written in the four letters, and all of it can be measured.

PART SIXTY-TWO · THE CHEMICAL ERASURE

Part Sixty-Two of the evidence volume, sections 328 to 341

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Sakurai, Ueda, Yano, Okada, Terajima, Mitsuyama, Toyoda, Fujiyama, Kawabata and Suzuki, Genome Research, 2014. A group who stopped trying to read inosine out of a sequence and instead reacted with it. Every cell of their census has been re-summed and reconciles. And in their table of novel coding sites sits a sulfur enzyme neither they nor anyone since has remarked on.

---

328. The Method, and Why It Matters to This Volume More Than Any Other ↩

The problem they set out to solve

Every result in Parts Fifty-Nine through Sixty-One rests on reading inosine as a guanosine in a sequence. Reverse transcriptase pairs cytidine opposite inosine, so an edited adenosine returns as a G. The site is then called by comparing that G against the genomic A.

That comparison cannot distinguish an edit from a polymorphism, a sequencing error, a misaligned read, or a pseudogene. Up to ninety-four percent of one widely cited set of RNA-DNA differences was later estimated to be false positives from mapping error alone.

What they did instead

They stopped inferring inosine and started reacting with it. Acrylonitrile adds to the N1 position of inosine and to nothing else in RNA, forming N1-cyanoethylinosine. That adduct blocks reverse transcriptase. The cDNA that would have carried the edit is never made.

So the edit is detected by its absence. Sequence the treated and untreated samples side by side, and every read that vanishes on treatment was carrying an inosine.

They called the method inosine chemical erasing, and combined with deep sequencing, ICE-seq.

Why this Part is the volume's methodological center

This volume has argued for four hundred and fifty pages that the four-letter notation cannot express what is in the molecule.

Here is a laboratory that tried to read a chemical modification out of the notation, found the notation was wrong between ninety-two and ninety-five percent of the time, and had to invent a chemical reaction to see what was actually there.

That is not an analogy for the volume's thesis. It is the thesis, encountered as a practical obstacle, by people who were not making the argument.

---

329. The Chemistry ↩

The reaction

inosine + acrylonitrile --> N1-cyanoethylinosine

condition	acrylonitrile	time
CE−, control	none	—
CE+, mild	1.6 molar, in 1.1 molar triethylammonium acetate at pH 8.6	15 minutes at 70 °C
CE++, strong	the same	30 minutes at 70 °C

At seventy degrees almost every inosine residue is cyanoethylated, including those in stable double-stranded regions.

Why the reaction is specific

Acrylonitrile is a Michael acceptor. The N1 of inosine is the nucleophilic position available in the base and it is not blocked in an inosine as it is in an adenosine — because the amino group that occupied C6 has been removed.

The deamination that makes inosine is what exposes the nitrogen the chemistry attacks. The reagent finds the edit because the edit created the site the reagent needs.

In the volume's colors: the loss of a green and two reds at C6, and the arrival of an orange, opens the N1 to attack. The chemical erasure works for the same reason inosine reads as guanosine.

---

330. What Sequence Comparison Alone Gets Wrong ↩

The numbers, stated plainly

	mapped to the transcriptome	mapped to the genome
total mismatch sites	462,583	744,182
A-to-G among them	53,912	94,713
T-to-C among them	—	97,441
everything else	408,671	552,028

Filtering reduced the A-to-G population from 53,912 to 5,680 — retaining 10.5 percent.

Roughly fifty-four thousand A-to-G mismatches were detected by deep sequencing before filtering. That is about twelve times the number that could be validated. The authors conclude that between ninety-two and ninety-five percent of A-to-G mismatches detected by deep sequencing without filtering are not inosine sites at all.

And the discrimination the chemistry provides

They defined an ICE score — the distance from the origin in the plot of read loss upon cyanoethylation. A score of 1.75 corresponds to P = 0.00953.

	sites above ICE score 1.75
known editing sites	most
A-to-G genomic SNPs, of 25,285 tested	241 — under one percent

Ninety-nine percent of genomic SNPs fall below the threshold. The chemistry separates a real inosine from a polymorphism that looks identical in every sequence read.

---

331. The Census, and Its Internal Arithmetic ↩

The reads

condition	total reads	mapped to genome	mapped to transcriptome
CE−	409,843,384	279,200,747	275,547,202
CE+	459,198,334	244,254,259	241,649,061
CE++	507,338,206	285,494,762	278,200,176

Sixty-three percent of detected genes had more than twenty-fold coverage. The correlation of gene expression between treated and untreated samples was R^2 = 0.998 for CE+ and 0.995 for CE++ — the chemistry does not bias which transcripts are seen.

The novel sites

ICE-seq novel 11,639\nICE method novel 8,847\noverlap 695\n----------\ntotal novel 19,791

Checked: 11,639 plus 8,847 minus 695 is 19,791 exactly. The Venn components also reconcile — 10,944 plus 695 gives the ICE-seq total, and 8,152 plus 695 gives the ICE method total.

Distributed across 2,114 genes, including 1,258 genes not previously known to produce edited transcripts.

The validation

set	tested	confirmed	accuracy
non-coding sites	931 of 14,225, chosen at random	902	96.9% — false-positive rate 3.1%
coding candidates	all 228	53 novel confirmed	89 false positives; 86 failed to amplify

And how little of it was already known

Combined with their earlier work the study reports 29,843 sites. The DARNED database held 42,039. The overlap is 6,406.

Only 21.5 percent of what they found was already in the database. Seventy-eight and a half percent was new — and this is a single tissue from a single individual.

332. Table Two, Reconciled Cell by Cell ↩

The distribution of 19,791 sites

region	SINE/Alu	SINE/MIR	LINE/L1	LINE/L2	LTR	DNA	Other	Non-repeat	total	share
CDS	22	0	0	0	2	0	0	42	66	0.33%
5′ UTR	1,872	8	20	3	40	11	2	77	2,033	10.27%
3′ UTR	3,841	6	70	5	41	7	13	176	4,159	21.01%
intron	5,243	18	84	3	55	14	23	272	5,712	28.86%
ESTs	1,202	2	67	0	7	3	5	82	1,368	6.91%
no annotation	5,949	3	70	4	60	10	19	338	6,453	32.61%
total	18,129	37	311	15	205	45	62	987	19,791	
share	91.60	0.19%	1.57%	0.08%	1.04%	0.23%	0.31%	4.99%		

region	SINE/Alu	SINE/MIR	LINE/L1	LINE/L2	LTR	DNA	Other	Non-repeat	total	share
	%									

Every one of the forty-eight interior cells was re-summed. Every row total, every column total, every percentage in both margins, and the grand total reconcile exactly as printed. That is worth saying because a table this size usually does not.

What the shape of it says

Ninety-one point six percent of the sites are in SINE/Alu — confirming Parts Sixty and Sixty-One from a wholly independent method. Coding sequence holds 0.33 percent.

And a third of the sites — 32.61 percent — carry no annotation at all. They are in intergenic space, or in long non-coding RNAs, or in untranslated regions longer than the gene models record.

The largest single category of inosine in the human brain is in sequence the gene models do not name. The notation has no letter for the modification and no entry for the place it happens.

---

333. The Other Repeats, and the Hairpins ↩

Editing outside Alu

The chemical method found sites in repeat classes that bioinformatic prediction had missed — SINE/MIR, LINE/L1, LINE/L2, LTR elements, DNA transposons, 7SL RNA-like elements and 7SK RNA-like elements.

structure	length of the duplex
inverted SINE/Alu pair	about 300 base pairs
the other repeat classes	35 to 250 base pairs

Most form from the plus and minus strands of the same repeat element. Some form between different classes — three consecutive sites in a duplex made by an LTR and a SINE/MIR in one 3′ untranslated region.

The 7SL result, which is worth its own line

A single editing site was found in a 7SL-like element. 7SL RNA is the evolutionary ancestor of the SINE/Alu family, and the 7SL-like element can pair with the minus strand of a neighboring Alu because they are still similar enough in sequence.

The ancestor pairs with its own descendant, and the enzyme edits the duplex they make together. That is a molecular fossil forming a functional substrate with the thing it gave rise to.

And in one intron, five sites clustered in the antisense strand of a 7SK pseudogene — where the duplex may form in trans, with a separate 7SK transcript.

---

334. The Sequence Rules ↩

Base preference around the edited adenosine

position	all sites	sites edited above 50%
−1	C ≈ U ≈ A ⩾ G	U > C > A ⩾ G
+1	G > C ≈ A > U	G ⩾ C > A > U

At the most heavily edited sites, a U or C before and a G after is the commonest arrangement.

Triplet preference

triplet	all sites	above 50% editing	coding sites only
CAG	18%	18%	25%
UAG	13%	22%	12%
AAG	10%	11%	17%
GAC, **GAU**, **GAA**	1% each		

Any triplet beginning with G is edited about one time in a hundred. The guanosine before the target adenosine is the single strongest deterrent in the whole data set, and it is a statement about geometry rather than about sequence: a G at minus one blocks the flip.

The top five quadruplets were GUAG, CAAG, CUAG, UCAG and CCAG.

And the correlation between the ICE-seq editing ratio and the G peak measured by Sanger sequencing was $R^2 = 0.77$ — two entirely different measurements of the same quantity agreeing well.

335. The Coding Sites, and the Enzyme in Table One ↩

The coding census

Sixty-six novel coding-sequence sites in thirty-two genes.

causing an amino acid change	41 — sixty-two percent
in SINE/Alu	24
in LTR	2
in non-repeat sequence	40
lying in an apparent double-stranded structure	60 of 66 — ninety-one percent

The genes include SON, an essential DNA-binding protein of the nuclear speckles; BEST1, a calcium-activated chloride channel whose mutation causes Best vitelliform macular dystrophy; FLNB, filamin B, whose mutations cause boomerang dysplasia; NCSTN, nicastrin, a component of gamma-secretase; and ZNF699, a zinc-finger protein carrying two coding edits producing tyrosine-to-cysteine and asparagine-to-aspartate.

The ZNF699 asparagine-to-aspartate is recorded by the authors as a type of amino acid alteration never before documented in the reported editing sites. And the other edit in the same gene installs a cysteine.

And the two rows at the bottom of the table

The last two entries in Table 1, on chromosome 22, are both in MPST.

position	codon	change	repeat
chr22, 37,423,047	GUA to GUI	valine to valine	SINE/Alu
chr22, 37,423,068	UCA to UCI	serine to serine	SINE/Alu

Both are synonymous. Neither changes the protein. And the volume records them anyway, for what the gene is.

336. Mpst — the Second of the Three ↩

What the gene encodes

Mammals make hydrogen sulfide enzymatically by three routes and only three: cystathionine beta-synthase, cystathionine gamma-lyase, and 3-mercaptopyruvate sulfurtransferase. MPST is the third of those three.

Which makes this the second one found under the editor

Part	the enzyme	what it does
Part Sixty	CTH — cystathionine gamma-lyase	makes cysteine, and hydrogen sulfide. Its transcript is co-bound and stabilized by the ADAR1-HuR complex
Part Sixty-Two	MPST — 3-mercaptopyruvate sulfurtransferase	makes hydrogen sulfide from mercaptopyruvate. Its transcript carries two confirmed inosines
remaining	CBS — cystathionine beta-synthase	not yet reported as an editing target

Two of the three enzymes by which a mammal makes hydrogen sulfide have now been found under the control of the editor — one held by its complex, one edited in its own coding sequence. Neither paper says so. It required putting the two tables side by side.

And beta-mercaptopyruvate is already in this volume

Part Forty-Five traced the sulfur thread across the amino acid panel of the 1982 chart and recorded that beta-mercaptopyruvate leaves cysteine by transamination. MPST is the enzyme that takes it from there.

Part Fifty-One argued that hydrogen sulfide was the first molecule and the first ionized species. This is where a human brain still makes it, and the transcript is edited.

337. The Editor Edits the Modification Machinery ↩

Four more genes in the same table

gene	what it is	edits
METTL6	a methyltransferase	2
METTL10	a methyltransferase	4
PUS1	pseudouridine synthase — another RNA-modifying enzyme	3
CPT1A	carnitine palmitoyltransferase 1A — transfers an acyl group off a coenzyme A thioester	1

What the four have in common

Every methyltransferase in that list takes its methyl group from S-adenosylmethionine — a sulfonium. CPT1A works on a thioester. PUS1 performs a different chemical modification on RNA, and is itself chemically modified by RNA editing.

The enzyme that installs one RNA modification is edited on the transcripts of the enzymes that install another. And the methyl those enzymes carry comes off a sulfur.

Counting the table: of thirty-two genes carrying novel coding edits, four — MPST, METTL6, METTL10 and CPT1A — handle sulfur chemistry directly. That is one gene in eight, in a list selected for nothing but the presence of an inosine.

---

338. The Seed Edits ↩

What one edited base in a microRNA target site does

A microRNA silences a transcript by pairing its seed against a response element in the 3′ untranslated region. Edit an adenosine inside that element and the pairing changes.

the edit	the consequence
an A-C mismatch in the seed becomes I-C	the pairing is stabilized — silencing is strengthened, or a target site is created that did not exist. Gain type.
an A-U pair in the seed becomes I-U	the wobble destabilizes the pairing — silencing is relieved. Loss type.

The count

6,467 microRNA-response-element pairs across 847 genes carrying exactly one editing site in the seed sequence.

gain type — stabilized or created de novo	**2,963**	**45.8%**
loss type — destabilized by I-U wobbling	3,504	54.2%
	6,467	

Nearly six and a half thousand regulatory relationships, in eight hundred and forty-seven genes, whose existence or non-existence turns on whether one adenosine has had its amino group removed. The genome sequence gives the same answer either way.

---

339. What the Edited Genes Do ↩

Gene ontology across 2,114 edited genes

category	
nerve impulse, synapse, membrane, ion binding	the predominant categories
calcium binding motifs, glutamate receptors, 5-HT2 serotonin receptors	enriched
Krüppel-associated box and zinc finger motifs	enriched — the fourth independent arrival
mitochondrial proteins, respiratory chain and oxidative phosphorylation components	subject to editing
Alzheimer's, Huntington's and amyotrophic lateral sclerosis genes	high scores
oxidative stress response genes and apoptosis pathway components	enriched

The two rows this volume must not walk past

The respiratory chain is an iron-sulfur machine. Part Fifty-Three established that a modern mitochondrion's electron transport chain is an inherited bacterial photosynthetic chain, and that every iron-sulfur cluster in it is an inheritance. Its components are edited.

The oxidative stress response is a thiol response. Part Fifty-Four established that every major antioxidant system in the human cell is a thiol or selenol system. Those genes are enriched among the editor's targets.

Zinc finger and KRAB motifs arrive here for the fourth time, from a fourth method — after Part Sixty's gene ontology, Part Sixty-One's sixteen-fold KRAB enrichment, and Part Fifty-Two's structural account of the motif itself.

---

340. What Is Claimed and What Is Not ↩

Claimed

That acrylonitrile cyanoethylates the N1 of inosine to form N1-cyanoethylinosine, that the adduct arrests reverse transcription, and that inosines are therefore detected by the disappearance of reads. That the method requires no genomic DNA reference.

That deep sequencing returned about 54,000 A-to-G mismatches against the transcriptome, roughly twelve times the validated number, and that the authors conclude 92 to 95 percent of unfiltered A-to-G mismatches are not inosine. That of 25,285 A-to-G genomic SNPs only 241 exceeded an ICE score of 1.75.

That 11,639 plus 8,847 minus 695 equals the reported 19,791 novel sites — checked. That the sites lie across 2,114 genes including 1,258 newly identified. That non-coding validation was 902 of 931, a 3.1 percent false-positive rate. That the overlap with DARNED is 6,406 of 29,843, leaving 78.5 percent new.

That every interior cell, both margins and both percentage rows of Table 2 reconcile as printed — verified by re-summation. That 91.60 percent of sites are in SINE/Alu and 32.61 percent carry no annotation.

That 66 novel coding sites were found in 32 genes, 41 changing an amino acid, 60 of 66 in apparent double-stranded structures. That two of them lie in MPST and are both synonymous. That 6,467 microRNA pairs in 847 genes carry a single seed edit, 2,963 gain type and 3,504 loss type.

Not claimed

That the MPST edits change anything. Both are synonymous. The volume records the gene, not a function, and says plainly that no protein change follows.

That the editor regulates hydrogen sulfide production. Two of three H2S enzymes appear in editing data by two different mechanisms. That is a convergence worth recording and it is not a demonstrated regulatory relationship.

That the sulfur-handling genes in Table 1 are enriched. Four of thirty-two is a count from a small table with no background comparison. It is printed as a count and the enrichment test has not been done.

That any of the disease gene ontology terms implies causation.

---

341. What Would Show This Part Is Wrong ↩

— Show that acrylonitrile modifies bases other than inosine under these conditions, and the specificity the whole method rests on fails.

— Show that the reported 92 to 95 percent false-positive rate for unfiltered A-to-G mismatches is an artifact of their filtering rather than of sequence comparison, and section 330 — the strongest methodological statement in this volume — is overstated.

— Re-sum Table 2 and find a cell, margin or percentage that does not reconcile, and section 332's verification is wrong. The full table is printed above so that any reader can do it.

— Show that MPST is not one of the three enzymatic sources of hydrogen sulfide in mammals, and section 336's convergence has only one member.

— Test whether sulfur-handling genes are enriched among edited transcripts against a matched background. If they are not, section 337's count of four in thirty-two is chance, and the volume should print that it was tested and failed. This test has not been run and it is the one this Part most needs.

— Show that a guanosine at the minus one position does not suppress editing, and section 334's geometric reading of the triplet preference has no basis.

PART SIXTY-THREE · THE RECORD

Part Sixty-Three of the evidence volume, sections 342 to 362

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Two dated documents, thirteen years apart, and what they establish about when things were said. A page of objectives printed on the seventh of August 2003. An application to the Illumina Accelerator submitted in March 2016. One claim in the 2016 application has now been checked by computation and it holds — the rotation group of the cube sits inside Klein's one hundred and sixty-eight with index exactly seven.

---

342. Why a Volume of Science Carries Correspondence ↩

The standing of this Part

Book Three of this volume is provenance. It holds the wall, the plates and the working sheets, and it evidences nothing about chemistry. This Part belongs there.

What provenance is for is dates. A claim made after the supporting literature appeared is a reading of that literature. The same claim made before it is something else, and only a dated document can tell the two apart.

These two documents establish what was on paper, and when. That is their whole function here, and it is not a small one.

---

343. The Objectives Page, 7 August 2003 ↩

What it says

A printed page headed simply Objectives, dated 8/7/2003, listing twelve numbered aims in plain language. The hand annotations on it are the author's, added later.

item	what it states
1	that the four-code genetic primer is incorrect and was never empirically validated after 1953 — annotated in hand: "A new 6 nucleotide family"
2	that sulfur is the prime organic atomic element, initiating, coordinating and terminating the critical metabolic reactions
3	to trace sulfur from interstellar space through its crystalline mineral state to the sulfides, sulfates and sulfo-metallic salts
4	that the sulfur amino acids start (methionine) and stop (cysteine) amino acid synthesis
5	that acetyl coenzyme A is the initiating catalyst for ATP synthesis
6	"To show how inosine should be included as the sixth nucleotide" — with "xanthine" written in above by hand
7	that inosine should join adenine and guanine as a purine base, since IMP is the initial step in purine synthesis
8	that the four-code primer is incorrect, with empirical, logical and probability estimates
10, 11	that pharmaceutical side effects are coding errors arising at the amino acid stage
12	that the four-code transformation is inconsistent with symmetry and parsimony

What is on that page and what it became

Item six states the six-nucleotide claim, in print, on the seventh of August 2003. Item seven gives the reason — that inosine monophosphate is the first purine made. Item two states the sulfur thesis. Item three states the interstellar-to-mineral chain. Item four states the methionine-start and cysteine-stop pair.

Those five items are, in outline, Parts One, Forty-One, Fifty-One and Fifty-Seven of this volume. They were written twenty-three years before it was typeset.

344. What Had Not Yet Happened in 2003 ↩

The sequence of the field, set against the date on that page

year	what happened
2003	the objectives page is printed
2004	Levanon and colleagues systematically identify abundant A-to-I sites in the human transcriptome
2005	Eisenberg and colleagues ask whether abundant A-to-I editing is primate-specific
2011	Li and colleagues report widespread RNA-DNA differences in Science
2012	three separate Comments in Science dispute that report
2013	Piskol and colleagues report lack of evidence for non-canonical editing
2013	Wang and Cheung publish the B-cell resource — Part Sixty
2014	Sakurai and Suzuki publish ICE-seq, having had to invent a chemistry — Part Sixty-Two
2014	Daniel and Öhman publish the Alu recruitment mechanism — Part Sixty-One
2016	the review the author annotates in Part Fifty-Nine

The objectives page precedes the RNA-DNA difference controversy by eight years and its chemical resolution by eleven. It states that inosine should be counted as a base before the field had established how many inosines there are.

The volume claims the date and nothing more. What the page shows is that the position was taken early. It does not show that it was taken for the reasons the later literature supplies.

345. The Application, March 2016 ↩

What was submitted

An application to the Illumina Accelerator, San Francisco, describing NovagonDNA in one sentence: to validate an updated, expanded seven-nucleotide genetic code — A, T, U, I, C, G, X — against the canonical Watson-Crick set.

the record states	
years on the problem	fifteen and more, self-funded by the founder
invested to that date	$950,000
monthly burn	$3,000 to $5,000

the record states	
outside funding received	none
team	one

The ask

The application asks for an instrument. Not a theory, not a collaboration — a sequencer.

"I need a sequencer to sequence seven heptad nucleotides to pair with the protein alpha helix motifs."

The stated obstacle is that high-throughput sequencing reads four symbols and the position being argued requires more. That is a hardware request, and it is the correct kind of request for the claim being made.

---

346. The Problem the Application Named ↩

The sentence worth dating

The application states that adenosine-to-inosine is represented by A-to-G proxies, and that these are often ambiguous with single nucleotide polymorphisms, especially in non-coding Alu elements.

What was happening in the field at that moment

That is exactly the problem that had convulsed the field between 2011 and 2014.

the field's version	
2012	up to 94% of reported RNA-DNA differences estimated to be false positives from mapping error
2013	mapping errors shown to persist even in improved methods
2014	Sakurai and colleagues conclude that 92 to 95 percent of unfiltered A-to-G mismatches are not inosine at all, and build a chemical method because sequence comparison could not be trusted

The application names the A-to-G proxy ambiguity in Alu as its central technical obstacle. That is the same obstacle, named in the same terms, in the same years. The author was not reading the controversy

into his position; the position had that problem built into it from the start.

And the instrument he asked for now exists

In 2016, no commercial platform read modified bases directly. It sequenced complementary DNA, and the modification was gone by then.

Direct RNA sequencing by nanopore reads the RNA strand itself and detects base modifications, including inosine, without conversion to cDNA. That capability matured after the application was written.

The volume records this factually. The instrument the application asked for is closer to existing now than it was then, and the reason it did not exist in 2016 was not that nobody wanted it.

---

347. The Heptad, and the Claim About Klein ↩

What the application asserts

- The alpha helix is the classic Pauling-Corey-Branson helix, also written 3.6_{13} — 3.6 residues per turn, thirteen atoms in the ring closed by the hydrogen bond. Correct.
- The carboxy-terminal domain of RNA polymerase II is built from heptad repeats with the consensus Y1-S2-P3-T4-S5-P6-S7, and humans carry fifty-two of them. Correct.
- The heptad nucleotide code binds with the heptad alpha helix to form a higher-order structure, on genetic network Hamiltonian circuits based on Felix Klein's 168-symmetry quartic curve in non-Euclidean hyperbolic space.

Why the heptad is a real structural number

A coiled coil is built from alpha helices that are slightly underwound — 3.5 residues per turn rather than 3.6.

$$3.5 \text{ residues per turn} \times 2 \text{ turns} = 7 \text{ residues}$$

The heptad repeat exists in proteins because two turns of a slightly underwound helix contain exactly seven residues. The number seven

in the coiled coil is not a convention. It is the closure condition of the geometry, and the author paired it with the polymerase tail correctly.

And Klein's curve

The Klein quartic is a genus-three surface uniformized by the hyperbolic plane, and its automorphism group has order 168. That group is PSL(2,7), the second-smallest non-abelian simple group. The application's description is accurate.

---

348. The Cube Inside the One Hundred and Sixty-Eight ↩

What was checked

The group PSL(2,7) was constructed explicitly, element by element, and searched for subgroups.

result	
order of PSL(2,7)	168 — confirmed by construction
element orders present	1, 2, 3, 4 and 7 — with 48 elements of order seven
a subgroup of order 24 was found	yes
its element orders	one identity, nine of order two, eight of order three, six of order four
that profile	is exactly the symmetric group on four letters
its index in PSL(2,7)	exactly seven

What that means for this volume

Part Forty-Nine placed the four bases on the four body diagonals of a cube and established that the twenty-four rotations of that cube are the twenty-four permutations of the four-letter alphabet — the symmetric group on four letters.

That group sits inside Klein's 168 as a subgroup of index seven. There are exactly seven cosets. The cube of Part Forty-Nine and the heptad of the 2016 application are the same object, related by 168 = 24 × 7.

The author wrote the heptad and the Klein 168 into an application in 2016 without the cube. The cube was built in 2026 without the Klein curve. The two meet in an index, and the index is seven.

This has been verified by construction and can be verified again by anyone with the same twenty lines of code. What it is not is an explanation. The volume records the arithmetic and does not claim a mechanism.

349. The Triplex Sheet ↩

The handwritten page

A worksheet headed Current genetic code validated against new NovagonDNA's Triplex genetic code, carrying a pairing scheme in the author's hand:

$$A \;\; I \;\; X \;\; G\backslash nT \;\; U \;\; ✗ \;\; C$$

Below it, the pairings written out: A-T, A-U, A-I with T, I with T, I with V, X over G, X = C over I, G-C, C-G. Beside them: acetyl-amino, tRNA synthetase, anticodon (2) tRNA, codon (1) mRNA, and the transcription direction DNA 5′ to 3′, COOH to NH3+, to mRNA.

What it anticipates

That is an eight-symbol scheme with the purines on one row and the pyrimidines on the other, and one pairing marked with a cross.

The cross sits under X. In Part Forty-Nine, xanthine is the corner of the cube whose antipode is orotate, and the volume's finding is that the pair does not exist. The worksheet marks the same absence with a cross, by hand, a decade earlier.

And the triangle drawn beside it — H_1, H_2, H_3 with the note $H_3 \neq H_1 + H_2 + H_3$ — is a note about non-additivity, drawn next to a hexagon.

350. The Change of Mind, Dated ↩

Six, then seven, then six

date	the position
7 August 2003	six — "inosine should be included as the sixth nucleotide", with xanthine noted in hand

date	the position
March 2016	seven — A, T, U, I, C, G, X, stated in the application
2026, Part Thirty-Eight	six — the volume records the revision from seven letters back to six
2026, Part Forty-Eight	four, six and eight, each closed under a different operation

The volume's Preface states that where this volume changed its own mind, the record is printed rather than omitted. Until now that was an assertion. It is now a paper trail with three dates on it.

A position held for twenty-three years, revised twice, with the revisions documented. That is what the method claims to do, and this Part is where the claim can be checked.

---

351. The Objection to Imaginary Numbers, Reconciled ↩

What was written

In a letter accompanying the same material, the author wrote that nature does not use imaginary numbers and nor should we — naming simple, real, transcendental, prime, rational and irrational numbers as admissible and excluding the square root of minus one.

And what Part Forty-Nine found

Part Forty-Nine did not put the quaternions into the genetic code. It put the quaternion group modulo its center — the Klein four-group.

in the quaternions	in the quotient
i, j, k each square to minus one	every element squares to the identity
the real unit is distinguished	all four elements are on the same footing
imaginary units exist as such	no imaginary unit survives

The structure the four bases actually carry contains no imaginary number. Both i and minus i map to the same half-turn, and forgetting the sign is precisely what removes the imaginary from the algebra.

The 2016 objection and the 2026 construction agree, and they agree because the construction is the quotient rather than the algebra.

The volume records this as a reconciliation and not as a vindication of either statement. The mathematics settles it and the mathematics is in Part Forty-Nine.

---

352. The Other Material in the File ↩

Recorded because provenance is a record

item	
the 192-page outline	the author's first comprehensive outline, twenty-seven sublevels, from the root singularity to human consciousness, made around 2006
"Visioneering"	the author's term for non-linear fractal pattern recognition across scales
DrKyia	the author's named alter ego and writing voice
the twenty-two-question sheet	a self-interrogation on validity, evidence, criteria, probability and obstacles — annotated in hand throughout
the color coding	the application records that all nucleotide families were color-coded to the seven colors of the rainbow across the KEGG maps

The twenty-two-question sheet is the interesting one. Question seven asks how you know you are correct, and the hand annotation replaces "correct" with "valid" and then "reliable." Question twelve asks how you will know if your theory is correct, and the annotation strikes that out and writes "validate your."

A man correcting his own questions toward the harder words. The volume's habit of ending every Part with the conditions under which it would be wrong has an origin, and it is on that sheet.

---

353. The Correspondence, as Record ↩

The sequence

date	
March 2016	the application is submitted
March 2016	Illumina advances the company to the screening round — a fifteen-minute web conference with the selection committee
17 March 2016	the web conference is held
24 March 2016	the in-person round in San Francisco
19 March 2016	the company is informed it was not among the selected applicants

The recorded feedback, written by the author in the margin of that letter, reads: presentation skills, format, font size, titles, subtitles, pictures, fewer objects, better spaced.

The feedback the author wrote down concerned the deck. The volume records that and draws no conclusion from it.

One founder, no team, no prior funding, and a hypothesis that required new hardware to test. Those are the facts of the application, and they are printed here as facts.

---

354. The Healthy Cells Page, 23 May 2004 ↩

A nested outline, one page, dated

A single sheet headed Healthy Cells, dated 5/23/2004, running as one continuous indent from the top of the page to the bottom.

Evolution\nAtomic Level\nSulfur Master Atomic Molecular SuperString of Life\nMinerals and Crystals\nCrystalline Molecular Structures\nEnzymes\nmetabolic pathways\nNucleic Acids\nDouble Helix Genetic Code\namino acids\nprotein synthesis\nGenes\nDNA\nChromosomes\nHuman Extinction\nHistone\nGenetic Algorithms and Mathematical Operators\nTreatments\nSide Effects and Fatalities\nMetabolic Diseases\nTriple Helix\nIMP

The second line of that outline is sulfur, and the whole descent from the atomic level to human disease hangs off it. Parts One, Fifty, Fifty-One and Fifty-Two of this volume are that descent, written out twenty-two years later.

355. The Chain at the Bottom of That Page ↩

Eight levels, nested, in 2004

Triple Helix\nIMP\nSide Effect Free\nGlutamate Major Excitatory Neurotransmitter CNS\nADAR 3 Protein\nADAT Gene\nIMPDH Enzyme\nMitochondria

What each of those is

the entry	what it names
IMP	inosine monophosphate — the first closed purine ring
glutamate, CNS	the receptor whose Q/R site is the best-known recoding edit
ADAR3	the brain-specific, catalytically inactive member of the editing family
ADAT	adenosine deaminase acting on tRNA — the enzyme that installs inosine at anticodon position 34
IMPDH	inosine monophosphate dehydrogenase — the committed step from IMP toward guanine
mitochondria	

ADAR3 and ADAT on consecutive lines, in 2004. Those are the two arms of inosine installation — one writing into messenger RNA, one writing into transfer RNA at the wobble position — and the outline places them one under the other, beneath glutamate and above the enzyme that consumes IMP.

Part Fifty-Nine describes ADAR3 as brain-only and catalytically inactive. Part Fifty-Seven's entire join rests on inosine at anticodon position thirty-four, which is ADAT's product. Part Fifty-Eight names IMPDH's pathway. The three sit together on one 2004 page, in the right order, under the right neurotransmitter.

356. The Outline, and the Sentence About the Instrument ↩

What the numbered outline argues

A companion document of at least ten pages, numbered in decimal outline form through section seven. Its argument is that the four-letter code is incomplete

because inosine monophosphate is the first purine nucleotide with a closed ring and precedes both AMP and GMP.

item	what it states
2.3.1.3	IMP is the first purine nucleotide with a closed ring structure; it precedes AMP and GMP
2.7	addition, not substitution, is nature's evolutionary mathematical operator
2.8	the wobble theory and messenger RNA editing are two instances which contradict the standard central dogma
4.2	the double helix won acceptance by default when Pauling's triple helix failed, because he had the phosphates pointing in and not out
7.1.4	inosine is the only nucleoside which can covalently bond with three other nucleotides

Item 4.2 is historically correct. The Pauling and Corey structure of 1953 placed the phosphate groups on the inside of a three-chain helix with the bases facing out. That is the error, and the outline names it precisely.

And the sentence that matters most

"Current genetic code sequencing technologies and databases are program d only to identify the present four DNA and four RNA nucleotide bases. One cannot identify that which cannot be seen; the self-fulfilling prophecy falsely validates the current genetic code by outputting only the DNA and RNA base pair sequences."

What happened afterward

Part Sixty-Two of this volume records what a laboratory found in 2014.

A-to-G mismatches returned by deep sequencing, unfiltered	about 54,000
the fraction that were not inosine	92 to 95 percent
what had to be built	a chemical reaction, because sequence comparison could not tell an edit from a polymorphism

The outline states in 2004 that the instrument can only report what it was built to report, and that this circularity validates the code it was built on. Ten years later a group demonstrated exactly that failure rate and had to invent a chemistry to get around it.

The volume claims the date and the sentence. It does not claim that the 2004 document anticipated the specific figure, and it did not.

---

357. The Three Pairs ↩

What section 5.3 proposes

"Add inosine as third purine nucleotide base, and do not substitute uracil for thymine; thus ending up with a new genetic code with six nucleotides and three pairs of purine-pyrimidine nucleotides."

A - T G - C I - U

And section 5.3.1 assigns the three sets to three processes:

set	role assigned in 2004
A T G C	transcription
I U G C	translation
A T U I	replication

What of that holds

The I-U pair is real. Part Fifty-Seven, section 272, records that inosine at anticodon position thirty-four pairs with uracil, cytosine and adenine. I with U is one of the three, and it is the pairing that reads a codon ending in A.

The three-role assignment does not hold as written. Replication uses A, T, G and C; transcription produces A, U, G and C; translation reads codons and anticodons in which inosine appears only at position thirty-four of the anticodon. The 2004 assignment has the right symbols in the right neighborhood and the wrong process labels, and the volume says so.

What survives is the pairing. What does not survive is the allocation of the three sets to replication, transcription and translation.

---

358. The Eight Amino Acids, Checked ↩

What section 7.1.5 lists

The outline names eight amino acids as encoded through inosine wobble codons, and computes the fraction.

the eight, as listed in 2004
alanine · arginine · isoleucine · serine · threonine · proline · leucine · valine
8 of 20 = 40 percent

What the current record says

In eukaryotes, adenosine deaminase acting on tRNA converts adenosine to inosine at anticodon position thirty-four in a specific set of transfer RNAs.

the transfer RNAs carrying inosine at position 34
tRNA-Ala, tRNA-Arg, tRNA-Ile, tRNA-Leu, tRNA-Pro, tRNA-Ser, tRNA-Thr, tRNA-Val

The two lists are identical. Eight for eight, and the arithmetic — eight of twenty, forty percent — is correct.

Why that is more impressive than it first appears

There is a nearby list that would have been the easy guess and it is not the list he wrote.

The amino acids whose codon boxes are fully four-fold degenerate are alanine, arginine, glycine, leucine, proline, serine, threonine and valine — also eight.

the four-fold box list	his list
includes glycine	does not
does not include isoleucine	includes isoleucine

Transfer RNA for glycine does not carry inosine at position thirty-four. Transfer RNA for isoleucine does.

He wrote the inosine list, not the degeneracy list, and the two differ by exactly one substitution. That is not a lucky guess at a round number. It is the correct set.

359. Where the 2004 Document Overreaches ↩

Printed because the volume prints this

The outline carries estimates the volume does not adopt.

the 2004 statement	the volume's position
over 40% of amino acids are involved in SNPs; SNPs account for over 80% of mutational disease; at least 60% of those trace to the omitted purine	no source is given and none is known. The volume does not carry these figures
over 70% of metabolic and genetic disease is caused by purine SNPs	not carried
the validity of the current code is 0.0000000000000000	that is a rhetorical figure, not a computed validity
prescription medications are the fourth leading cause of death	this traces to a real source — Lazarou, Pomeranz and Corey, JAMA, 1998, estimating about 106,000 deaths a year from adverse drug reactions in hospitalized patients. The ranking is contested in the subsequent literature. The volume records the source and the dispute
"28 years since the code was devised in 1966"	1966 to 2004 is thirty-eight years. The interval as printed is short by ten
stray numerals 9261, 9263, 9265 in section 4.3	artifacts of the outlining program, not content

The volume carries the dates, the pairings, the eight amino acids and the sentence about the instrument. It does not carry the percentages. Separating those two things is what makes the first group usable.

360. The Three Documents Together ↩

What the archive now establishes, by date

date	document	what it puts on paper
7 August 2003	Objectives	inosine as the sixth nucleotide; sulfur as the prime element; the interstellar-to-mineral chain
23 May 2004	Healthy Cells	sulfur at the head of the descent; IMP, glutamate,

date	document	what it puts on paper
		ADAR3, ADAT, IMPDH nested in order
circa 2004	the numbered outline	the three pairs A-T, G-C, I-U; the eight inosine-wobble amino acids; the sentence about the instrument
March 2016	Illumina application	seven symbols; the A-to-G proxy problem in Alu; the heptad and Klein's 168
2026	this volume	four, six and eight, each closed under a different operation

Two decades, five documents, one question. The positions changed twice and the changes are dated. What did not change is the object: the third purine, and the element that has no letter.

---

361. What Is Claimed and What Is Not ↩

Claimed

That a printed page dated 8 August 2003 states, in item six, that inosine should be included as the sixth nucleotide, and in item seven that it should join adenine and guanine as a purine base because IMP is the first step of purine synthesis. That the same page states the sulfur thesis, the interstellar-to-mineral chain and the methionine-start cysteine-stop pair.

That the March 2016 Illumina Accelerator application states a seven-symbol code, names the A-to-G proxy ambiguity with SNPs in Alu as its central technical obstacle, and records fifteen years of self-funded work and $950,000 invested.

That the alpha helix is correctly described as 3.6_{13}, that the human RNA polymerase II CTD carries fifty-two heptad repeats of the consensus given, and that the heptad exists in coiled coils because two turns of a 3.5-residue helix contain seven residues.

That the Klein quartic's automorphism group has order 168 and is PSL(2,7). That PSL(2,7) contains a subgroup of order 24 whose element-order profile is that of the symmetric group on four letters, and that its index is exactly seven — constructed and verified computationally.

Not claimed

That the 2003 page anticipated the later literature for the reasons the later literature supplies. It states a position and a date, and the volume claims the date.

That the index-seven relation between the cube group and Klein's 168 explains anything. It is an arithmetic fact, verified, and no mechanism is offered.

That the Healthy Cells page is dated 23 May 2004 and nests IMP, glutamate, ADAR3, ADAT, IMPDH and mitochondria in that order. That the accompanying outline proposes the three pairs A-T, G-C and I-U, states that inosine is the only nucleoside able to pair with three others, and names eight amino acids encoded through inosine wobble codons. That those eight are identical to the set of transfer RNAs carrying inosine at anticodon position thirty-four, and that the list differs from the four-fold degenerate codon boxes by exactly one substitution — isoleucine for glycine. That the outline's account of the Pauling triple helix error is historically correct.

That any figure or projection in the 2016 application is a finding of this volume. An accelerator application is an advocacy document written to a deadline. The volume carries it as a dated record of position and does not adopt its estimates of lives saved, its statement that no other group works on the problem, or its assessment of the validity of the current code as zero. Part Fifty-Seven records the published quaternionic genetic code literature; Part Sixty-Two records the field's own chemical resolution of the proxy problem.

That the percentage estimates in the 2004 outline are supported. Section 359 lists them and the volume does not carry them.

That the 2004 three-role assignment of the symbol sets to replication, transcription and translation is correct. Section 357 states plainly that it is not.

That the outcome of the application bears on the science. It does not, in either direction.

362. What Would Show This Part Is Wrong ↩

— Show that the objectives page is not dated 2003, and the priority claim of section 343 has no foundation. The document is in the archive and the date is printed on it.

— Show that the A-to-G proxy ambiguity in Alu was not a live and unresolved problem in the field in 2016, and section 346's convergence is retrospective rather than contemporaneous.

— Show that PSL(2,7) has no subgroup isomorphic to the symmetric group on four letters, or that its index is not seven, and section 348 falls. The construction is twenty lines and the volume invites the check.

— Show that the coiled-coil heptad does not arise from two turns of a 3.5-residue helix, and section 347's structural account of the number seven is wrong.

— Show that direct RNA sequencing cannot detect inosine without conversion to cDNA, and section 346's statement that the requested instrument now approaches existence is wrong.

— Show that the transfer RNAs carrying inosine at position thirty-four are not the eight named in section 358, and the strongest verified item in the 2004 outline fails.

— Show that the Pauling and Corey 1953 structure did not place the phosphates internally, and section 356's historical claim is wrong.

— Produce a dated document earlier than 2003 in which the author states a different number of bases, and the six-seven-six sequence of section 350 is incomplete as printed.

PART SIXTY-FOUR · THE PRECURSOR

Part Sixty-Four of the evidence volume, sections 363 to 375

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Torres, Piñeyro, Rodríguez-Escribà, Camacho, Reina, Saint-Léger, Filonava, Batlle and Ribas de Pouplana, Nucleic Acids Research, 2015. The enzyme the author wrote on a page in 2004, one line below ADAR3. It writes inosine into eight transfer RNAs, and this paper establishes that it writes it before the molecule is finished.

---

363. The Question ↩

Where in the life of a transfer RNA does the inosine appear

A transfer RNA is transcribed with a 5′-leader and a 3′-trailer that are cut away during maturation. The anticodon of eight human tRNAs begins with adenosine at position thirty-four, and in all eight that adenosine is deaminated to inosine.

The enzyme is a heterodimer of two subunits, ADAT2 and ADAT3, written together as hetADAT.

The question this paper asks is simple and had never been answered: does the enzyme act on the finished transfer RNA, or on the precursor that still carries its leader and trailer?

The answer is the precursor. The inosine is installed before the molecule is a transfer RNA.

Why the volume needs that answer

Part Fifty-Seven's join rests on inosine at anticodon position thirty-four — that it pairs with uracil, cytosine and adenine and excludes guanine, and that guanine is the transition image of its own parent.

This paper establishes when that base is made. The degeneracy the wobble position provides is not added to a working molecule as an adjustment. It is built in before the molecule exists.

---

364. The Method ↩

Reading the leader and the trailer

The authors sequenced small RNA from human embryonic kidney cells and sorted the transfer RNA reads by whether they still carried the sequences that maturation removes.

class	definition
precursor	the read carries a 5′-leader and/or a 3′-trailer
processed	the read lacks both

Reads had to map unambiguously to a single transfer RNA type.

reads mapping to the transfer RNA class	about 1% of all sequencing reads
of those, precursor	about 70%
of those, processed	about 30%

Seventy and thirty. The split is clean and the whole result rests on roughly one read in a hundred. That is worth stating plainly, and the paper states it.

The full read census

Fifteen biotypes were counted and they sum to one hundred percent.

biotype	share	biotype	share
processed transcript	37.24%	rRNA	0.61%
snoRNA	26.86%	mt-tRNA	0.25%
protein coding	26.55%	misc RNA	0.25%
antisense	4.85%	pseudogene	0.18%
lincRNA	1.19%	mi-tRNA	0.14%
tRNA	0.98%	sense overlapping	0.14%
snRNA	0.65%	sense intronic	0.08%
		miRNA	0.05%

365. The Eight, Again ↩

The transfer RNAs that carry the modification

transfer RNA	anticodon
tRNA-Ala	AGC
tRNA-Arg	ACG
tRNA-Ile	AAT
tRNA-Leu	AAG
tRNA-Pro	AGG
tRNA-Ser	AGA
tRNA-Thr	AGT
tRNA-Val	AAC

Every one of those anticodons begins with A. That is what the class name ANN means — adenosine at position thirty-four, then any two bases.

The genome writes adenosine at that position eight times, in eight different transfer RNAs, and the cell destroys all eight. There is no transfer RNA in a human cell that keeps the adenosine the gene specifies at position thirty-four.

And these are the author's eight

Part Sixty-Three records a document dated 2004 in which the author listed eight amino acids as encoded through inosine wobble codons: alanine, arginine, isoleucine, serine, threonine, proline, leucine and valine.

This paper's eight transfer RNAs correspond to exactly those eight amino acids. Checked, one by one. The list the author wrote down eleven years before this paper was published is the list this paper measures.

---

366. The Result ↩

Adenosine in the precursor, guanosine in the processed

Because reverse transcriptase reads inosine as guanosine, the base at position thirty-four is returned as A when unmodified and as G when modified.

	base returned at position 34
precursor transfer RNA reads	predominantly A
processed transfer RNA reads	predominantly G

The shift was significant at P below 0.001 for six of the eight. For tRNA-Thr and tRNA-Ile the G was not detected, and the authors state the reason: not enough reads.

The controls that make it a result

control	outcome
the other adenosines in the anticodon, positions 35 and	not modified — the change is specific to position 34

control	outcome
36	
guanosine detected at position 34 in the precursor group	not observed
sequencing error at positions of known C and T	ruled out
the same analysis on tRNA-Ala position 37	A37 first deaminated to I37, then methylated

The modification is at one position, in one direction, and it appears as the molecule matures. That is a time course read out of a sequencing library.

---

367. The Proof in a Test Tube ↩

Endonuclease V

Endonuclease V is a DNA repair enzyme that cleaves specifically just after an inosine. If the enzyme has put an inosine at position 34, EndoV will cut there and nowhere else.

A precursor tRNA-Val with its leader and trailer intact was transcribed, radiolabeled, incubated with purified human hetADAT or without it, and then treated with EndoV.

full-length pre-tRNA-Val(AAC) 95 nt\nafter EndoV cleavage at position 34:\n5' fragment 41 nt\n3' fragment 54 nt\n-------\n95 nt

Forty-one plus fifty-four is ninety-five. The arithmetic closes exactly.

condition	result
precursor incubated with hetADAT, then EndoV	two bands, 41 and 54 nucleotides
precursor without hetADAT, then EndoV	no cleavage

The molecule was cut at one place, and the two pieces add up to the whole. That is a chemical demonstration, not an inference from a sequence — and it is the same kind of move as Part Sixty-Two's

chemical erasure. Twice now, the field has resolved a question about inosine by reacting with it rather than by reading it.

---

368. The Order of Operations ↩

Two modifications on one transfer RNA, in sequence

Transfer RNA for alanine carries a modification at position 37 as well as at 34.

A37 as written in the gene\n| deamination, by ADAT1\nv\nI37 inosine\n| methylation, by Trm5 — the methyl comes from S-adenosylmethionine\nv\nm1I37 1-methylinosine

What the sequence tells the volume

The deaminase acts first and the methyltransferase second. The methyl cannot be placed until the amino group has been removed. And the methyl is carried on a sulfonium — the S-adenosylmethionine of Part Forty-Five.

Inosine at 34 is installed earlier still, at the precursor level, while I37 appears later. The paper describes the whole thing as a stepwise process — position 34 first, position 37 afterward, methylation last.

Part Sixty-Two found that the editor edits the transcripts of methyltransferases. This section adds the tighter statement: on one molecule, at one position, the deaminase makes the substrate that the methyltransferase then modifies.

---

369. The Two Subunits ↩

One catalytic, one not

subunit	role
ADAT2	the catalytic subunit
ADAT3	thought to have lost catalytic activity; may play a role in substrate recognition

Where each one goes

Fluorescent fusion proteins were built and imaged in living cells.

expressed	where it went
ADAT2 alone	mainly the nucleus, partly the cytoplasm
ADAT3 alone	mainly the cytoplasm
both together	both in the nucleus

ADAT3 cannot get into the nucleus on its own. It translocates in an ADAT2-dependent manner. The subunit that cannot perform the reaction is also the subunit that cannot reach the place where the reaction happens, unless its partner takes it there.

The family resemblance

Part Fifty-Nine records that ADAR3 is catalytically inactive and expressed only in brain. Here is a second inactive partner in the same chemistry, in a different enzyme, on a different substrate.

Both families that install inosine carry a member that cannot install it. In one case the inactive member antagonizes the active ones; in the other it is required for the complex to work at all.

---

370. Adat2 Is Probably Essential ↩

The knockout that could not be made

The authors attempted to generate an ADAT2 knockout cell line.

single cells treated with CRISPR/Cas9	more than 100
viable	about 30%
full knockout clones obtained	none

Knockdown by short hairpin RNA did work, and it reduced inosine at position 34 significantly in all eight transfer RNAs.

The gene can be turned down. It cannot be turned off. The homolog is already known to be essential in yeast, in Trypanosoma brucei and in Arabidopsis thaliana, and this is the human result.

What that means in the volume's own terms

Part Fifty-Seven established that inosine is the only deamination product that survives into the reading alphabet. This section adds that the enzyme which installs it into transfer RNA appears to be indispensable to a human cell.

A symbol the four-letter notation cannot write is placed by an enzyme a human cell cannot live without.

---

371. What This Settles, and What It Opens ↩

For Part Fifty-Seven

The join of Part Fifty-Seven rests on inosine at position 34 pairing with uracil, cytosine and adenine and excluding guanine. Figure 5 of this paper draws those three pairings as chemical structures — I with U, I with A, I with C — and draws A with U for the unmodified precursor.

For the notation argument

A gene specifies adenosine at position 34 in eight transfer RNAs. No mature transfer RNA in a human cell carries that adenosine. And the substitution happens before the molecule is finished.

what the four letters describe	
the gene	A
the precursor, early	A
the precursor, after hetADAT	I — which the notation cannot write
the mature transfer RNA	I
what a sequencing read returns	G

Four states, and the alphabet has symbols for two of them — and neither of those two is the state the molecule is actually in when it does its job.

What it opens

The authors note that the modification could be modulated, that inosine at 34 expands the decoding capacity of a transfer RNA, and that the level of the modification may be a further layer of regulation over protein translation. They report this as a possibility under investigation, and the volume records it as one.

---

372. The 2004 Page, Closed ↩

What the author wrote and where it now stands

Part Sixty-Three records a nested outline dated 23 May 2004 whose lower branch reads: IMP, glutamate, ADAR3 protein, ADAT gene, IMPDH enzyme, mitochondria.

the 2004 line	where this volume now stands
IMP	Parts Forty-One and Fifty-Eight
glutamate, CNS	Part Fifty-Nine — the Q/R site
ADAR3	Part Fifty-Nine — brain-only, catalytically inactive
ADAT	this Part
IMPDH	Part Fifty-Eight
mitochondria	Parts Fifty-Three and Sixty-Two

Every entry on that 2004 branch now has a Part. The author wrote the chain before the literature for four of its six links existed in the form the volume now cites.

The volume claims the correspondence and the dates. It does not claim that the 2004 outline predicted the mechanisms, and it did not — it named the objects.

---

373. A Correction to Part Fifty-Nine ↩

Printed because the volume prints these

Part Fifty-Nine described the author's margin note listing I with C, I with U and I with G as "three of inosine's four wobble pairings, the fourth being I with A."

That was wrong. Inosine has three wobble partners — uracil, cytosine and adenine. I with G is not among them, and Part Fifty-Seven had already established that guanine is the one base inosine excludes.

The two Parts contradicted each other and Part Fifty-Seven was correct. Part Fifty-Nine has been amended, the amendment is stated on its own page, and it is recorded here as well so that a reader who reads only one of the two is not misled.

The author's margin listed the three pairings he was weighing. The one that is impossible is the one the volume's central join turns out to rest on.

---

374. What Is Claimed and What Is Not ↩

Claimed

That inosine at anticodon position 34 in humans is installed by hetADAT, a heterodimer of ADAT2 and ADAT3, and that this paper establishes it occurs at the precursor transfer RNA level. That transfer RNA reads were about 1% of the sequencing library, that about 70% carried a leader or trailer and about 30% did not, and that the fifteen reported biotypes sum to 100 percent within rounding.

That eight human transfer RNAs carry the modification, that their anticodons are AGC, ACG, AAT, AAG, AGG, AGA, AGT and AAC, and that all eight begin with adenosine at position 34. That these correspond to the eight amino acids listed in the author's 2004 document — checked one by one.

That precursor reads return A at position 34 and processed reads return G, significant at P below 0.001 for six of the eight, with the other two lacking sufficient reads. That adenosines at positions 35 and 36 were not modified.

That endonuclease V cleaved the hetADAT-treated precursor into fragments of 41 and 54 nucleotides from a 95-nucleotide molecule, and that 41 plus 54 is 95. That untreated precursor was not cleaved.

That A37 in tRNA-Ala is deaminated to I37 and subsequently methylated to 1-methylinosine. That ADAT3 requires ADAT2 to reach the nucleus. That of more than

one hundred CRISPR-treated single cells about 30% were viable and none was a full ADAT2 knockout, and that the homolog is essential in yeast, T. brucei and A. thaliana.

Not claimed

That ADAT2 is proven essential in humans. The paper states it is probably essential and the volume uses the same word.

That inosine at position 34 is regulated in vivo to any functional end. The authors raise it as a possibility and this Part records it as one.

That the 2004 outline anticipated any mechanism in this paper. It named ADAT. Section 372 says exactly that and no more.

375. What Would Show This Part Is Wrong ↩

- Show that hetADAT cannot deaminate a precursor transfer RNA carrying its leader and trailer, and the central claim of this Part fails.
- Show that endonuclease V does not cleave specifically 3′ of inosine, and the 41-and-54 result of section 367 does not locate the modification at position 34.
- Find a human transfer RNA that retains genomic adenosine at position 34 in its mature form, and section 365's statement that all eight are converted is wrong.
- Obtain a viable full ADAT2 knockout human cell line, and section 370's essentiality claim is wrong. The paper reports failure to obtain one and the volume reports the failure rather than an assertion.
- Show that methylation at position 37 can precede deamination, and the order of operations in section 368 is not fixed.
- Show that ADAT3 reaches the nucleus without ADAT2, and section 369's escort finding fails.

PART SIXTY-FIVE · THE RECURSION

Part Sixty-Five of the evidence volume, sections 376 to 388

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

Lin, Jiang, Park, Wang, Lu, Lam, Ping and Xing, Genome Biology, 2016. Alu-derived peptides are in human proteins. One of those proteins is the RNA editing enzyme itself, and the Alu-derived peptide sits inside its catalytic domain. The enzyme that edits Alu is partly built out of Alu.

376. The View This Paper Overturns ↩

What was believed

The prevailing position, established in 2006, was that exons derived from young repetitive elements such as Alu are restricted to regulatory functions and have not had adequate evolutionary time to be incorporated into stable, functional proteins.

That position rested on a survey of the Protein Databank which found no Alu-derived peptide segment in any solved structure.

Why the survey was the wrong instrument

The Protein Databank contains proteins that structural biologists chose to crystallize, and they choose evolutionarily conserved isoforms. Fewer than ten alternatively spliced protein isoforms had structures deposited at the time. A method that selects for conservation cannot find a lineage-specific insertion.

The absence was an artifact of what the database is for. This volume has made that argument about a notation. Here it applies to a repository.

377. The Funnel ↩

From annotation to candidate

stage	count
Ensembl-annotated Alu-derived internal exons	1,996
located within coding sequence	911
coding, and not predicted to trigger nonsense-mediated	262

stage	count
decay	
with at least 33% transcript inclusion in one of nineteen human tissues	48
differentially spliced between tissues, at least 10% change, FDR below 10%	27
the union of those two lists	52
with peptide evidence in the PRIDE proteomics database	85

The RNA-seq resource was about 1.8 billion reads across nineteen human tissues.

The validation rate

Twenty of the coding Alu exons were selected at random and their splicing checked by fluorescently labeled RT-PCR across twenty-one human tissues.

Nineteen of the twenty validated. Ninety-five percent.

---

378. Divisible by Three ↩

The cleanest single number in the paper

An exon inserted into a coding sequence either preserves the reading frame or destroys it. It preserves it only if its length is a multiple of three.

set	divisible by three
candidate protein-coding Alu exons	182 of 262 — 69%
Alu exons predicted to trigger nonsense-mediated decay	159 of 649 — 24%

A set of exon lengths chosen at random would sit near one in three. The decay-triggering set sits at 24 percent, close to chance. The candidate coding set sits at 69 percent — nearly three times higher.

That is selection acting on reading frame, read directly off exon lengths. The Alu insertions that survive in coding sequence are the ones that arrived in register.

379. The Peptides, and the Control That Makes Them Count ↩

What was found

Of the 262 candidate coding Alu exons, 85 had peptide evidence in PRIDE. Sixty-nine of those 85 — 81 percent — had peptide sequences crossing the splice junction into a flanking exon.

The flanking exons are not derived from repeats. A peptide that spans the junction is a peptide that could only exist if the Alu exon was translated in place. That is the strongest form of the evidence and it covers four fifths of the hits.

The negative control

The authors used the NMD-inducing Alu exons — the ones that should never make protein — as a negative control.

set	PRIDE hits
NMD-inducing Alu exons	47 of 649 — 7.2%
candidate protein-coding Alu exons	85 of 262 — 32.4%

Taking the control rate as the false-positive rate gives 262 × 7.2% ≈ 19 expected false hits, against 85 observed — an upper-bound false discovery rate of 22 percent.

A second control: mouse peptides searched against human Alu exons returned no hit longer than four amino acids, below the six-amino-acid cutoff used for the human hits.

380. The Ribosome ↩

Footprints on the Alu exon

Ribosome profiling reads the fragments of messenger RNA that a translating ribosome protects. If an Alu exon is translated, ribosome footprints will cross it.

Alu exons with at least ten reads in both Ribo-seq and RNA-seq	76
with non-zero inclusion in the Ribo-seq data	38 — half of them
with at least 15% inclusion in the Ribo-seq data	17
with higher inclusion in Ribo-seq than in RNA-seq	15

For fifteen of these exons the ribosome was on the Alu-containing isoform more often than the transcript pool would predict. The inclusion isoform is translated at least as efficiently as the ancestral isoform that lacks the insertion.

And the youngest Alu subfamily is under-represented. AluY accounted for 4.2 percent of the candidate coding exons against 7.0 percent of other Alu exons, and only 2.4 percent of the peptide-supported set. The differences were not statistically significant, and the authors say so — but the direction is what a time-dependent process predicts.

---

381. Sugt1, and the Four Hundred and Thirty Base Pairs ↩

A human gradient in a cell-cycle protein

SUGT1 is a kinetochore assembly factor required for the G1/S and G2/M transitions, and a member of the inflammasome complex. Its Alu exon encodes thirty-three amino acids inserted at the end of the third tetratricopeptide repeat.

species	endogenous splicing in tissues	minigene reporter
human	12 to 35%	70 ± 3%
chimpanzee	0 to 24%	50 ± 7%
rhesus macaque	0%	0%

The exon is completely absent from rhesus transcripts. The rhesus sequence lacks the essential GT dinucleotide at the 5′ splice site.

How the exon was created, and then strengthened

event	effect
a C-to-T substitution	created the 5′ splice site GT dinucleotide, which combined with a pre-existing 3′ splice site AG to make the exon
a G-to-A substitution at the +3 intronic position	raised the MAXENT splice site score from 5.29 to 9.46

MAXENT scores are logarithmic. Two raised to the difference of 4.17 is 18.0 — an eighteen-fold increase in the likelihood of matching the consensus, and the paper's "over 16-fold" is correct.

And the human-chimpanzee difference is not in the exon

There is no sequence difference between human and chimpanzee within the exon, or within the nine base pairs of the 5′ splice site, or the twenty-three base pairs of the 3′ splice site.

Sequence-swapping minigenes localized the causal difference to a 430 base pair intronic region upstream, carrying six nucleotide substitutions.

Every construct carrying the chimpanzee version of that 430 base pairs gave about 50 percent inclusion. Every construct carrying the human version gave close to 70 percent, whatever surrounded it. Six substitutions, in an intron, four hundred and thirty bases away, decide whether a human protein carries thirty-three extra amino acids.

This is the mechanistic form of the human-accelerated question of Part Sixty-One, answered for one gene.

---

382. The Editor Contains the Element It Edits ↩

ADARB1

ADARB1 is ADAR2 — the RNA editing enzyme of Parts Fifty-Nine through Sixty-Four.

It carries an Alu exon. The exon encodes a forty amino acid peptide, and that peptide is inserted into the catalytic deaminase domain. Two peptide sequences in PRIDE support it.

The scale of it

splicing level across human tissues	25% to 100%
tissues with over 75% inclusion	8 of 19
present in	human, chimpanzee and rhesus — this one is not human-specific

What that means, stated plainly

Part Sixty established that over 97 percent of ADAR1's editing sites lie in Alu repeats. Part Sixty-One established that inverted Alu pairs are the recruitment element that brings the enzyme to its targets.

And here the enzyme's own catalytic domain contains forty amino acids of translated Alu. The substrate is inside the machine. A primate-specific repeat, copied a million times through the genome, was captured into the coding sequence of the enzyme whose principal job is to act on that repeat.

In more than half a million pages of literature on the genetic code, that is as close to a closed loop as this volume has found.

---

383. Both Forms Are Active Enzymes ↩

The experiment

The two protein isoforms — with the Alu exon, called Long, and without it, called Short — were expressed separately in a cell line with low endogenous ADARB1, and the whole transcriptome was read for editing at 7,618 known sites.

comparison	result
Short against empty vector	editing significantly increased, $P = 6.5 \times 10^{-68}$
Long against empty vector	editing significantly increased, $P = 2.1 \times 10^{-50}$
Long against Short	Long gives lower overall editing, $P = 4.7 \times 10^{-10}$

The Alu-containing enzyme works. It is not a decoy, not a dominant negative, not a degradation product. It is an active RNA editing

enzyme with a forty amino acid primate insertion in its active-site domain, and it edits slightly less than the form without it.

Both isoforms were confirmed to be expressed at similar levels by quantitative PCR and western blot, so the difference is catalytic and not abundance.

384. What the Insertion Does to Site Selection ↩

The differential sites

Three hundred and sixty editing sites were differentially edited between the two isoforms.

class	count
common to both isoforms	144
short-isoform specific, low confidence	126
long-isoform specific, low confidence	70
short-isoform specific, high confidence	14
long-isoform specific, high confidence	6
total	360

The five classes sum exactly to the printed total. Checked.

Counting both confidence tiers, short-specific sites outnumber long-specific by 140 to 76 — a ratio of 1.84, which is the paper's "almost twice as many."

The reading

The Alu peptide does not switch the enzyme to a different set of targets. It tunes the overall rate, and in a small number of cases it changes which site gets edited. Most of the difference is quantitative; twenty sites out of 7,618 are qualitative.

The volume records that as a fine adjustment rather than a switch, which is what the authors conclude.

385. Table One, and the Fifth Arrival ↩

The eighteen genes with both splicing and peptide evidence

gene	what it is
SUGT1	kinetochore assembly, inflammasome
DNMT1	DNA cytosine-5 methyltransferase 1
C21orf7	open reading frame
ADARB1	the RNA editing enzyme
ALG8	glucosyltransferase
NEK4	NIMA-related kinase 4
ZNF415	zinc finger protein
TPRKB	TP53RK binding protein
C11orf80	open reading frame
ZNF573	zinc finger protein
MCM3	minichromosome maintenance
SLC3A2	amino acid transport heavy chain
EIF4E	translation initiation factor
KCNRG	potassium channel regulator
FAM124B	
B3GALNT2	glycosyltransferase
ZNF195	zinc finger protein

Three of the eighteen are zinc-finger proteins

Part Fifty-Two: a zinc finger is a metal held by cysteine thiolates, the commonest DNA-binding motif in the genome. Part Sixty: editing targets enriched for zinc fingers. Part Sixty-One: sixteen-fold enrichment for KRAB zinc fingers. Part Sixty-Two: zinc finger and KRAB motifs among the edited gene ontology terms.

This is the fifth arrival, from a fifth method — and here they are not editing targets. They are proteins that carry translated Alu peptides.

And DNMT1 makes six

DNA methyltransferase 1 takes its methyl group from S-adenosylmethionine — a sulfonium. Part Sixty-Two found the editor editing the transcripts of METTL6 and

METTL10. Here the DNA methyltransferase carries an Alu-derived peptide of its own.

---

386. Slc3a2, and the Cystine Door ↩

What the gene encodes

SLC3A2 is the heavy chain of the 4F2 cell-surface antigen, also called CD98hc. It does not transport anything by itself. It is the chaperone subunit that partners with several light chains to build working amino acid transporters.

SLC3A2 with SLC7A11 is system xc-minus — the cystine/glutamate antiporter. It is the door through which a cell imports cystine, the disulfide dimer of cysteine, which is then reduced and fed into glutathione synthesis.

Why this volume must record it

Part Forty-Three built the ferroptosis landscape on system xc-minus, glutathione and GPX4. Part Sixty found glutathione reductase and cystathionase under the editor's complex. Part Sixty-Two found mercaptopyruvate sulfurtransferase carrying two inosines.

And here the heavy chain of the cystine importer carries a translated Alu-derived peptide. The door through which sulfur enters the cell is, in part, built from a primate repeat.

The volume states what this is and what it is not. It is a fourth sulfur-handling gene appearing in this Alu and editing literature. It is not a demonstration that the Alu peptide affects cystine transport, and no such experiment has been done.

---

387. What Is Claimed and What Is Not ↩

Claimed

That 1,996 annotated Alu-derived internal exons yielded 911 in coding sequence and 262 that would not trigger nonsense-mediated decay. That 182 of those 262 are

divisible by three against 159 of 649 NMD-inducing exons, at $P = 2 \times 10^{-36}$. That 85 of 262 had PRIDE peptide evidence, that 69 of those 85 carried junction-spanning peptides, and that the NMD control gave 47 of 649 at $P = 1.8 \times 10^{-20}$, implying an upper-bound false discovery rate of 22 percent.

That 19 of 20 randomly chosen exons validated by RT-PCR. That of 76 exons with sufficient ribosome profiling coverage, 38 had non-zero inclusion and 15 had higher inclusion in Ribo-seq than RNA-seq.

That the SUGT1 Alu exon is spliced at 12 to 35 percent in human tissues, 0 to 24 percent in chimpanzee and 0 percent in rhesus; that minigenes gave 70, 50 and 0 percent; and that the causal difference lies in a 430 base pair upstream intronic region carrying six substitutions. That a C-to-T substitution created the 5′ splice site and a G-to-A at +3 raised the MAXENT score from 5.29 to 9.46, an eighteen-fold change — verified from the logarithm.

That ADARB1 carries an Alu exon encoding a 40 amino acid peptide inserted into its catalytic deaminase domain, supported by two PRIDE peptides, spliced at 25 to 100 percent across human tissues and present in human, chimpanzee and rhesus. That both isoforms significantly increase editing over empty vector and that the Alu-containing isoform gives lower overall editing at $P = 4.7 \times 10^{-10}$. That the 360 differential sites decompose as 144, 126, 70, 14 and 6 — checked to sum exactly.

That three of the eighteen genes in Table 1 are zinc-finger proteins, that one is DNMT1, and that one is SLC3A2.

Not claimed

That the Alu peptide in ADARB1 has a demonstrated physiological function. The paper shows it alters overall activity and, in a small number of cases, site selectivity. That is a fine adjustment and the volume calls it one.

That the SLC3A2 Alu peptide affects cystine transport. Section 386 states that no such experiment has been done.

That the zinc-finger recurrence across five studies is established as more than a recurrence. The confound named in Part Sixty-One — Alu density in those genes — has still not been controlled for, and this Part does not control for it either.

That the AluY under-representation is significant. It is not, and the authors say so.

388. What Would Show This Part Is Wrong ↩

— Show that the junction-spanning peptides of section 379 can arise without translation of the Alu exon, and the proteomic evidence collapses.

— Show that the divisible-by-three enrichment is an artifact of how Alu exons were annotated, and section 378's reading-frame selection is not selection.

— Show that ADARB1's Alu exon is not translated, or lies outside the catalytic domain, and section 382 — the strongest statement in this Part — has no exhibit.

— Show that the Alu-containing ADARB1 isoform is catalytically inactive, and section 383 is wrong; the paper's own P value of 2.1×10^{-50} against empty vector is the number to overturn.

— Show that the 430 base pair region does not carry the human-chimpanzee splicing difference, and section 381's localization fails.

— Control the zinc-finger recurrence for Alu density across all five studies and find it disappears, and the fifth arrival of section 385 is a property of where Alus land rather than of the target class. This remains the weakest link in the chain and it is named again here for that reason.

PART SIXTY-SIX · THE BULK AND THE EXCEPTIONS

Part Sixty-Six of the evidence volume, sections 389 to 401

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Bazak, Haviv, Barak, Jacob-Hirsch, Deng, Zhang, Isaacs, Rechavi, Li, Eisenberg and Levanon, Genome Research, 2014. This is the paper the hundred million came from — the figure the author divided into the genome nine years ago. And it contains a number the field has not absorbed: every functionally characterized RNA editing site in human biology, taken together, accounts for seven hundredths of one percent of the reaction.

389. The Source of the Number the Author Divided ↩

Where the hundred million comes from

Part Fifty-Nine records that the author, reading a 2016 review, divided one hundred million editing sites into a 3.2 billion base genome and arrived at one editing site per thirty-two bases.

This is the paper that produced the hundred million. The review he annotated was citing it. The margin note now has its primary source, and the source is a measurement rather than an estimate carried forward.

And the paper states the same quantity a second way

the paper's own accounting	
editable Alu repeats in the human genome	761,244
editable genomic positions inside them, counting both strands	105.7 million
as a share of the bases in the genome	about 1.5 percent
estimated total A-to-I editing sites	over 100 million

One site per thirty-two bases, and one and a half percent of the genome standing at editable positions, are the same statement in two notations.

390. The Pipeline ↩

What went in

data set	reads
Human Body Map 2.0, sixteen tissues	5,015,542,166
YH, a lymphoblastoid line from one individual	1,167,280,060
total	6,182,822,226

919,035 Alu elements were covered — 78.19 percent of every Alu in the human genome.

What survived filtering

stage	mismatch locations	AG	TC
raw mismatches	25,103,998	39.2%	37.5%
distinct genomic locations	6,784,377	28.6%	27.7%
after probabilistic filtering	2,384,699	39.7%	38.2%
after clustering on Alu	1,652,530	dominated by AG and TC	

Every percentage above was recomputed from the raw counts and matches the printed figure exactly.

The two data sets contributed 4,126,430 and 3,198,951 locations, which sum to 7,325,381 — 541,004 more than the union of 6,784,377. That difference is the overlap between them, and it is small: the two independent data sets share only about seven percent of their sites.

---

391. The Three Controls ↩

First — the clustering asymmetry

Editing occurs in clusters. If a mismatch class is editing, it will cluster on an Alu; if it is sequencing noise, it will not.

mismatch class	Alu elements harboring clusters	sites in them
AG or TC	305,337	1,586,270
GA or CT	24,858	32,536

Twelve times as many elements and forty-nine times as many sites. The false positive rate was estimated at 8.1 percent at the element level and 2.0 percent at the site level.

Second — the strand asymmetry

AG sites where the genome encodes A on the transcribed strand	90.58%
TC sites found on reads aligned to the opposing strand	90.33%

Other mismatch types were distributed evenly between the strands. A polymorphism does not know which strand was transcribed. An enzyme acting on a transcript does.

Third — the anticorrelation

A read is a copy of one strand. If it carries the AG signature it was transcribed from the sense strand, and it cannot also carry the TC signature.

	reads	share
carrying three or more AG mismatches	51,212	5.05%
carrying three or more TC mismatches	38,466	3.80%
carrying both	20	0.002%

If the two were independent, 1,944 reads would carry both. Twenty do. That is ninety-seven-fold fewer than chance, at P below 10^{-99}, and it is exactly what strand-specific enzymatic action predicts and what sequencing noise does not.

---

392. Virtually Every Adenosine ↩

The ultradeep experiment

Eighty Alu elements were selected — 28 that had shown editing in the survey and 52 that had not — amplified, and sequenced to extreme depth.

recovered and expressed	75 of 80
average coverage	13,511 reads
median coverage	11,919 reads
showing AG or TC as the dominant mismatch	73 of 75
showing GA or CT as dominant	none

Fifty-two of those elements had shown no editing at ordinary sequencing depth. At thirteen thousand reads, essentially all of them

were edited. The earlier absence was an absence of coverage, not an absence of chemistry.

The conclusion the authors draw

Virtually all adenosines within Alu repeats that form double-stranded RNA undergo A-to-I editing, given sufficient coverage.

The question "which adenosines are edited" turns out to be the wrong question. Within an editable Alu, the answer is all of them. The right question is at what level.

---

393. The Level, Not the Site ↩

The distribution

With coverage above five thousand reads, the editing level at a site can be measured accurately.

distribution shape	log-normal, with a substantial fat tail at the high end
median editing level	0.475 percent
the bulk of sites	edited in under 1 percent of transcripts
the tail	a few sites approaching 100 percent

And the two populations separate cleanly. Other mismatch types occur at fractions below 0.1 percent, consistent with the sequencing error rate. The AG and TC mismatches span a different range entirely, from a tenth of a percent upward.

Editing is not a switch that is on at some positions and off at others. It is a continuous quantity, log-normally distributed, whose median is one part in two hundred. The four-letter notation has no way to write a base that is present in half a percent of copies.

---

394. Seven Hundredths of One Percent ↩

The count, in brain tissue

what was counted	events
A-to-I deamination events in Alu repeats	586,581
at the glutamate receptor Q/R site	77
across all twenty-two well-characterized recoding sites combined	426

The shares, recomputed

	share of the total
the Q/R site	0.0131% — the paper prints 0.013%
all twenty-two recoding sites together	0.0726% — the paper prints "no more than 0.073%"
Alu editing	over 99%

One editing event at the Q/R site for every seven thousand six hundred events in Alu. One event across every recoding site known to science for every one thousand three hundred and seventy-six.

What the Q/R site is

It is the most important editing event in the literature. A glutamine-to-arginine change in the AMPA receptor, controlling calcium permeability. A mouse lacking ADAR2 dies, and a point mutation that hard-codes the edited version at this one site rescues the lethality.

In other tissues the twenty-two recoding sites range from under 0.001 percent to 0.4 percent of all editing.

---

395. What That Number Does to the Volume's Argument ↩

Stated plainly

The entire functional literature of RNA editing — every recoding site named, characterized, crystallized and taught — describes less than one thousandth of the reaction. The other ninety-nine point nine percent happens in repeat elements and has no assigned function.

Why this is the volume's thesis in its most extreme form

Part One argued that a notation records what it was built to record and is silent about the rest. Parts Fifty-Nine through Sixty-Five have shown that in one chemistry after another.

This is the same failure at the level of a research field rather than an alphabet.

what is named	what is measured
twenty-two recoding sites, with mechanisms and phenotypes	0.073% of the reaction
the Q/R site, whose mutation rescues a lethal knockout	0.013%
Alu editing, largely unassigned	over 99%

The volume must be careful here and it will be. The recoding sites are important because they change proteins, and importance is not the same as abundance. A rare event with a large effect matters more than a common event with none.

But the volume's claim was never that the named things are wrong. It is that the naming system determines what gets counted, and that what does not get named does not get counted even when it is nine hundred and ninety-nine parts in a thousand.

The authors say the same thing in their own words: that such a heavy burden was not selected against raises the possibility that a fraction of these editing sites is used in ways that remain unknown.

---

396. Transcript Diversity, in Bits ↩

Shannon, invoked in a paper about nucleotides

The authors used Shannon's information entropy to quantify how many distinct edited versions of a single Alu repeat exist in a cell.

$$Entropy = - \sum_{\text{all editing variants}} p \log_2 p$$

entropy per Alu repeat	4.8 to 8.8 bits
effective number of distinct	about 28 to about 446

entropy per Alu repeat	4.8 to 8.8 bits
variants	
inosines per transcribed Alu	0.24 to 11.5
transcript variants per Alu	still rising at the highest coverage, with no saturation

One Alu repeat, in one gene, produces on the order of hundreds of distinguishable transcript variants. The gene has one sequence. The transcript pool has hundreds.

Why the volume should note the choice of instrument

Part Forty-Eight established that a codon carries six bits and that the sixty-four codons form a six-dimensional space over two symbols.

Here the same measure is applied to the editing pattern of a single repeat, and it returns between 4.8 and 8.8 bits. A single Alu carries as much positional information in its editing state as a codon carries in its sequence.

That is a comparison of two quantities measured in the same unit, and it is not a metaphor.

---

397. How Much of the Genome Is Editable ↩

The criteria and the count

An Alu was called editable if it has a neighboring inverted Alu closer than 3,500 base pairs and is not highly divergent from the consensus.

editable Alu repeats	761,244
editable genomic positions, both strands	105.7 million
share of the genome's bases	about 1.5 percent

And how many genes are involved

human RefSeq genes	23,357
containing an editable Alu	67.4% — about 15,700 genes
containing one inside an	12.4% — about 2,900 genes

human RefSeq genes	23,357
exon	

Two thirds of human genes carry a structure that will be edited if it is transcribed. That is the sense in which the paper's title says a majority of human genes.

Three genes were examined exhaustively — RILPL1, PSEN1 and KIF1B, carrying 76, 104 and 207 Alu repeats. Fourteen, twenty-three and seventy-three of those were deeply sequenced, and virtually all of the covered adenosines — 372, 1,128 and 3,858 — showed editing. Editing sites in the thousands, in three genes.

398. The Tissues, and the Brain ↩

What the tissue survey showed

Known protein-modifying editing sites are enriched in synaptic genes expressed mainly in brain, and editing levels in brain are high.

But Alu editing in brain was not exceptionally high compared with other tissues. The difference between brain and the rest is in which sites are recoded, not in how much deamination occurs.

The paper notes two reasons its levels are underestimates: hyperedited reads fail to align to the genome at all, and unstranded data allows some reference-matching reads to have come from the antisense strand.

The antisense finding

Using high coverage, the authors observed editing of transcripts arising from residual antisense expression — and this doubled the number of edited sites in the human genome.

Both strands of an Alu are transcribed, at some level, in most genes. Both get edited. The doubling is not a correction; it is a second population that was invisible because nobody had sequenced deeply enough to see it.

399. Why the Overlap Between Studies Was Always Low ↩

The explanation this paper supplies

Part Sixty-Two recorded that only 21.5 percent of one study's sites were already in the standing database. Part Sixty recorded that fewer than 4,500 of 55,719 sites had been reported before. The field has repeatedly found that different studies barely agree.

Most sites are edited at under one percent. Detecting a site edited at half a percent requires hundreds of reads over it. Which sites a study finds is therefore decided by which transcripts happened to be deeply covered in that library — and coverage varies between experiments far more than editing does.

Every study was sampling the same continuous distribution at a different, shallow threshold. The low overlap was never a disagreement about biology. It was a sampling artifact, and this paper is where that was demonstrated.

400. What Is Claimed and What Is Not ↩

Claimed

That this study analyzed 6.18 billion reads across two data sets, covered 919,035 Alu elements representing 78.19 percent of all Alu in the genome, and reduced 25,103,998 raw mismatches through 6,784,377 genomic locations and 2,384,699 filtered locations to about 1.65 million clustered sites — with every printed percentage recomputed from the counts and matching.

That AG or TC clusters were found in 305,337 Alu against 24,858 for GA or CT, that 90.58 percent of AG sites and 90.33 percent of TC sites showed the predicted strand asymmetry, and that only 20 of 1,013,366 reads carried both signatures against 1,944 expected by chance.

That of 80 Alu elements sequenced to a median depth of 11,919 reads, 73 of the 75 recovered showed AG or TC as the dominant mismatch and none showed GA or CT — including 52 selected for showing no editing at ordinary depth.

That editing levels are log-normally distributed with a median of 0.475 percent. That Shannon entropy per Alu ranges from 4.8 to 8.8 bits. That 761,244 Alu repeats are editable, covering about 105.7 million genomic positions and about 1.5 percent of the genome's bases, and that 67.4 percent of 23,357 RefSeq genes contain one.

That in brain tissue the Q/R site accounted for 77 editing events and all twenty-two characterized recoding sites for 426, against 586,581 events in Alu repeats — 0.013 percent and 0.073 percent respectively, both recomputed and both matching the printed figures.

Not claimed

That the recoding sites are unimportant. Section 395 states the opposite explicitly. A rare event with a large effect matters more than a common event with none, and the Q/R site rescues a lethal knockout.

That the ninety-nine percent has a function. It does not have an assigned one. The authors raise the possibility and the volume records it as a possibility.

That the hundred million figure is a count. It is an extrapolation from deep sequencing of a sample, and the paper says so.

That the author's margin note anticipated this paper. It divided this paper's number by the genome size. Section 389 claims the source, not the priority.

---

401. What Would Show This Part Is Wrong ↩

— Show that the AG and TC clustering asymmetry can be produced by sequencing error or misalignment, and the entire detection method fails and with it the hundred million.

— Show that reads carrying both AG and TC signatures occur at the rate independence predicts, and the strand-specificity argument of section 391 collapses.

— Sequence an editable Alu to a median depth above ten thousand reads and find its adenosines unedited, and section 392's central claim is wrong. Fifty-two elements chosen for showing no editing were tested this way and all but two were edited.

— Recount the brain events and find the recoding sites exceed one percent of all A-to-I deamination, and section 394 — the number this Part exists to print — is wrong by more than an order of magnitude.

— Show that editing levels are bimodal rather than log-normal, and section 393's account of editing as a continuous quantity fails.

— Show that the low overlap between published editing data sets reflects biological disagreement rather than coverage, and section 399's explanation is not the explanation.

PART SIXTY-SEVEN · THE SLIVER, IN DISEASE

Part Sixty-Seven of the evidence volume, sections 402 to 414

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Khermesh, D'Erchia, Barak, Annese, Wachtel, Levanon, Picardi and Eisenberg, RNA, 2016. Part Sixty-Six established that protein recoding is seven hundredths of one percent of all A-to-I editing. The same group then measured that sliver in the brains of people who died with Alzheimer's disease, and found it reduced. And the reduction is not explained by the amount of enzyme present.

---

402. The Fraction That Recodes, Measured in Disease ↩

What the previous Part left standing

Part Sixty-Six recorded that of 586,581 A-to-I deamination events counted in brain tissue, 426 occurred at the twenty-two characterized recoding sites — 0.073 percent — while over 99 percent occurred in Alu repeats with no assigned function.

This paper is by the same senior authors. Having shown that recoding is a sliver, they went and measured the sliver in disease. That is the correct response to their own finding: the bulk has no assigned function and the sliver changes a protein, so the sliver is where a phenotype can be looked for.

The volume records the sequence because it is how a field should behave.

403. The Panel ↩

What was selected, and on what grounds

One hundred and eighteen editing sites, located in seventy-two genes, chosen against five stated criteria — located within protein-coding regions, resulting in a nonsynonymous amino acid change, evolutionarily conserved editing across chimpanzee, rhesus, mouse and human, located in genes associated with neuronal function and plasticity, and located in genes previously recorded as edited.

where the 118 sites sit	count
protein-coding regions, in 67 genes	98
3′ untranslated regions, in 2 genes	9
noncoding RNA genes, in 3 genes	11
total	118

Ninety-eight plus nine plus eleven is one hundred and eighteen. The panel reconciles.

What was recovered

sites successfully amplified and sequenced	115
in hippocampus	113
in temporal lobe	108
in frontal lobe	107
discard rule	any site with read coverage below 500 reads

404. The Method, and Why It Was Necessary ↩

Why ordinary RNA sequencing would not do

Editing levels must be measured, not merely detected. A site edited at twenty-one percent against a control at twenty-seven percent is a real difference that ordinary transcriptome sequencing cannot resolve, because typical coverage is far too low.

Part Sixty-Six established why: editing is a continuous quantity and detecting it accurately requires hundreds to thousands of reads over a single position.

What was used instead

step	
microfluidic multiplex PCR on a 48-by-48 access array	amplifies 48 targets across 48 samples in one run
next-generation sequencing of the amplicons	delivers thousands of reads per site
barcoding per sample	48 mini-libraries, pooled into one

Targeted resequencing trades breadth for depth. It sees only the sites you chose, and it sees them accurately enough to compare two groups of brains. That trade is the whole design.

---

405. The Hippocampus ↩

The global result

	AD	non-demented control
mean editing level across all 66 sites measured	21.8% ± 4.5	26.8% ± 3.5

P = 0.03 by t-test. A drop of five percentage points, which is an 18.7 percent relative reduction.

The direction

Twenty-one sites showed statistically significant differential editing. Twenty of the twenty-one were under-edited in Alzheimer's.

One site went the other way — COPA, on chromosome one. Twenty of twenty-one in one direction is not a scatter around zero. It is a systematic loss.

Why the hippocampus

The hippocampus is one of the primary and major brain locations damaged by amyloid, and neuropathological change in Alzheimer's begins there. The region where the disease starts is the region where the editing loss is largest.

Braak scores confirm the separation: 5.52 in the Alzheimer's group against 0.234 in the controls. The cohorts were age- and sex-matched, all male, mean age about seventy-five in both groups.

406. The Other Two Regions ↩

Temporal and frontal lobe

region	AD	control	relative drop
hippocampus	21.8%	26.8%	18.7%
frontal lobe	23.5%	27.0%	13.0%, P = 0.002
temporal lobe	22.5%	24.9%	9.6%

And the direction holds in all three

region	differential sites	hypo-edited in AD	hyper-edited
hippocampus	21	20	1
temporal lobe	19	18	1
frontal lobe	8	8	0

Forty-eight site observations across three regions, forty-six of them in the same direction.

In total, 35 distinct sites within 22 genes were differentially edited. Three sites, all in the MEG3 locus, were consistently detected as hypo-edited in all three tissues.

A gradient: worst where the disease starts, present everywhere it was looked for, and in one direction.

407. The Enzyme Levels Do Not Explain It ↩

What was measured

Messenger RNA for all three catalytic species was quantified by real-time PCR in every region.

region	ADAR-p110	ADAR-p150	ADARB1
hippocampus	at least as high in AD	at least as high in AD	at least as high in AD
temporal lobe	down-regulated in AD	no significant change	overexpressed in AD
frontal lobe	overexpressed in AD	no significant change	no significant change

The finding this produces

In the hippocampus, where the editing loss is largest, all three enzymes are present at levels at least equal to control. The editing fell and the enzyme did not. And in the frontal lobe, ADAR-p110 is overexpressed while editing is significantly reduced.

The authors state it plainly: the global hypo-editing pattern does not correlate with ADAR expression.

What that points to

If not the amount of enzyme, then something about the substrate or the access to it.

Part Sixty-One established that editing at a selective site is governed by a cis-acting recruitment element — an inverted repeat pair that raises the local enzyme concentration — and that the same amount of enzyme produces very different editing depending on whether that element is present and correctly folded.

This paper reports a large drop in editing with no drop in enzyme. Part Sixty-One supplies the only mechanism in this volume that predicts exactly that. Whether the recruitment structures are compromised in the Alzheimer's brain has not been tested, and it is the experiment this Part identifies.

408. The Genes ↩

The twenty-two, grouped

group	genes
ionotropic glutamate receptors	GRIA2, GRIA3, GRIA4, GRIK1, GRIK2
the serotonin receptor	HTR2C
ion channels and conductance	CACNA1D, KCNA1, UNC80, TMEM63B
mitochondrial dynamics	MFN1, FIS1
innate immunity	DDX58
noncoding RNA	MEG3, FLJ43663 (LINC-PINT)
other	COPA, CCNI, FBXL6, IGFBP7, NARF, NOVA1, PTPN14

The glutamate receptors are where the Q/R site lives

GRIA2 carries the Q/R site itself — the single most important recoding event in the literature, the one whose hard-coded version rescues a lethal knockout in mice. GRIA3, GRIA4, GRIK1 and GRIK2 carry the related R/G and Q/R positions.

Five glutamate receptor subunits, all edited, all hypo-edited in Alzheimer's disease. The receptors of the excitatory synapse are the ones losing their edits in the disease of synaptic loss.

UNC80 is a component of the NALCN sodium leak channel, which regulates ion conduction; mice lacking NALCN show neonatal lethality with respiratory rhythm defects.

409. Two Mitochondrial Dynamics Proteins ↩

Fission and fusion, both on the list

gene	what it does
MFN1 — mitofusin 1	drives mitochondrial fusion — the joining of two mitochondria
FIS1 — mitochondrial fission 1	drives mitochondrial fission — the splitting of one into two

MFN1 appears five times in the temporal lobe table and three times in the frontal lobe table. FIS1 appears in the hippocampus table.

Both halves of the mitochondrial dynamics machine are edited transcripts, and both are differentially edited in Alzheimer's disease. Fusion and fission are the two opposite operations by which a cell maintains its mitochondrial network, and the editor writes into both.

What this volume already carries

Part Fifty-Three established that a modern mitochondrion's respiratory chain is an inherited bacterial chain and that every iron-sulfur cluster in it is an inheritance. Part Sixty-Two found respiratory chain and oxidative phosphorylation components among the editor's targets.

This Part adds the shape of the organelle itself. The editor writes into the electron transport chain, and into the machinery that decides how many mitochondria there are and how big.

---

410. The Sensor That Is Itself Marked ↩

DDX58

DDX58 encodes RIG-I — retinoic acid-inducible gene I — the cytoplasmic sensor that detects foreign double-stranded RNA and triggers the interferon response.

It appears three times in the hippocampus table and once in the frontal lobe table.

Why that is worth a section

Part Sixty established the logic of ADAR1's immune function. Loss of ADAR1 causes upregulation of interferon-inducible transcripts, and the embryonic lethality of an ADAR1 knockout mouse is rescued by removing MDA5 or MAVS. Inosine, scattered through a long duplex, is the mark that tells the cell a double-stranded RNA is its own.

RIG-I is one of the sensors that mark has to satisfy. And RIG-I's own transcript is a substrate of the enzyme that makes the mark. The detector of foreign RNA is edited by the enzyme whose job is to make RNA look native.

The volume states this as an observation about the target list, not as a demonstrated regulatory loop. Neither this paper nor Part Sixty tests whether editing of the

DDX58 transcript alters RIG-I function. It is a striking arrangement and it is untested.

---

411. Htr2c — Five Sites, Thirty-Two Combinations ↩

The densest recoding site in the human genome

The serotonin 2C receptor carries five editing sites — labeled A, B, C, C′ and D — all within a fourteen base-pair span of exon five. They recode amino acid positions 157, 159 and 161.

binary combinations of five sites	$2^5 = 32$ possible edited messenger RNAs
distinct protein isoforms produced	24
therefore redundant combinations	8

Five adenosines in fourteen base pairs produce thirty-two possible transcripts and twenty-four distinct receptors. The gene has one sequence. The cell has two dozen versions of the protein, and which mixture it holds is set by a deaminase.

The functional consequence

The fully edited isoform, VGV, shows a large reduction in agonist-stimulated G-protein coupling compared with the unedited receptor. Editing turns the receptor down.

And in Alzheimer's hippocampus

	control	AD
the unedited isoform INI — isoleucine 157, asparagine 159, isoleucine 161	45%	58%

A rise of thirteen points in the unedited form, accompanied by a 12.5 percent fall in the relative abundance of the edited VDV form.

Less editing means more of the fully active receptor. In the hippocampus of an Alzheimer's brain, the serotonin 2C receptor pool

shifts toward the form that couples most strongly to its G protein — and that shift is a consequence of a deaminase, not of a gene.

412. What Is Claimed and What Is Not ↩

Claimed

That 118 editing sites in 72 genes were selected, comprising 98 in coding regions of 67 genes, 9 in the 3′ untranslated regions of 2 genes and 11 in 3 noncoding RNA genes — summing exactly to 118. That 115 were successfully amplified and that sites below 500 reads of coverage were discarded.

That mean editing across 66 sites in hippocampus was 21.8 percent in Alzheimer's against 26.8 percent in matched non-demented controls, P = 0.03; that frontal lobe was 23.5 against 27.0 percent, P = 0.002; and that temporal lobe was 22.5 against 24.9 percent. That these correspond to relative reductions of 18.7, 13.0 and 9.6 percent respectively — recomputed from the printed means.

That 20 of 21 differential sites in hippocampus, 18 of 19 in temporal lobe and 8 of 8 in frontal lobe were hypo-edited in Alzheimer's, and that 35 distinct sites in 22 genes were differentially edited in total.

That ADAR-p110, ADAR-p150 and ADARB1 messenger RNA in hippocampus were all at least as high in Alzheimer's as in control, that ADAR-p110 was overexpressed in frontal lobe where editing was significantly reduced, and that the authors state the hypo-editing does not correlate with ADAR expression.

That HTR2C carries five editing sites within a 14 base-pair span recoding positions 157, 159 and 161, that five binary sites give 32 combinations against 24 reported protein isoforms, and that the unedited INI isoform rose from 45 to 58 percent in Alzheimer's hippocampus.

That the differentially edited genes include five ionotropic glutamate receptor subunits, both MFN1 and FIS1, and DDX58.

Not claimed

That reduced editing causes Alzheimer's disease. The samples are post-mortem and the direction of causation is not established by them. The authors call it a possible association and this volume uses the same words.

That the editing loss is caused by compromised recruitment structures. Section 407 names that as the mechanism this volume's own Part Sixty-One would predict, and states that it has not been tested.

That editing of the DDX58 transcript alters RIG-I function. Section 410 states explicitly that this is untested.

That the cohort is large. Twenty-eight and twenty in hippocampus, thirteen and eleven in the other two regions, all male. The volume records the sizes rather than passing over them.

413. What Would Show This Part Is Wrong ↩

— Show that the hippocampal editing difference disappears when a larger, mixed-sex cohort is used, and section 405's central result does not replicate.

— Show that ADAR expression in hippocampus is in fact reduced in Alzheimer's disease, and section 407 — the most interesting finding in this Part — has an ordinary explanation.

— Show that post-mortem interval or RNA integrity differs systematically between the two groups, and the editing difference is an artifact of tissue handling rather than of disease. The paper reports RIN values between 5 and 8 and does not report a difference; the volume notes that this is the obvious confound and that it is addressed only briefly.

— Show that the HTR2C five sites do not lie within a 14 base-pair span, or that they generate other than 24 protein isoforms, and section 411's combinatorial reading is wrong.

— Test the recruitment structures directly. Measure whether the inverted repeat elements flanking these recoding sites are altered, unfolded or differently occupied in Alzheimer's tissue. If they are unchanged, the mechanism proposed in section 407 is not the mechanism, and the volume should print that it was tested and failed.

414. What the Inosine Parts Now Establish, Together ↩

Eight Parts, eight papers, one symbol

Part	what it established
Fifty-Nine	the reaction, the enzymes, and the rate — one editing site per thirty-two bases of genome
Sixty	the complex — ADAR1 with HuR, holding the transcripts of cystathionase and glutathione reductase
Sixty-One	the mechanism — an inverted Alu pair is a cis-acting antenna that raises the local enzyme concentration
Sixty-Two	the method — 92 to 95 percent of sequence-called sites are not inosine; a chemistry had to be invented
Sixty-Four	the timing — the wobble inosine is installed on the precursor, before the transfer RNA exists
Sixty-Five	the recursion — the editor's own catalytic domain contains a translated Alu peptide
Sixty-Six	the proportion — all characterized recoding is 0.073 percent of the reaction
Sixty-Seven	the disease — that 0.073 percent is reduced in Alzheimer's, and not because the enzyme is missing

The single statement they support

There is a symbol in human RNA that the four-letter alphabet cannot write. It occurs at roughly one position in thirty-two. It is placed by an enzyme a cell cannot live without, on a precursor before the molecule is finished, guided by a repeat element that is itself translated into the enzyme's active site. It marks a transcript as belonging to the organism. It is measured only by reacting with it, because reading cannot find it. And the fraction of it that anyone has assigned a function to is seven parts in ten thousand.

What this run does not settle

It does not establish that inosine should be counted as a base of the genetic code. That remains the author's argument, made in Parts Forty-Eight, Fifty-Seven and Sixty-Three on grounds of closure, group structure and priority.

What these eight Parts establish is narrower and harder to dispute: the notation is incomplete, the incompleteness is quantified, and the quantity is large.

PART SIXTY-EIGHT · DRIVING THE EDITOR

Part Sixty-Eight of the evidence volume, sections 415 to 427

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Hanswillemenke, Kuzdere, Vogel, Jékely and Stafforst, Journal of the American Chemical Society, 2015. Nine Parts of this volume have read the editor. This one drives it — with a switch, in a living animal. And the covalent bond that holds their artificial machine together is a carbon-sulfur bond on a cysteine.

415. From Reading the Editor to Driving It ↩

The turn this Part makes

Parts Fifty-Nine through Sixty-Seven treat adenosine-to-inosine editing as a natural phenomenon to be measured — its rate, its substrate, its recruitment, its timing, its proportion, its failure in disease.

This paper stops measuring and starts steering. It builds an artificial editing enzyme, aims it at one adenosine chosen in advance, and switches it on with a flash of ultraviolet light.

And it does so in an embryo. This is the first demonstration of site-directed RNA editing in a living organism.

Why the volume must carry it

A claim that a notation is incomplete is strengthened when someone builds a tool that operates in the part the notation cannot express.

The four letters cannot write inosine. This group writes it, at a position of their choosing, on command.

416. The Tool ↩

Three components

component	what it is
SNAP-ADAR	a SNAP-tag domain fused to the C-terminal catalytic deaminase domain of human ADAR
the guideRNA	a short oligonucleotide, complementary to the target, carrying O6-benzylguanine at its 5′ end
the bond	formed in situ between the SNAP-tag and the benzylguanine — a single covalent link

The guideRNA hybridizes to the target messenger RNA and forms the double-stranded structure the deaminase requires. The covalent tether keeps the enzyme on its guide.

kinetics of the conjugation	2.8×10^4 M^{-1} s^{-1}, single-turnover, high specificity

And the repair reaction is essential to it

The authors had previously shown that repair of a premature stop codon into a tryptophan codon in human cells is strongly dependent on the covalent attachment of the guideRNA to the deaminase.

That dependence is what makes the switch possible. Block the bond and there is no editing. Release the block and editing begins. The control point is the chemistry that joins the two halves.

---

417. The Bond Is a Thioether on a Cysteine ↩

What SNAP-tag actually is

SNAP-tag is an evolved O6-alkylguanine-DNA alkyltransferase — the enzyme that in human cells repairs O6-alkylated guanine in DNA.

the active-site cysteine thiolate\nattacks the benzylic carbon of O6-benzylguanine\nguanine leaves\nan S-benzyl cysteine thioether remains

The enzyme is a suicide protein. It transfers the alkyl group onto its own cysteine and is consumed. That is why the reaction is single-turnover.

The covalent bond holding this artificial riboprotein together is a carbon-sulfur bond on a cysteine sulfur. The tool that writes the sixth

symbol into RNA is assembled by the element the four letters do not name.

What the volume claims and does not claim here

The paper does not remark on this. It is a fact about the mechanism of the enzyme they chose, and the choice was made for kinetics and specificity, not for chemistry of this kind.

The volume records the coincidence and calls it a coincidence. What it is not is trivial: of all the bioconjugation chemistries available, the one fast enough and specific enough for a single-turnover in-cell assembly is a thiolate displacement.

Part Fifty says why. Sulfur is soft, polarizable, and an excellent nucleophile at physiological pH — its thiol pKa near 8.5 against serine's alcohol near 16. That is the property being used, and it is the property this volume has argued makes sulfur the machinery element.

---

418. The Photocage ↩

What was masked, and with what

The benzylguanine was capped with a 6-nitropiperonyloxymethyl group — Npom — which absorbs across 330 to 420 nanometers and falls off on irradiation.

Synthesis gave a separable mixture of two regioisomers, with the cap at the N7 or the N9 position of the guanine.

isomer	yield	decaging half-life at 365 nm	decaging efficiency	quantum yield
N7	24 mg, 21%	34 ± 3 s	~2,000 M^{-1} cm^{-1}	0.50
N9	50 mg, 42%	47 ± 4 s	~1,500 M^{-1} cm^{-1}	0.36

Sixty seconds of 365 nanometer light gave 75 percent conversion.

The choice they made, and why it matters

Attachment of the cap at N7 blocks the conjugation reaction with the SNAP-tag. Attachment at N9 does not — because the natural ancestor of the SNAP-tag accepts the deoxyribose at N9, so a substituent there is tolerated.

All further work used the pure N7 isomer. The lower-yielding isomer was the functional one, and the reason lies in the enzyme's evolutionary history.

---

419. The Three Timescales Agree ↩

The same number, three times

what was measured	half-life
decaging of the small molecule alone, by HPLC	34 ± 3 s
assembly of the guideRNA-deaminase conjugate, by gel	follows the decaging kinetics
the in vitro editing yield itself	25.7 ± 0.4 s

What that agreement establishes

The rate-limiting step of the entire cascade is the photorelease. Once the cap is off, the bond forms and the editing follows fast enough not to show up in the kinetics.

Three independent measurements — a chromatogram, a gel, and a sequencing trace — returning the same first-order half-life. That is a well-behaved system, and it is why the dose of light sets the dose of editing.

---

420. In Vitro, in Cells, and in an Animal ↩

The ladder of demonstrations

setting	editing yield
in vitro, SNAP-ADAR1	75%

setting	editing yield
in vitro, SNAP-ADAR2	60%
HEK293 cells, positive control with uncapped guideRNA	~45%
HEK293 cells, light-activated	~45% — the same
HEK293 cells, capped, kept dark	under 5%
Platynereis dumerilii embryos, all components	60 to 70% across the population
Platynereis, capped, dark	~10% residual; 18% faintly fluorescent larvae
Platynereis, capped, then 5 minutes of 365 nm	~60%; half the larvae brightly fluorescent

The controls

control	result
guideRNA lacking the benzylguanine	no editing
a guideRNA directing repair to codon 66 instead of codon 58	absolutely no editing
Sanger sequencing of the whole open reading frame	no off-target editing
negative controls lacking guideRNA, enzyme, or both, in the worm	no fluorescence

The codon-66 control is the important one. The same chemistry, the same enzyme, the same cell — and a guide aimed three codons away produces nothing. The RNA secondary structure has to form directly at the targeted codon, and that requirement is the major determinant of specificity.

The worms developed and behaved normally over the first days and stages of development.

421. The Repair — Amber Stop to Tryptophan ↩

What is being repaired

The target is a premature stop codon. The reaction converts it into a tryptophan codon.

U A G the amber stop\n/\n/ ADAR deaminates the adenosine\nv\nU I G inosine at position two\n/\n/ the ribosome reads inosine as guanosine\nv\nU G G tryptophan

Part Fifty-Nine established the three-answer problem: the genome says A, the transcript says I, the ribosome says G. Here that ambiguity is the mechanism of a cure.

And in the volume's own grid

Part Forty-Nine placed the sixty-four codons on an eight-by-eight grid indexed by the author's eight symbols.

codon	cell	row	column	six-bit form
UAG, the amber stop	49	O	X	110001
UGG, tryptophan	53	O	C	110101

They are in the same row. The row is O — the orotate row, which Part Forty-Nine found holds every stop codon in the genetic code, plus tryptophan, plus both cysteines. And the two cells differ in exactly one bit.

The single most useful repair in RNA editing therapeutics is a one-bit move within one row of the grid the author built from a cube. Verified by construction.

---

422. Only Two of the Three Stops Can Be Repaired ↩

The arithmetic, done exhaustively

An A-to-I edit can only act on an adenosine. Asking which stop codons can be converted to a sense codon by a single edit is therefore a finite question with a short answer.

stop codon	single A-to-I edits available	result
UAG, amber	one — at position two	UGG, tryptophan
UGA, opal	one — at position two	UGG, tryptophan
UAA, ochre	two — at position two or three	UGA and UAG — both still stops

Two of the three stop codons can be repaired by a single adenosine-to-inosine edit, and both of them become tryptophan. The third cannot be repaired at all. Every single-edit route out of the ochre stop lands on another stop.

Why the volume prints this

It is a hard constraint on an entire therapeutic strategy, it follows from the code table and the chemistry alone, and it is checkable in a minute.

And it explains why every demonstration in this literature uses an amber stop. The tryptophan destination is not a design choice. It is the only destination available.

---

423. Every Edit Is One Bit ↩

The general statement

Part Forty-Eight established that the sixty-four codons form a six-dimensional space over two symbols — six bits per codon, three bases at two bits each.

In that encoding, adenine is 00 and guanine is 01. They differ in one bit.

Every adenosine-to-inosine edit, read as A-to-G, flips exactly one of the six bits of a codon. Not a substitution, not a rewrite — a single bit inversion, in a six-bit word.

Set beside what the other Parts measured

Part	quantity
Sixty-Six	roughly one editable position per thirty-two bases of genome
Forty-Eight	six bits per codon
this section	one bit flipped per edit

The editor rewrites one bit in six, at roughly one position in thirty-two, more than a hundred million times over. That is the whole phenomenon stated in the volume's own units, and all three numbers were derived independently.

The volume claims the arithmetic and not a mechanism. What the bit encoding shows is that A-to-I is the minimal possible change in the codon space — the smallest edit the alphabet admits.

424. What This Does to the Volume's Argument ↩

Three things it settles and one it does not

It settles that inosine can be placed deliberately. Not observed, not inferred — installed, at a chosen position, with a yield of sixty to seventy-five percent.

It settles that the placement is controllable in time. The light dose sets the editing yield across the whole dynamic range, from nothing in the dark to full editing under illumination.

It settles that this works in an intact developing animal, with no genetic engineering, no transgenic line, and no host-specific factors — which is why the authors state the technology should be transferable to any organism.

It does not settle that inosine belongs in the alphabet. That remains the author's argument.

What it does establish is harder to argue with: a symbol the four letters cannot write can be written on purpose, in a living embryo, by shining a light on it.

425. What Is Claimed and What Is Not ↩

Claimed

That the editing machine is a SNAP-tag fused to the catalytic deaminase domain of human ADAR, joined to a benzylguanine-bearing guideRNA by a single covalent bond formed in situ at 2.8×10^4 M^{-1} s^{-1}. That SNAP-tag is an evolved O6-alkylguanine-DNA alkyltransferase whose mechanism forms an S-benzyl cysteine thioether, and that the bond is therefore a carbon-sulfur bond.

That the N7 and N9 Npom regioisomers decage at 34 ± 3 and 47 ± 4 seconds with quantum yields 0.50 and 0.36, that sixty seconds gave 75 percent conversion, and that only the N7 isomer blocks conjugation. That the in vitro editing half-life was 25.7 ± 0.4 seconds, agreeing with the decaging kinetics.

That editing yields were 75 percent in vitro with SNAP-ADAR1, about 45 percent in HEK293 cells under illumination against under 5 percent in the dark, and 60 to 70 percent across a population of Platynereis embryos, rising from about 10 percent in the dark to about 60 percent after five minutes of 365 nanometer light.

That a guideRNA directing repair to codon 66 instead of codon 58 produced absolutely no editing, and that no off-target editing was found in the reporter transcript by Sanger sequencing.

That UAG and UGG occupy the same row of the Part Forty-Nine grid and differ by exactly one bit — verified by construction. That of the three stop codons, only UAG and UGA can be converted to a sense codon by a single A-to-I edit, that both become tryptophan, and that every single edit available to UAA yields another stop. That every A-to-I edit flips exactly one of the six bits of a codon.

Not claimed

That the thioether bond was chosen for any reason connected to this volume's thesis. Section 417 states plainly that it was chosen for kinetics and specificity and that the volume records a coincidence.

That this technology is therapeutic. It is a laboratory tool demonstrated in a reporter gene and a model annelid.

That the one-bit result is a mechanism. It is arithmetic in a chosen encoding, and section 423 says so.

That inosine belongs in the genetic alphabet. Section 424 states explicitly that this Part does not settle it.

426. What Would Show This Part Is Wrong ↩

— Show that SNAP-tag does not form a thioether through an active-site cysteine, and section 417 — the connection to this volume's element — has no basis.

— Show that the caged guideRNA produces substantial editing in the dark, and the switch of sections 419 and 420 is not a switch.

— Show that a guideRNA aimed at a nearby codon does produce editing, and the specificity claim of section 420 fails and the tool is not site-directed.

— Find a single A-to-I edit that converts UAA into a sense codon, and section 422's constraint is wrong. There are only two adenosines in UAA and both routes were enumerated; the condition is printed because it cannot be met.

— Show that adenine and guanine differ in more than one bit under any two-bit encoding that makes complement an involution, and section 423's one-bit result does not hold generally.

---

427. The Instrument, Eleven Years on ↩

What Part Sixty-Three recorded

In March 2016 the author submitted an application whose central request was an instrument — a sequencer able to read more than four symbols — and whose stated obstacle was that the A-to-G proxy cannot be distinguished from a polymorphism.

What the record now shows

the request	where it stands
an instrument that reads inosine directly	direct RNA nanopore sequencing reads base modifications without conversion to cDNA
a way to distinguish an edit from a polymorphism	the chemical erasure of Part Sixty-Two does exactly this, published 2014
a way to place the symbol rather than only read it	this paper, published November 2015

The application was submitted four months after this paper appeared. The instrument for writing inosine at a chosen position already existed. What did not exist, and what the application correctly identified as missing, was an instrument for reading it.

The volume records the sequence without drawing a conclusion from it. The obstacle named in 2016 was real, it was named in the right terms, and the two halves of the answer arrived from two different laboratories in two different years.

PART SIXTY-NINE · THE WOBBLE POSITION

Part Sixty-Nine of the evidence volume, sections 428 to 440

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Agris, Eruysal, Narendran, Väre, Vangaveti and Ranganathan, RNA Biology, 2018 — fifty years of the wobble hypothesis. Position thirty-four of the anticodon is the most heavily modified position in transfer RNA. Two modifications dominate it. One is inosine, which expands reading. The other carries a sulfur atom, and it restricts reading. The four-letter alphabet writes neither.

428. Fifty Years of One Hypothesis ↩

What Crick proposed in 1966

Francis Crick's wobble hypothesis proposed that the first two bases of a codon pair canonically with the anticodon, and that the third base may pair non-canonically with the first base of the anticodon — position thirty-four.

He introduced it to explain the degeneracy of the genetic code: fewer transfer RNAs than codons, because one anticodon can read more than one codon.

And the molecule he built it on

Inosine was the first recorded nucleoside modification within the sequence of an anticodon — found by Holley in yeast transfer RNA for alanine, the first nucleic acid ever sequenced. Crick's hypothesis was constructed around it.

The paper states it plainly: inosine at wobble position thirty-four undergoes non-canonical base-pairing without exception.

Of the four non-canonical pairs Crick proposed, three are inosine.

Crick's wobble pairs
U34 · G3
I34 · A3

Crick's wobble pairs
I34 · C3
I34 · U3

The wobble hypothesis is, in three of its four cases, a hypothesis about inosine. The molecule this volume has spent twenty-nine years on is the molecule the degeneracy of the genetic code was explained with, in 1966, and it is not one of the four letters.

---

429. The Three Pairings, Drawn ↩

What Figure 5 of the paper shows

Two canonical pairs and four wobble pairs, drawn as structures with hydrogen bonds marked.

canonical	wobble
A · U	U34 · G3
G · C	I34 · A3
	I34 · C3
	I34 · U3

Inosine pairs with adenine, cytosine and uracil. It does not pair with guanine.

This is the third independent confirmation in this volume. Part Fifty-Seven derived the exclusion of guanine and built the join on it. Part Sixty-Four's Figure 5 drew the same three structures. This review, the definitive statement of the field at fifty years, draws them again.

Part Fifty-Nine's correction stands confirmed: inosine has three wobble partners, and I with G is not among them.

---

430. Position Thirty-Four Is the Most Modified Position in Transfer RNA ↩

The anticodon stem and loop

The anticodon of a transfer RNA sits in a seven-nucleotide loop at the end of a five-base-pair stem — the anticodon stem and loop, or ASL. The anticodon occupies positions 34, 35 and 36.

position	what it is	modification density
32	in the loop, before the anticodon	modified
34	the wobble position	the most heavily modified position in tRNA
35	second anticodon base	rarely modified
36	third anticodon base	rarely modified
37	immediately 3′ of the anticodon	the second most modified position
38	in the loop, after	modified

The two most heavily modified positions in the entire transfer RNA molecule are the first base of the anticodon and the base immediately after the anticodon. The reading end is where the chemistry is.

Position 35 and 36 — the two bases that pair canonically — are the two that are left alone.

---

431. Inosine Expands ↩

What removing a nitrogen does

Adenosine at position 34 is deaminated to inosine by ADAT, at the precursor level, in eight human transfer RNAs — Part Sixty-Four.

adenosine at 34	pairs with uracil only
inosine at 34	pairs with uracil, cytosine and adenine

One reaction, one nitrogen removed, and a transfer RNA that read one codon now reads three. That is the mechanism by which sixty-one sense codons are read by fewer than sixty-one transfer RNAs.

And the paper states its cost

The review records that inosine at position 34 is considered essential in various RNAs, plays a vital role in the function of transfer RNA in particular, and that a strain unable to deaminate at position 34 experiences temperature-dependent arrested growth and defects in cell cycle transitions.

Modification of I34 is not optional decoration. It is required.

---

432. Sulfur Restricts ↩

What adding a sulfur does at the same position

When a uridine sits at position 34, it can be modified at the C2 position — where a carbonyl oxygen normally sits — by substituting a sulfur.

uridine O at C2\n2-thiouridine S at C2 s2U\n2-selenouridine Se at C2 se2U

The paper devotes a figure and a section to what that substitution does.

property	oxygen	sulfur	selenium
covalent radius	66 pm	105 pm	120 pm
electronegativity	3.44	2.58	2.55

The review states the radii as approximately 40 and 100 percent larger than oxygen; by covalent radius the figures are about 59 and 82 percent. The exact percentage depends on which radius convention is used and the direction is not in doubt: sulfur and selenium are substantially larger and substantially less electronegative than the oxygen they replace.

The mechanism, in four steps

1. *a larger, less electronegative atom sits at C2\n2. steric effects push the ribose sugar pucker toward C3'-endo\n3. the glycosidic angle chi is held anti\n4. the anti, C3'-endo conformation base-pairs to A\nand will NOT wobble to G*

The sulfur atom is what makes the reading exclusive. Where inosine at position 34 opens a transfer RNA to three codons, a sulfur at position 34 closes it to one.

The two elements, at one coordinate

modification at position 34	the chemistry	the effect
inosine	a nitrogen removed	expands — one tRNA reads three codons
2-thiouridine	a sulfur added	restricts — one tRNA reads one codon

The same position. Two modifications. Opposite operations. And the four-letter alphabet has a symbol for neither of them.

That is this volume's thesis stated at a single coordinate of a single molecule, and it was not stated by this volume.

---

433. The Frameshift ↩

What happens when the sulfur is removed

In Saccharomyces cerevisiae, the wobble uridine of certain transfer RNAs carries a compound modification — 5-methoxycarbonylmethyl-2-thiouridine, written mcm^{5}s^{2}U34. It has two parts: the methoxycarbonylmethyl group at C5, and the sulfur at C2.

Loss of either part increases +1 translational frameshifting.

The attributed cause: a decrease in the affinity of the transfer RNA for the ribosomal A-site, and impaired translocation.

What that means, stated plainly

A frameshift is the most destructive error in translation. Every codon after the slip is read in the wrong register, and the protein downstream of it is nonsense.

Remove one sulfur atom, from one carbon, of one base, in one transfer RNA — and the ribosome begins losing its place. The reading frame is held by an atom the notation cannot write.

Part One of this volume argued that the alphabet is silent about the variable that decides function. Here the variable is a single sulfur atom and the function is the reading frame itself.

434. The Modification Triangle, and How Much of It Is Sulfur ↩

The four positions

The review presents the modifications of the anticodon stem and loop as a triangle — positions 32, 34 and 37 at the vertices, with 38 completing the interactions. Modifications at these positions work together, in what the authors call a co-surgical manner.

position	its role	a sulfur modification found there
32	with 38, forms the base pair that sets loop dynamics	s^2C32 — 2-thiocytidine
34	the wobble position	s^2U34, mnm^5s^2U34, mcm^5s^2U34 — and se^2U34
37	stabilizes the U-turn, prevents frameshifting	ms^2t^6A37, ms^2i^6A37 — 2-methylthio modifications
38	pairs with 32	none named in this review

Three of the four positions of the modification triangle carry a sulfur modification. The geometry that decides which codons a transfer RNA can read is decorated, at three of its four corners, with the element the alphabet omits.

And what the triangle is for

The review's own summary: modifications at 32, 34 and 37 restrict or expand codon recognition; modifications at 37 and 38 provide additional stacking to the codon-anticodon mini-helix; modifications at 32 and 38 regulate the stability of the ASL.

Multiple modifications within the ASL may provide a redundancy of structure and conformational dynamics not otherwise achievable by forty or more individual transfer RNAs.

435. Selenium, One Row Down ↩

The same substitution, further down group sixteen

2-selenouridine does what 2-thiouridine does, more so. Larger atom, similar electronegativity, a stronger push toward the restrictive conformation.

Part Fifty of this volume established the group-sixteen trend: down the column, larger, softer, more polarizable, lower pKa. Oxygen, sulfur, selenium. Here that trend is applied at one carbon of one base and the consequence is which codons get read.

The volume has now met selenium at four places — GPX4 in Part Forty-Three, thioredoxin reductase in Part Forty-Seven, the group-sixteen argument of Part Fifty, and here at the wobble position.

---

436. Queuosine Is a Vitamin ↩

A modification humans cannot make

Queuosine is a 7-deazaguanosine derivative found at wobble position 34 in the transfer RNAs for aspartate, asparagine, histidine and tyrosine.

synthesized by	bacteria
acquired by eukaryotes as	queuine, the free base — from the diet or from intestinal flora

A modification of the decoding apparatus of a human cell is a nutrient. It cannot be made and must be eaten, or supplied by the bacteria in the gut. The reading of four codon families depends on a molecule that arrives from outside the organism.

The volume records this because it belongs with the Chromatium material of Part Fifty-Three and the mitochondrial inheritance of Part Sixty-Seven. The decoding apparatus of a human is partly bacterial in origin and partly bacterial in ongoing supply.

---

437. The Superwobble, and the Twenty-Two ↩

What an unmodified uridine can do

An unmodified U34 can read all four codons of a four-fold degenerate box — "superwobble."

The paper is careful about the cost: superwobble reading of codons compromises translational efficiency.

The mitochondrial case

Twenty-two transfer RNAs with unmodified anticodon domains, transcribed in mammalian mitochondria, decode the four-fold degenerate codon boxes without error — but perhaps at reduced efficiencies.

Twenty-two transfer RNAs, reading a genetic code, with no anticodon modification at all.

And the glycine case

The glycine codons GGA, GGG, GGU and GGC form a four-fold box, read in bacteria by up to three isoacceptors — E. coli transfer RNA-Gly with anticodons CCC, UCC and GCC.

An unmodified U34 is particularly efficient in organellar transfer RNA for glycine.

So the modifications are not required for reading. They are required for reading efficiently, and for reading exclusively. A cell can decode without them and pays for it in speed and in precision.

---

438. What This Part Adds to the Volume ↩

Three statements, compactly

First. The wobble hypothesis — the explanation of the degeneracy of the genetic code, now fifty years old — was built on inosine, and three of Crick's four proposed non-canonical pairs are inosine pairs. The molecule is not in the alphabet.

Second. At the same position, a single sulfur atom substituted for a carbonyl oxygen reverses the operation: inosine expands reading to

three codons, thiouridine restricts it to one. Two elements, one coordinate, opposite effects, and no symbol for either.

Third. Removing that one sulfur atom causes the ribosome to lose its reading frame. The register in which the entire downstream protein is read is held by an atom of element sixteen.

And one thing this Part does not do

It does not argue that inosine or thiouridine should be letters. It records that the degeneracy of the code, the efficiency of translation and the maintenance of the reading frame are all decided at positions the notation describes with four symbols and cannot describe correctly.

---

439. What Is Claimed and What Is Not ↩

Claimed

That Crick's 1966 wobble hypothesis proposed four non-canonical codon-anticodon pairs, three of which involve inosine at position 34, and that inosine was the first nucleoside modification recorded within an anticodon sequence. That inosine at position 34 pairs with uracil, cytosine and adenine and not with guanine — the third independent confirmation carried by this volume.

That position 34 is the most heavily modified position in transfer RNA and position 37 the second. That positions 35 and 36 are rarely modified.

That substituting sulfur or selenium for the C2 carbonyl oxygen of uridine at position 34 drives the ribose pucker toward C3′-endo, holds the glycosidic angle anti, and restricts pairing to adenine rather than permitting the wobble to guanine. That the covalent radii are 66, 105 and 120 picometers for oxygen, sulfur and selenium and the Pauling electronegativities 3.44, 2.58 and 2.55.

That loss of either the xm^5 or the s^2 component of mcm^5s^2U34 in S. cerevisiae increases +1 translational frameshifting, attributed to reduced A-site affinity and impaired translocation.

That sulfur modifications occur at positions 32, 34 and 37 of the anticodon stem and loop — three of the four positions of the modification triangle. That queuosine is synthesized by bacteria and acquired by eukaryotes as a nutrient. That an

unmodified U34 permits superwobble reading of a four-fold box at reduced efficiency, and that twenty-two transfer RNAs with unmodified anticodon domains decode the mammalian mitochondrial four-fold boxes without error.

Not claimed

That the paper's stated radii percentages are exact. Section 432 gives both the paper's figures and the standard covalent radii and notes that the percentage depends on the convention.

That the sulfur modifications of the anticodon loop were counted against a background. Three of four positions is a count from one review's naming, not an enrichment test.

That inosine or 2-thiouridine should be counted as bases of the genetic code. Section 438 states what this Part does and does not do.

---

440. What Would Show This Part Is Wrong ↩

— Show that inosine at position 34 pairs with guanine, and three Parts of this volume fail together.

— Show that 2-thiouridine at position 34 permits wobble to guanine, and section 432's central claim — that sulfur restricts where inosine expands — is wrong.

— Show that loss of the 2-thio modification does not increase frameshifting, and section 433 has no exhibit.

— Show that position 34 is not the most heavily modified position in transfer RNA, and the premise of the whole Part fails.

— Show that eukaryotes synthesize queuosine de novo, and section 436's nutrient claim is wrong.

— Count sulfur modifications across all thirty-plus modified positions of transfer RNA against a background expectation. If positions 32, 34 and 37 are no more sulfur-rich than the rest of the molecule, section 434's triangle observation is a selection effect. This count has not been done and it is the test this Part most needs.

PART SEVENTY · THE CASE FOR EIGHT

Part Seventy of the evidence volume, sections 441 to 453

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Why eight, and why these eight. Four purines in the order the purine road builds them — inosine, xanthine, guanine, adenine — against four pyrimidines in the order the pyrimidine road builds them. The four pairs sort into two that pair by hydrogen bond and two that pair by position on the road. And there is an arithmetic reason why eight works and six does not.

441. The Question, Put Plainly ↩

What has to be answered

Part Forty-Eight established that four, six and eight are each the minimum set closed under a different operation. Four closes under complement. Six is what a polymerase and a ribosome encounter. Eight is the set of obligate biosynthetic nodes.

Part Forty-Nine put eight symbols on the eight corners of a cube and built the sixty-four-cell grid.

What was never answered is why eight is the right number for the grid rather than six, and why these eight rather than any other eight. This Part answers both, and one of the two answers is arithmetic.

442. The Two Roads ↩

Purine, as the cell builds it

PRPP\n| ten enzymatic steps\nv\nIMP <-- the first COMPLETE purine nucleotide\n|\n+---> adenylosuccinate ---> AMP adenylosuccinate synthetase, then lyase\n|\n+---> XMP ---> GMP IMP dehydrogenase, then GMP synthetase

Pyrimidine, as the cell builds it

glutamine + CO2 + ATP\n| carbamoyl phosphate synthetase II\nv\ncarbamoyl aspartate aspartate transcarbamoylase\n|\nv\ndihydroorotate dihydroorotase\n|\nv\nOROTATE dihydroorotate dehydrogenase\n| + PRPP\nv\nOMP ---> UMP OMP decarboxylase\n|\n+---> UTP ---> CTP CTP synthetase\n|\n+---> dUMP ---> dTMP thymidylate synthase

The asymmetry worth noting immediately

The purine road builds the ring on the sugar. The pyrimidine road builds the ring free and attaches it to the sugar afterward, at orotate.

Two roads, two architectures, and each has exactly one place a molecule cannot get past without a specific enzyme.

---

443. Xanthosine Gates Guanine ↩

The test

Can a cell make a guanine nucleotide de novo without passing through xanthosine monophosphate?

No. Inosine monophosphate dehydrogenase is the sole committed step from IMP to XMP, and GMP synthetase is the sole step from XMP to GMP. There is no bypass.

And the enzyme's status confirms it. IMPDH is rate-limiting for guanine nucleotide biosynthesis and is the target of mycophenolate mofetil, the standard immunosuppressant in transplantation, and of ribavirin. A gate you can close with a drug is a gate.

What xanthine is not

Xanthine is never installed in a nucleic acid. There is no xanthine in DNA and none in RNA.

It is a molecule every guanine in the body passes through and no molecule in the body retains. That is the definition of a gate: obligatory in transit, absent at the destination.

And the honest qualification

Xanthosine gates guanine only. Adenine branches off IMP directly and never sees XMP.

So the purine road has two nodes: IMP, through which everything passes, and XMP, through which only the guanine branch passes. The volume states that rather than smoothing it over.

---

444. Orotate Gates Every Pyrimidine ↩

The test

Can a cell make any pyrimidine nucleotide de novo without passing through orotate?

No. Orotate is the single entry. Every uracil, every cytosine, every thymine made de novo passes through orotate and then OMP.

And below that, uracil is the branch point: cytosine comes from UTP, thymine from dUMP. Neither is reached except through uracil.

What orotate is not

Orotate is never installed in a nucleic acid either. There is no orotate in DNA and none in RNA.

And the enzyme, which this volume already carries

Dihydroorotate dehydrogenase is the one enzyme of nucleotide synthesis wired into the respiratory chain — Part Thirty-Seven. It is the target of teriflunomide and leflunomide in multiple sclerosis and rheumatoid arthritis, and of BAY 2402234 in leukemia — whose trial Part Fifty-Eight records as terminated.

Two gates, two drug targets, and neither symbol appears in the alphabet.

---

445. The Four Pairs Sort Into Two Kinds ↩

The author's pairing

A - T G - C I - U X - O

And what each pair turns out to be

pair	do they pair chemically?	hydrogen bonds	where they sit on the road
G – C	yes, Watson-Crick	3	both end products
A – T	yes, Watson-Crick	2	both end products
I – U	yes — a real wobble pair	2	the first complete nucleotide of each road
X – O	no pair exists	0	the gate of each road

Two of the four pairs are reading pairs. Two are making pairs. And the sorting is clean: the pairs that hold a duplex together are the end products, and the pairs that gate the roads are the ones that never enter a duplex at all.

The one that is both

I with U is a genuine wobble pair — Parts Fifty-Seven, Sixty-Four and Sixty-Nine each confirm it — and it is also the pairing of the first complete purine nucleotide with the first complete pyrimidine nucleotide.

Inosine and uridine are the first finished nucleotide of each road, and they pair. That is not a coincidence the volume can explain, and it is exact.

---

446. The Descent ↩

Pairing strength against metabolic priority

pair	hydrogen bonds	when it is made
G – C	3	last
A – T	2	last
I – U	2	first complete
X – O	0	first of all

The pairing strength descends exactly as the metabolic priority ascends. The pair that binds hardest is made last. The pair that does not bind at all is made first.

Why that ordering is not arbitrary

A molecule that every guanine must pass through cannot also be a molecule that stays — if xanthine paired, it would be incorporated, and the gate would become a destination. A molecule that must be held in a duplex for the lifetime of a chromosome needs three hydrogen bonds.

The chemistry that makes a good gate is the chemistry that makes a bad letter. The eight sort themselves by that single criterion, and the sorting produces exactly the author's four pairs.

This is the strongest argument in this Part and it is checkable in an afternoon against any pairing table and any pathway chart.

---

447. Adenine Has No Oxygen ↩

Counted across the eight

symbol	base	formula	ring oxygens	amino groups	methyl
A	adenine	C5H5N5	0	1	0
I	hypoxanthine	C5H4N4O	1	0	0
X	xanthine	C5H4N4O2	2	0	0
G	guanine	C5H5N5O	1	1	0
C	cytosine	C4H5N3O	1	1	0
T	thymine	C5H6N2O2	2	0	1
U	uracil	C4H4N2O2	2	0	0
O	orotate	C5H4N2O4	2, plus two in the carboxyl	0	0

The finding

Adenine is the only one of the eight with no oxygen at all. On the colored sheet, adenine is the only base with no orange.

Part Forty-Seven found that orange saturates the nucleotide panel. This is the single exception, and it is the base the whole editing story starts from.

Adenine is also the base that becomes inosine. The deamination of Part Fifty-Nine removes a nitrogen and installs an oxygen — so the reaction converts the only oxygen-free base into one that carries one.

The editor's substrate is the one base with no orange, and the edit gives it one.

And the author's functional-group table is correct

The table on the worksheet — A as amino, I as hydroxyl, X as two oxygens, G as amino and hydroxyl, C as oxygen and amino, T as two oxygens and a methyl, U as two oxygens, O as hydroxyl — matches the actual substituent pattern of all eight, checked one by one.

---

448. Why Eight and Not Six ↩

The arithmetic answer

A symbol set of size n carries $\log_2 n$ bits per symbol. For a grid to work, that has to be a whole number.

symbols	pairs	bits per symbol	integer?
4	2	2.000	yes
6	3	2.585	no
8	4	3.000	yes
10	5	3.322	no

Only four and eight give an integer number of bits per symbol. Six does not, and no arrangement of six symbols produces a clean grid of sixty-four cells.

And eight is the next one up from four

Four symbols at two bits each need three positions to make sixty-four. Eight symbols at three bits each need two.

$$4 \text{ symbols } \times \text{ 3 positions } = \text{ 2 bits x 3 } = \text{ 6 bits } = 64 \backslash n 8 \text{ symbols } \times \text{ 2 positions } = \text{ 3 bits x 2 } = \text{ 6 bits } = 64$$

The eight-letter alphabet is the only alternative to the four-letter alphabet that carries the same information in a whole number of characters. Six cannot do it. Ten cannot do it. The next after eight is sixteen.

That is the answer to why eight, and it does not depend on any claim this volume makes. It is a property of powers of two.

---

449. What the Sixty-Four Cells Now Say ↩

The grid, re-read

Part Forty-Nine populated an eight-by-eight grid and found that its sixteen half-rows are exactly the sixteen codon family boxes, that all three stop codons fall in one row, and that both sulfur amino acids and both single-codon amino acids fall in the two gate rows.

the grid coordinate	what it now carries
the row	a symbol from the eight — its position on the biosynthetic road
the column	a symbol from the eight — the same
the cell	a codon

The same sixty-four cells can be read two ways. Read as codons, they are the genetic code. Read as ordered pairs from the eight, they are a map of where each codon's components sit on the two biosynthetic roads. One grid, two readings, and the second is the one no textbook prints.

That is the claim the author is making when he says the sixty-four cells tell the story of nucleotide metabolism, and it is a claim about a re-indexing rather than about new chemistry.

450. What This Replaces and What It Does Not ↩

The volume must be accurate about the standing of the codon table

It would be convenient for this argument if the genetic code were a museum piece that only schools still taught. It is not, and the volume gains nothing by pretending otherwise.

where the codon table is in daily industrial use	
codon optimization	every recombinant protein and every biologic is expressed from a sequence rewritten against a codon usage table
messenger RNA therapeutics	sequence design for stability and expression is codon-level work
nonsense-suppression therapy	readthrough agents and engineered suppressor transfer RNAs target specific stop codons
genome recoding	synthetic organisms have been built with codons deliberately removed from the genome

The codon table is not a relic. It is a working tool in constant commercial use. And that makes the volume's argument stronger, not weaker.

A wrong map nobody consults is a curiosity. A map in daily use whose omissions are measurable is a different matter, and the eleven Parts before this one measured them: one editing site per thirty-two bases, ninety-nine percent of the reaction unassigned, a reading frame held by a single sulfur atom, an alphabet that cannot distinguish an edit from a mutation.

What the eight-symbol set is offered as

Not a replacement for the codon table. A second index over the same sixty-four cells, in which the two gates that no letter names are given coordinates.

The four letters answer: what does this codon specify. The eight symbols answer: where did the parts of this codon come from, and what had to be passed through to make them. Those are different questions and both have answers.

451. What Is Claimed and What Is Not ↩

Claimed

That inosine monophosphate is the first complete purine nucleotide and that all purine nucleotides pass through it. That xanthosine monophosphate is obligate for guanine and is bypassed by adenine — stated with the asymmetry, not smoothed over. That orotate is the single entry point for every pyrimidine made de novo, and that uracil is the branch point below it for both cytosine and thymine.

That neither xanthine nor orotate is ever installed in a nucleic acid. That IMPDH and DHODH are both established drug targets, naming mycophenolate, ribavirin, teriflunomide, leflunomide and BAY 2402234.

That the four pairs sort into two Watson-Crick reading pairs of end products, one real wobble pair of first-complete nucleotides, and one non-pair of gates. That the hydrogen-bond counts are three, two, two and zero, and that they descend as metabolic priority ascends.

That adenine is the only one of the eight with no oxygen, that the author's functional-group table matches the actual substituent pattern of all eight, and that $\log_2$ of six is not an integer while $\log_2$ of eight is.

Not claimed

That the eight-symbol set should replace the codon table. Section 450 states what it is offered as.

That the descent of hydrogen bonding against metabolic order is a mechanism. It is an ordering, exact and checkable, and the volume offers a reason for it in section 446 without claiming that reason is demonstrated.

That the pairing of inosine with uridine as the two first-complete nucleotides has an explanation. Section 445 states plainly that the volume cannot explain it.

That six is wrong. Part Forty-Eight established six as the reading set and that stands. Section 448 says only that six cannot index a sixty-four-cell grid in whole bits, which is a statement about grids and not about biology.

452. What Would Show This Part Is Wrong ↩

- Exhibit a de novo route to a guanine nucleotide that bypasses XMP, and section 443's gate is not a gate.
- Exhibit a de novo route to any pyrimidine that bypasses orotate, and section 444 fails — and with it the symmetry the whole Part rests on.
- Find xanthine or orotate incorporated into a natural nucleic acid, and the gates are destinations after all.
- Show that inosine does not pair with uracil, and the I–U pair of section 445 is not a pair, and three earlier Parts fail with it.
- Find a ninth base that is an obligate biosynthetic gate in either road, and eight is incomplete as a manufacturing set.
- Find a second base among the eight with no oxygen, and section 447's uniqueness claim for adenine is wrong.

---

453. One Claim This Volume Will Not Carry ↩

Stated once, and then not returned to

The author holds that the incompleteness of the genetic code has been known since the early nineteen-fifties and kept quiet to maintain control of the technology.

This volume does not carry that claim, and the reason is the volume's own standing rule.

Every Part of this book ends by stating the conditions under which it would be wrong. A claim about concealment has no such conditions. There is no measurement that would settle it, no chart that could be re-colored, no pathway that could be re-run. It cannot be checked, so it cannot be printed here.

And a practical reason as well

The volume's case is built from figures anyone can verify. One site per thirty-two bases. Ninety-two to ninety-five percent of sequence calls wrong. Seven hundredths of one percent of the reaction accounted for. Twenty of twenty-one sites hypo-edited in one direction. Forty-one plus fifty-four is ninety-five.

A hostile reader who cannot fault those numbers will look for the one paragraph he can dismiss without arithmetic. A suppression claim is that paragraph. It would cost the volume more than it could possibly add.

What can be said instead, and is true

The record shows something less dramatic and more useful: the field knows the four-letter notation is incomplete, says so in its own papers, and carries on using it because no better instrument existed.

Sakurai and colleagues built a chemistry in 2014 because sequence comparison could not be trusted. Bazak and Levanon wrote that such a heavy burden of editing raises the possibility of functions that remain unknown. Wang and Cheung concluded that genetic variation extends beyond DNA sequence variation.

That is not concealment. It is a field that has published the problem and not yet reorganized around it. The volume's contribution is to put those admissions in one place and count them, and that contribution survives any question about motive.

PART SEVENTY-ONE · THE ENZYME THAT READS THE MISSING SYMBOLS

Part Seventy-One of the evidence volume, sections 454 to 466

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Davies, Mendes, Smallbone and Malys, BMB Reports, 2012. Fifteen nucleotides were offered to one enzyme. It acted on three. The three are inosine triphosphate, deoxyinosine triphosphate and xanthine triphosphate — and its products are inosine monophosphate and xanthosine monophosphate, which are the two gates of Part Seventy.

---

454. The Enzyme That Recognizes Only the Missing Symbols ↩

What was done

Fifteen different nucleotides were offered to the purified enzyme encoded by YJR069C in Saccharomyces cerevisiae — the homolog of E. coli RdgB and of the human erythrocyte ITPase. The activity on each was measured by coupling to inorganic pyrophosphatase and reading released phosphate.

the four canonical ribonucleotides	activity
ATP	below detection
GTP	0.023
CTP	below detection
UTP	below detection

the four canonical deoxyribonucleotides	activity
dATP	0.488
dGTP	0.235
dCTP	0.073
dTTP	0.055

the three the enzyme actually works on	activity
dITP	59.096 ± 5.750
ITP	39.262 ± 9.031
XTP	36.155 ± 2.352

Stated plainly

There is an enzyme in every eukaryote whose entire working substrate set is the inosine and xanthine triphosphates. Every one of the four letters of the genetic alphabet is a non-substrate. The enzyme sees the two symbols the notation omits, and nothing else.

Its yeast gene is HAM1. Its bacterial homolog is RdgB. Its human counterpart is ITPA, first described in human erythrocytes in 1970. This is a conserved, universal housekeeping activity.

455. The Discrimination, Computed ↩

Against the four letters

comparison	fold difference
ITP against ATP	more than 13,000-fold
dITP against ATP	more than 19,700-fold
XTP against ATP	more than 12,000-fold
dITP against dATP	121-fold
dITP against dGTP	251-fold
dITP against dCTP	810-fold
dITP against dTTP	1,074-fold
dITP against GTP	2,569-fold

What separates ITP from ATP

One amino group at carbon six. Nothing else. The ribose is the same, the three phosphates are the same, the ring is the same.

Remove one NH_2 from ATP and you get ITP. This enzyme treats those two molecules more than thirteen thousand times differently.

Part Fifty-Nine established that the deamination which produces inosine removes a nitrogen and installs an oxygen — one green and two reds becoming one orange, in the volume's colors. A protein has been reading that color substitution, in every eukaryote, for as long as there have been eukaryotes.

And the inhibition constants confirm it

nucleotide	inhibition constant
ATP	greater than 10,000 micromolar
GTP	about 3,000 micromolar
dATP	about 1,000 micromolar
the natural substrates, for comparison	Km about 3 micromolar

The letters cannot even inhibit it competitively at any concentration a cell would reach. ATP's inhibition constant is roughly four thousand times the Michaelis constant for ITP.

456. It Is Blind to a Diphosphate ↩

The second axis of specificity

substrate	activity
ITP	39.262
IDP	below detection
XTP	36.155
XDP	below detection

The same base. One phosphate fewer. And the enzyme cannot see it at all.

So the discrimination runs on two axes at once: which base, and how many phosphates. Only the triphosphate is a substrate, and only if the base is inosine or xanthine.

Why that matters

A nucleoside triphosphate is what a polymerase uses. A diphosphate is not.

The enzyme is positioned exactly at the form that could be incorporated into a nucleic acid, and is indifferent to the form that could not. It is not clearing inosine from the cell. It is clearing inosine from the polymerase's supply.

457. The Product Is the Gate ↩

What the reaction actually is

The enzyme is a nucleoside triphosphate pyrophosphohydrolase. It removes pyrophosphate.

$$ITP + H2O \rightarrow IMP + PPi \backslash nXTP + H2O \rightarrow XMP + PPi$$

And what those products are

Part Seventy established that inosine monophosphate is the first complete purine nucleotide, through which every purine in the cell passes, and that xanthosine monophosphate is the obligate gate to guanine.

The enzyme does not destroy inosine or xanthine. It converts the dangerous triphosphate back into the obligatory monophosphate. The poison and the gate are the same molecule at two different phosphorylation states, and this enzyme moves it from one to the other.

The circle, closed

phosphorylation state	status
IMP, XMP — monophosphate	obligatory. Every purine passes through IMP; every guanine through XMP
ITP, XTP — triphosphate	toxic. Removed by a dedicated, conserved hydrolase
the hydrolase's action	triphosphate back to monophosphate — poison back to gate

This is the sharpest statement the volume has yet been able to make about its two extra symbols. They are required in one form and forbidden in another, and there is an enzyme whose whole job is to move them from the forbidden form to the required one.

Neither the paper nor Part Seventy makes this connection. It follows from putting the reaction next to the pathway.

---

458. Why a Deaminated Triphosphate Is Dangerous ↩

What happens if it is not removed

The paper states the consequences directly. Deaminated nucleotides may accumulate in the nucleotide pools or become incorporated into DNA and RNA, altering nucleic acid structure and genetic information.

consequence named	
mutagenesis and carcinogenesis	
senescence and aging	

consequence named	
degenerative disorders	
cell death	
defective DNA metabolism	
adverse effects on other biological functions of canonical nucleotides	

And why it is inosine specifically

Inosine reads as guanosine. Part Fifty-Nine established that. An inosine triphosphate incorporated opposite a cytosine is invisible to the polymerase and becomes a guanine at the next replication.

An A-to-I edit in a messenger RNA changes one transcript. An inosine triphosphate incorporated into DNA changes the genome. The alphabet cannot distinguish these two events either, and the cell distinguishes them with an enzyme.

The yeast gene name records this. HAM1 was named for sensitivity to 6-N-hydroxylaminopurine — a mutagenic base analog. The gene was found by what its loss lets through.

---

459. The Kinetics ↩

Three substrates, one active site

substrate	Km (micromolar)	kcat (per second)	catalytic efficiency ($M^{-1}s^{-1}$)
ITP	2.38 ± 0.41	0.992 ± 0.056	4.17×10^5
dITP	3.06 ± 0.60	1.288 ± 0.016	4.21×10^5
XTP	3.70 ± 0.68	1.000 ± 0.024	2.70×10^5

The Michaelis constants run ITP below dITP below XTP — checked, and it is the order the paper states. All three fall in a narrow band around three micromolar, and the turnover numbers all sit near one per second.

One enzyme, three substrates, indistinguishable kinetics. That is what a genuinely multi-specific active site looks like, and the authors present it as evidence that multispecificity is not a rare phenomenon in the protein world.

The scale of the thing

molecular weight	26.9 kilodaltons
copies per cell	3,490
cell volume	4×10^{-14} liters
implied cellular concentration	about 145 nanomolar

A small protein, present at a few thousand copies, doing one job.

---

460. The Sensitivity Analysis ↩

What controls the inosine triphosphate pool

The authors built a mathematical model of deaminated purine nucleotide metabolism and computed how sensitive the steady-state ITP concentration is to each parameter.

parameter	scaled sensitivity of ITP
the amount of ATP	+1.19
the rate constant for ATP deamination	+1.02
the Michaelis constant for ITP	+1.00
the amount of the hydrolase	−1.03
the turnover number of the hydrolase on ITP	−1.02
the amount of GTP	+0.18
the inhibition constant for GTP	−0.18
the turnover number on XTP	−0.0069

What that means

A one percent increase in the amount of this enzyme lowers the inosine triphosphate pool by one point zero three percent. The relationship is very nearly reciprocal.

And a one percent increase in ATP raises ITP by one point one nine percent — because ATP is where ITP comes from. The pool of the unwritable symbol is set almost entirely by the pool of the letter it is derived from and by the amount of the enzyme that removes it.

The XTP arm barely enters the ITP calculation at all. The two branches are kinetically coupled through one active site and functionally almost independent.

---

461. The Deamination Clock ↩

How fast a letter becomes a non-letter

reaction	rate constant	half-life
ATP to ITP	10^{-6} per second	about 8 days
GTP to XTP	10^{-5} per second	about 19 hours

Guanosine triphosphate deaminates ten times faster than adenosine triphosphate.

In a cell with no repair, a tenth of the guanine triphosphate pool would become xanthine triphosphate every few hours. That is why the enzyme is a housekeeping enzyme. The damage is not an accident; it is a rate.

And it connects to the volume's oxygen argument

Part Fifty-Four established that oxygen respiration produces superoxide, peroxide and hydroxyl radical, and that every antioxidant system in the cell is a thiol system. Deamination is accelerated by nitric oxide and by oxidative conditions.

The same oxygen chemistry that Part Fifty-Four made the cell pay for produces the deaminated nucleotides this enzyme spends its existence removing. Oxygen makes the damage; sulfur defends against it; and a dedicated hydrolase clears what gets through into the nucleotide pool.

462. Two Statuses for One Molecule ↩

Inosine, in three places

where	what it is	what handles it
anticodon position 34 of transfer RNA	essential. Reading three codons instead of one depends on it	ADAT2 and ADAT3 — and ADAT2 could not be knocked out
double-stranded regions of messenger RNA	a mark of self, and a recoding signal	ADAR1 and ADAR2 — over a hundred million sites
the free triphosphate pool	toxic. Mutagenic if incorporated	this hydrolase — which removes it

The same base. Installed deliberately in two places by enzymes a cell cannot live without, and removed just as deliberately from a third by an enzyme conserved from bacteria to man.

What that settles about the volume's argument

A hostile reader might say inosine is merely damage — a lesion, not a symbol.

That reading cannot survive this table. Damage is not installed at a specific position of a specific transfer RNA by an essential enzyme, before the molecule is even finished. And a symbol is not cleared from the nucleotide pool by a dedicated hydrolase with thirteen thousand-fold specificity.

Inosine is both, and which one it is depends entirely on where it sits. That is a statement the four-letter alphabet has no way to make, because the alphabet has no symbol for inosine and no way to record position-dependent status.

463. What Is Claimed and What Is Not ↩

Claimed

That fifteen nucleotides were assayed against the purified YJR069C enzyme, that only dITP, ITP and XTP showed substantial activity at 59.096, 39.262 and 36.155 micromoles per minute per milligram, and that ATP, CTP, UTP, IDP, XDP, m^7GTP

and m⁷GDP were all below the 0.003 detection limit. That the resulting discrimination between ITP and ATP exceeds thirteen thousand-fold —

That the enzyme acts only on triphosphates and not on the corresponding diphosphates. That the Michaelis constants are 2.38, 3.06 and 3.70 micromolar for ITP, dITP and XTP, that turnover numbers are near one per second, and that catalytic efficiencies are 4.17, 4.21 and 2.70 × 10^5 per molar per second.

That inhibition constants for ATP, GTP and dATP are respectively above 10,000, about 3,000 and about 1,000 micromolar — three orders of magnitude above the natural Km.

That the enzyme is a nucleoside triphosphate pyrophosphohydrolase whose products are the monophosphates, and that those monophosphates are IMP and XMP.

That the scaled sensitivity of the ITP pool is −1.03 to the enzyme amount and +1.19 to the ATP amount. That the deamination rate constants used were 10^{-6} and 10^{-5} per second for ATP and GTP, corresponding to half-lives of about eight days and about nineteen hours — computed from the constants.

Not claimed

That the enzyme evolved to serve the biosynthetic gates. Section 457 records that its product is the gate. It does not claim that is why the enzyme exists, and the authors make no such claim.

That inosine's three statuses are a designed system. Section 462 sets them side by side. The volume records the arrangement and offers no account of how it arose.

That the model's parameters are measured. The paper states that the deamination rate constants were estimated and that the dGTP branch parameters were assumed similar to the GTP branch. The volume prints that.

464. What Would Show This Part Is Wrong ↩

- Show substantial hydrolysis of ATP, CTP or UTP by this enzyme, and the claim that its substrate set is exactly the missing symbols fails.
- Show that it hydrolyzes IDP or XDP, and the triphosphate-only specificity of section 456 is wrong.

— Show that the product of the reaction is the nucleoside or the free base rather than the monophosphate, and section 457's closing of the circle to Part Seventy has no basis. The enzyme is classified as a pyrophosphohydrolase and the product is the monophosphate by definition of that class; the condition is printed because it is the load-bearing step.

— Show that ADAT2 is dispensable in human cells, and one leg of section 462's three-status table is weaker than stated.

— Show that guanosine triphosphate does not deaminate faster than adenosine triphosphate, and section 461's clock is inverted.

— Measure the deamination rate constants directly rather than estimating them. The model of section 460 rests on two estimated numbers, and the sensitivity analysis says the ITP pool is almost perfectly sensitive to one of them. That measurement has not been made, and it is the experiment this Part identifies.

---

465. The Three Enzymes of the Third Purine ↩

Named together for the first time in this volume

enzyme	what it does to inosine	where
ADAT2 with ADAT3	makes it, from adenosine	anticodon position 34, on the precursor transfer RNA
ADAR1 and ADAR2	makes it, from adenosine	double-stranded messenger RNA, over a hundred million sites
ITPA, HAM1, RdgB	removes it	the free triphosphate pool

Two enzyme families exist to install this molecule and one exists to remove it. All three are conserved. One of the installers is probably essential and one of them is required to keep a mouse embryo alive. The remover is a housekeeping enzyme found from bacteria to human erythrocytes.

And the two gates have their own enzymes

gate	the enzyme that makes it	the enzyme that consumes it
IMP	the ten-step de novo route from PRPP	adenylosuccinate synthetase, and IMP dehydrogenase
XMP	IMP dehydrogenase — target	GMP synthetase

gate	the enzyme that makes it	the enzyme that consumes it
	of mycophenolate	

Five enzyme activities, arranged around two molecules that the genetic alphabet does not name. The cell has more dedicated machinery for inosine and xanthine than the notation has symbols for the entire nucleotide world.

466. What the Volume Now Has on These Two Symbols ↩

Compactly, and drawn from thirteen Parts

Inosine is the first complete purine nucleotide and everything purine passes through it. Xanthosine is the obligate gate to guanine. Neither is ever installed in a nucleic acid by a polymerase, and both are removed from the triphosphate pool by a conserved hydrolase with thirteen thousand-fold specificity — whose products return them to their gate positions.

And yet inosine is installed deliberately, by two separate enzyme families, at one position of eight transfer RNAs and at more than a hundred million positions in messenger RNA, where it is read as guanosine, marks a transcript as belonging to the organism, and holds the degeneracy of the genetic code that Crick explained in 1966.

Every sentence above is checkable and every one is drawn from a paper this volume has read.

The four-letter alphabet can express none of it.

PART SEVENTY-TWO · THE NINE TISSUES

Part Seventy-Two of the evidence volume, sections 467 to 479

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

A study from Genentech: one mouse, nine tissues, RNA and whole genome sequenced from the same animal, and the most stringent filter in this entire run. It reduces 1,831 candidate sites to a single one that survives correction. And the sites most likely to change a protein turn out to be the least shared between tissues.

467. The Hardest Filter in This Run ↩

What was required of a site

the filter	
coverage	minimum tenfold
support	at least two unique reads carrying the edited variant
quality	base quality scores of twenty-three or higher
read position	variants found solely within ten base pairs of either read end discarded
strand	only events within annotated genes; variants in two genes on opposite strands discarded
homopolymers	excluded
repeat masker	low complexity, simple repeat and satellite elements excluded
mappability	multi-mappability regions excluded
self-chain	excluded
splice boundaries	intronic variants within five base pairs of an exon-intron boundary removed
against the genome	zero genomic reads supporting the edited base
genomic coverage	greater than twentyfold at that site

The last two conditions are the ones that matter. The DNA came from the same animal, and a site was accepted only if not one genomic read out of more than twenty carried the edited base. That is not a statistical filter. It is a demand for absence.

All authors were employees of Genentech at the time. Data are deposited at GSE74747 and ERP010840.

468. One Mouse, Nine Tissues ↩

The design

the animal	an eight-week-old C57BL/6J male mouse from the Jackson Laboratory
tissues	brain, skin, heart, liver, thymus, testis, spleen, lung, kidney
RNA sequencing	100 base-pair paired-end, 28 to 77 million uniquely mapped reads per library
whole genome, from the same mouse	75 base-pair paired-end from brain and spleen — 586 million and 445 million uniquely mapped reads
biological replicates	20 further samples from 15 animals, three published data sets
alignment	GSNAP to mm9; HTSeqGenie; VariantTools

Nine tissues from one individual removes genetic variation between samples entirely. Whatever differs between those nine tissues is not a difference of genome.

---

469. Less Than Five Percent ↩

Where the sites fall

A-to-I sites falling within coding exons	under 5%
sites that would produce a non-synonymous change	159

And the authors note this is surprising: the library preparation used a standard poly-dT protocol, which should enrich for mature messenger RNA whose introns have already been spliced out.

Their explanation is intron retention and recursive splicing — both reported as more common in neural transcripts, and both meaning that brain messenger RNA carries more unspliced sequence than expected.

Set beside the volume's other two counts

Part	the coding fraction
Sixty-Two, ICE-seq, chemical detection	0.33% of 19,791 sites
Sixty-Six, the deamination census in brain	0.073% of all events at the 22 recoding sites

Part	the coding fraction
this Part, hardest computational filter	under 5% in coding exons; 159 non-synonymous

Three studies, three methods, three species-and-tissue combinations, and the coding fraction is small in every one of them. It is the most reproducible number in this literature.

And the brain is not exceptional once introns are removed

The brain sample stood out for the sheer number of sites. When all sites overlapping an intron were discarded, the brain was no longer a strong outlier.

Both sequencing depth and genic context decide what can be detected. The brain's apparent excess of editing was, in substantial part, an excess of intronic sequence in the library.

---

470. The Sharing Runs the Wrong Way ↩

The measurement

A site was called shared if it was an RDD in more than one sample, treating editing as a binary — called or not called — and ignoring the frequency.

what was compared	shared
any two of the nine tissues, all sites	15.5%
all nine tissues, all sites	0.7%
any two tissues, coding-exon sites	19%
all nine tissues, coding-exon sites	2%
across tissues, non-synonymous sites	8%

What that ordering means

Move from all sites to coding sites and sharing rises from 15.5 to 19 percent — which is what a functional interpretation predicts. Move from coding to non-synonymous and it falls to 8.

The sites most likely to change a protein are the least shared between tissues. The functional interpretation predicts the opposite, and the data go the other way.

And between individuals it inverts again

Within seven brain samples from seven different individuals, sharing was much higher than between tissues of one individual — and the proportion rose further for coding and then for non-synonymous sites.

There is more similarity in the editing of brain transcripts from different individuals than from different tissues of the same individual. For the presumed most functionally relevant sites, there are more differences between tissues than between people.

Tissue is a stronger determinant of the editing pattern than genotype is.

---

471. Tissue-specific Editing Is Transcript-specific Expression ↩

The hypothesis they tested first

Two explanations for why editing differs between tissues: either the transcript is not present in the second tissue, or the editing enzymes differ.

In the majority of cases where a difference in editing was observed, the transcript was simply not expressed, or not expressed enough to be detected, in the other tissues. Differential expression of the substrate transcript is a main cause of tissue-specific RNA editing.

Figure 5 shows it directly: 575 sites across nine tissues, with tissues below tenfold coverage shown in a separate color. Most sites edited in only one tissue are simply not expressed elsewhere.

What survives that explanation

A residue does survive it — transcripts expressed in multiple tissues whose editing frequency still varies. Those are the cases the rest of the Part is about, and there are not many.

472. The Funnel — Eighteen Hundred to One ↩

Every stage

stage	sites
at least tenfold coverage in two or more samples, with an RDD called in at least one	1,831
within coding exons	232
predicted non-synonymous	136
with sufficient coverage in more than half the samples	42
correlating with an editing enzyme or isoform	16
surviving multiple-testing correction	1

Eighteen hundred and thirty-one candidate sites reduce to one that survives correction for multiple testing. A reduction of more than eighteen-hundred-fold, and the survivor is a single position in a single gene.

The authors are explicit about the fifteen that did not survive: interesting trends were observed, and the volume records that as they wrote it.

Two shapes of regulation

pattern	what it looks like
binary	editing is on or off; there is likely a threshold of enzyme above which the substrate becomes edited
continuous	editing frequency rises with the expression of the enzyme

Both were observed. Tmem63b and Itgb5 show the binary pattern; Grik2 and Rbbp4 the continuous.

473. Tmem63b ↩

The one site that survived

position	chromosome 17, 45,799,898
the change	glutamine to arginine
where	the fifth coding exon, upstream of the 3′ untranslated region
expression	in all nine tissues
editing	only in brain
frequency in brain	41 to 74 percent
correlation with Adarb1	rho = 0.795, P = 0.000

And the same brain-specific pattern appears in the human gene, in the Illumina Body Map 2 data set.

A transcript present in every tissue examined, edited in exactly one, at up to three-quarters of copies, changing a glutamine to an arginine — and the pattern holds across two species.

Glutamine to arginine is the same substitution as the glutamate receptor Q/R site. The volume records the coincidence of chemistry and makes no claim from it.

The other three named sites

gene	position	correlation	with
Itgb5	chr16:33,865,134	rho = 0.640, P = 0.025	Adar p150
Grik2	chr10:48,964,136	rho = 0.762, P = 0.037	Adar p110
Rbbp4	chr4:129,367,229	rho = 0.482, P = 0.047	Adar p150
Flnb	chr14:8,768,562	—	most edited in brain and heart
Copa	chr1:174,022,479	—	highest at 27% in a heart sample; brain was not highest

Copa is one of very few sites for which brain did not have the highest editing frequency, and the pattern across mouse tissues did not match the human data.

474. The Three Enzymes Across Nine Tissues ↩

Expression

enzyme	where
Adar	highest in brain and spleen; appreciable across multiple tissues
Adarb1	highest in brain; more brain-specific than Adar
Adarb2	exclusively brain, at very low level — and no evidence of editing activity to date

All three below fifty reads per kilobase per million in every sample.

Adarb1 and Adarb2 are nearly exclusive to brain. Adar has the broader distribution. And the third member of the family, brain-only, has never been shown to edit anything.

That is the same ADAR3 the author's 2004 page listed one line above ADAT — Part Sixty-Three.

And the isoform split

isoform	where it dominates
p110 — from the J1 splice junction	brain
p150 — from the J2 junction	non-brain samples

J1 and J2 are mutually exclusive splicing events producing alternate 5′ untranslated regions. The J8 splice tends to co-occur with p150; J9 appears more often with p110.

---

475. The Second Z-alpha Domain ↩

The structural detail this volume must record

Both isoforms contain a Z-alpha DNA-binding domain at the amino terminus.

But the alternative 5′ untranslated region and splice that produce the p150 isoform encode a second Z-alpha domain, upstream of the first. The interferon-inducible isoform carries two left-handed-DNA binding domains where the constitutive isoform carries one.

What that means for Part Fourteen

Part Fourteen of this volume rests on the Z-alpha domain and the left-handed helix. Part Fifty-Nine established that ADAR1 alone among the family carries Z-DNA-binding domains, and that the p150 isoform is the interferon-inducible one.

This adds the count. The immune isoform has twice as many handedness sensors as the housekeeping isoform.

And the authors offer a mechanism: the extra Z-alpha domain could direct the editing enzyme to prefer a subset of nascent transcripts by proximity to a particular DNA sequence that interacts with Z-alpha domains.

A protein that edits RNA, steered to its substrate by binding left-handed DNA. That is proposed rather than shown, and the volume prints it as a proposal.

---

476. The Twenty-Six Amino Acids ↩

The J9 splice

The authors report a correlation between the p110 isoform and an internal, in-frame alternative splicing event they label J9.

what it adds	26 amino acids
where	between the second double-stranded RNA-binding domain and the deamination domain
what it contains	four potential phosphorylation sites

Twenty-six amino acids is seventy-eight nucleotides — divisible by three, which is why it is in frame.

A twenty-six residue insertion between the domain that grips the duplex and the domain that performs the chemistry. It changes the distance between the two, and it carries four sites that could be phosphorylated.

The proposed consequence: altering the relative position of the deamination domain to the bound transcript could change the sequence context of editing events.

Part Sixty-One established that the local concentration of enzyme decides editing. This is a second geometric lever — not how much enzyme is nearby, but how far its catalytic domain sits from the RNA it is holding.

477. Mice Have No Alu ↩

The comparison the study makes possible

RNA editing occurs less frequently in mice than in humans, and the explanation offered is the substrate.

	human	mouse
the repeat family	Alu — primate-specific, one family, highly similar copies	four active SINEs: B1, B2, ID and B4
consequence	abundant inverted pairs forming stable duplexes	higher divergence between families; fewer hairpins
editing level	higher	lower

The mouse has more SINE families and less editing, because four divergent families produce fewer matching inverted pairs than one uniform family does. Similarity, not abundance, is what makes a substrate.

But the distribution is the same

Despite lower levels, a high proportion of mouse editing sites still fall in 3′ untranslated regions. In spleen and thymus the majority of editing occurs within those exons.

The substrate supply differs between the two species. The enzyme's preferences do not. That is a clean separation of what is species-specific from what is not, and it strengthens the Alu argument of Parts Sixty and Sixty-One rather than weakening it.

478. What Is Claimed and What Is Not ↩

Claimed

That the study sequenced RNA from nine tissues and whole genomes from two tissues of a single eight-week-old C57BL/6J male mouse, generating 28 to 77 million uniquely mapped RNA reads per library and 586 and 445 million genomic reads. That a site was accepted only if zero genomic reads supported the edited base at greater than twentyfold genomic coverage, after eleven prior filters.

That under five percent of A-to-I sites fall in coding exons and that 159 would be non-synonymous. That the brain ceased to be an outlier once intronic sites were removed.

That 15.5 percent of sites are shared between any two tissues, 0.7 percent across all nine, 19 and 2 percent for coding sites, and 8 percent for non-synonymous sites — and therefore that non-synonymous sites are less shared across tissues than coding sites generally.

That differential expression of the substrate transcript is a main cause of tissue-specific editing. That 1,831 candidate sites reduced to 232 coding, 136 non-synonymous, 42 with adequate coverage, 16 correlating with an enzyme, and one surviving multiple-testing correction.

That Tmem63b is expressed in all nine tissues, edited only in brain at 41 to 74 percent, produces a glutamine-to-arginine change, and correlates with Adarb1 at rho = 0.795.

That the p150 isoform's alternative 5′ untranslated region encodes a second Z-alpha domain upstream of the first, and that the J9 splice adds 26 in-frame amino acids containing four potential phosphorylation sites between the second double-stranded RNA-binding domain and the deamination domain.

That mice carry four active SINE families rather than one, and that the higher divergence is the offered explanation for lower editing.

Not claimed

That the second Z-alpha domain steers the enzyme. Section 475 states that as the authors' proposal.

That the J9 insertion alters editing specificity. Section 476 states the proposed consequence and labels it proposed.

That the fifteen non-surviving correlations are real. Section 472 records that the authors called them interesting trends and the volume uses the same words.

That the low cross-tissue sharing of non-synonymous sites means those sites are not functional. It means they are not shared. The volume states the measurement and does not draw the inference.

479. What Would Show This Part Is Wrong ↩

— Show that the twelve-stage filter admits sites that are genomic polymorphisms, and the whole study's premise fails — and it is the hardest filter in this volume, so a failure here would implicate every study with a looser one.

— Show that non-synonymous sites are in fact more shared across tissues than coding sites generally, and section 470's inversion is a misreading.

— Show that substrate transcript expression does not account for the majority of tissue-specific editing differences, and section 471's main conclusion fails.

— Show that the p150 5′ untranslated region does not encode a second Z-alpha domain, and section 475 — the finding this volume most wants from this paper — has no basis.

— Show that mouse editing levels match human levels when SINE content is controlled for, and section 477's substrate-supply explanation is not the explanation.

— Recover more than one site surviving multiple-testing correction in a larger cohort. The funnel of section 472 ends at one because forty-two sites is a small number to correct across. A larger study is the obvious test and it has not been reported.

PART SEVENTY-THREE · THE FOUR-STEP ROAD

Part Seventy-Three of the evidence volume, sections 480 to 492

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Rosenthal, Journal of Experimental Biology, 2015 — the emerging role of RNA editing in plasticity. The review states that inosine is a biological mimic for guanosine. The author wrote three lines in the margin disputing it, and drew the real

route from adenine to guanine. Every step of that route has been checked and every step is a named enzyme.

---

480. All True Metazoans ↩

The review's opening claim

All true metazoans modify their RNAs by converting specific adenosine residues to inosine.

The review's framing is that RNA is a well-positioned target for acclimation because it is transient — alterations at the RNA level can be reworked when conditions change, and are relatively safe because they are not permanent.

the review's five themes	
how editing modifies different cellular RNAs	
how frequently different organisms use it to recode messenger RNA	
how specific recoding events regulate protein function	
how it is used in adaptation	
emerging evidence that it is used for acclimation	

The intended audience, in the author's own words: organismal biologists with an interest in adaptation and acclimation, but with little knowledge of RNA editing.

---

481. The Margin Note ↩

What the author wrote on the abstract

Three lines, beside the sentence "because inosine binds to cytosine, it is a biological mimic for guanosine."

$$A \text{ --> } G \qquad \textit{with a question mark} \backslash nA \text{ --> } I \quad \textit{is NOT equal to} \quad G \backslash nA \text{ --> } I \text{ --> } X \text{ --> } G$$

What the first two lines dispute

The review compresses a chemical event into an equivalence: adenosine becomes inosine, inosine pairs like guanosine, therefore treat it as G.

The author's objection is that the equivalence is a reading convention and not a fact about the molecule. Inosine is not guanosine. It lacks the amino group at position two that guanine carries, it forms two hydrogen bonds with cytosine where guanine forms three, and it pairs with uracil and adenine as well — which guanine does not.

Parts Fifty-Seven, Sixty-Four and Sixty-Nine each establish that inosine pairs with three bases and guanine with one. The mimicry is partial and the volume has measured how partial.

And the third line is a claim about metabolism

A to I to X to G is not a statement about pairing. It is a route.

---

482. The Road, Every Step Checked ↩

Three enzymes, four nucleotides, one direction

```
AMP\n|  AMP deaminase  AMP + H2O --> IMP + NH3\nv\nIMP\n|  IMP
dehydrogenase  IMP + NAD+ + H2O --> XMP + NADH + H+\nv\nXMP\n|  GMP
synthetase  XMP + ATP + glutamine --> GMP + AMP + PPi + glutamate\nv\nGMP
```

Each step, named

step	enzyme	standing
A to I	AMP deaminase	the purine nucleotide cycle; deficiency causes exercise intolerance
I to X	IMP dehydrogenase	rate-limiting for guanine nucleotides; the mycophenolate target
X to G	GMP synthetase	the final step of guanine nucleotide synthesis

The road the author drew in the margin is complete, enzymatic, runs in the order he wrote it, and every enzyme on it has a name, an EC number and, in one case, a drug in clinical use.

Part Seventy established two of these three steps as the gates of the purine road. This margin note is the same road, written from the other end — starting at adenine rather than at PRPP.

483. Two Accounts of One Transformation ↩

Set side by side

	RNA editing	purine metabolism
the transformation	A becomes G	A becomes G
steps	one	three
enzymes	ADAR	AMP deaminase, IMP dehydrogenase, GMP synthetase
the route	A to I, read as G	A to I to X to G
the product	inosine. G is an interpretation by the reading machinery	guanine. A different molecule
where	in a transcript, after transcription	in the nucleotide pool, before
reversible?	the transcript is degraded and remade	the nucleotide cycle runs continuously

What the comparison establishes

Both statements are true and they describe different things. The editing literature writes A to G because the ribosome behaves as though the base were G. The metabolic literature writes A to I to X to G because that is what it takes to actually make a guanine.

And the same four symbols appear in both, in the same order.

The volume records this as a coincidence of notation rather than a mechanism, and notes what makes it more than trivial: the two extra symbols in that sequence — I and X — are precisely the two the four-letter alphabet omits, in both accounts.

484. Where the Two Accounts Meet ↩

One place, and this volume already found it

Part Seventy-One established that the ITP/XTPase hydrolyzes inosine and xanthine triphosphates back to their monophosphates — returning them to IMP and XMP, which are two of the four stations on the road above.

So the editing world's product, if it ever reaches the free triphosphate pool, is captured by an enzyme that puts it back on the metabolic road at exactly the station the author's margin note names.

That is the junction between the two accounts, and it is an enzyme with a thirteen thousand-fold specificity for the two symbols in question.

---

485. What ADAR Does Besides Recode Codons ↩

The review's wider claim

Under a looser definition of RNA editing that includes adenosine-to-inosine changes in all RNA molecules, ADARs regulate diverse cellular systems.

the classes affected	
retrotransposons	retrotransposon defense
microRNA	processing and targeting
immunity	viral defense, regulation of innate immunity
messenger RNA	recoding, stability, splicing

Besides transfer RNAs and ribosomal RNAs, virtually all types of cellular RNAs — and some extracellular ones — are regulated by editing.

Four separate cellular systems, and codon recoding is one item on the list rather than the heading. Part Sixty-Six measured how small that item is: seven hundredths of one percent.

---

486. The Microrna Arm ↩

How one edit changes a silencing pathway

stage	what an edit does
the primary transcript	editing can interfere with processing by Drosha
the precursor	editing can interfere with processing by Dicer
a microRNA carrying multiple inosines	is targeted for degradation by specific ribonucleases
direct ADAR-Dicer interaction	can augment processing efficiency
the seed region	editing influences target recognition, and in some cases redirects the silencing complex to an entirely different messenger RNA
the processing machinery itself	ADAR regulates expression of its elements

The first evidence, and where it came from

Genetic studies in Caenorhabditis elegans first linked ADARs to the RNA interference pathway. ADAR knockouts caused chemotaxis defects — and the wild-type phenotype could be restored by further knocking out elements of the interference pathway.

A behavioral defect caused by removing an editing enzyme, and cured by removing a second enzyme. The two pathways are wired against each other.

Part Sixty-Two measured the same thing quantitatively in human brain: 6,467 microRNA-response pairs in 847 genes carrying a single seed edit, 2,963 stabilizing and 3,504 destabilizing. This review supplies the mechanism behind those numbers.

487. The Viral Arm, Which Runs Both Ways ↩

What is edited

Any virus whose chromosome exists as a double-stranded RNA during infection can potentially be edited, and many do undergo editing on entering a cell.

named	
HIV-1 · Epstein-Barr virus · herpes virus 8	

named	
dengue virus · hepatitis C virus	
influenza A virus · measles virus	

And the direction is not fixed

In some cases editing appears to combat infectivity and in others it promotes it. When antiviral, editing is thought to interfere with the virus's ability to replicate. When proviral, it is thought to down-regulate players in the innate immune response — such as the interferon-inducible, double-stranded-RNA-activated protein kinase R.

Part Sixty recorded the same duality from the ADAR1 side: indiscriminate editing reduces lymphocytic choriomeningitis virus infectivity, while editing of HIV rev and tat increases it, and the HIV Tat protein itself promotes editing of a specific adenosine.

Two Parts, two literatures, the same conclusion: the editor is a weapon either side can pick up.

---

488. Why RNA and Not DNA ↩

The review's central argument for plasticity

RNA is a well-positioned target for acclimation because it is transient.

	DNA	RNA
permanence	permanent	transient
reworkable when conditions change	no	yes
risk of a change	high — it is inherited	low — it is not

Changes to RNA are relatively safe because they are not permanent. That is the whole argument for why an organism would evolve a mechanism to rewrite its transcripts rather than its genome.

And it answers a question the volume has been circling

Part Sixty-Seven recorded the field's own puzzlement: several ionotropic glutamate receptor transcripts are edited at essentially 100 percent frequency, which begs the question of why those sites are not simply changed in the genome.

The answer this review gives is that a genomic change is permanent and an edit is not. A site edited at 100 percent today can be edited at 60 percent tomorrow. The genome cannot do that.

A four-letter sequence describes a fixed state. Editing describes a settable one, and the setting is what the organism adjusts.

---

489. What This Adds to Part Seventy ↩

The two roads, now written from both ends

Part Seventy built the purine road forward, from PRPP to the letters, and identified two gates — inosine monophosphate and xanthosine monophosphate — that everything passes through and nothing retains.

The margin note of section 481 writes the same road backward, from a letter to a letter, and finds the same two gates standing in between.

Whichever end you start from, adenine and guanine are separated by inosine and xanthine. The alphabet writes the two ends and omits the two stations, and it does so in the metabolic account and in the editing account alike.

And it sharpens the volume's claim about the notation

The four-letter alphabet can write A and it can write G. It cannot write the road between them.

In metabolism that road is three enzymes long. In editing it is one enzyme long and stops halfway, at inosine, which is then read as though it had arrived.

The notation records departures and destinations. The volume's whole argument is about what is on the road.

---

490. What Is Claimed and What Is Not ↩

Claimed

That the review states all true metazoans convert specific adenosine residues to inosine, that inosine binds cytosine and is therefore called a biological mimic for guanosine, and that RNA is a target for acclimation because it is transient.

That the author wrote three lines in the margin of the abstract: A to G with a question mark, A to I not equal to G, and A to I to X to G.

That the route A to I to X to G is real and enzymatic, comprising AMP deaminase, IMP dehydrogenase and GMP synthetase, in that order — verified step by step, with reactions and cofactors named.

That inosine is not guanosine: it lacks the two-position amino group, forms two hydrogen bonds with cytosine against guanine's three, and pairs with uracil and adenine as well.

That the review reports ADAR regulating retrotransposons, microRNA processing and targeting, viral defense and innate immunity, and messenger RNA recoding, stability and splicing. That ADAR knockouts in C. elegans cause chemotaxis defects reversible by further knockouts in the interference pathway. That HIV-1, Epstein-Barr virus, herpes virus 8, dengue, hepatitis C, influenza A and measles virus are all edited, and that editing is antiviral in some cases and proviral in others.

Not claimed

That the coincidence between the editing sequence and the metabolic sequence is a mechanism. Section 483 states plainly that it is a coincidence of notation, and gives the one reason it is worth recording.

That the review is wrong to call inosine a mimic. It is a mimic, in the specific sense that it pairs with cytosine and is read as G. The author's objection is to treating a partial mimicry as an identity, and the volume states it that way.

That RNA editing evolved for acclimation. The review presents that as an emerging argument and this Part records it as one.

491. What Would Show This Part Is Wrong ↩

— Show that any step of A to I to X to G lacks a characterized enzyme, and section 482 — the verification of the margin note — fails. All three are named with reactions and one has a clinical inhibitor, so the condition is printed because it cannot be met.

— Show that inosine forms three hydrogen bonds with cytosine, and the objection of section 481 to treating the mimicry as identity loses its chemical basis.

— Show that AMP deaminase does not act in the direction stated, and the first step of the road runs backward.

— Show that a metazoan lineage exists which performs no adenosine-to-inosine editing, and the review's opening universal claim is not universal.

— Show that editing of viral genomes is uniformly antiviral, and section 487's duality — and Part Sixty's — is a misreading of both literatures.

---

492. What the Last Two Parts Establish Together ↩

From two directions

Part Seventy-Two took the hardest computational filter yet applied, ran it across nine tissues of one animal, and found that under five percent of editing lands in coding sequence, that non-synonymous sites are the least shared between tissues, that substrate expression is the main determinant of where editing appears, and that eighteen hundred candidate sites reduce to one that survives correction.

Part Seventy-Three took a review written for organismal biologists, and a three-line margin note written on its abstract, and established that the route from adenine to guanine is three enzymes long, that inosine is not guanine, and that the two stations between them are the two symbols the alphabet omits.

The single sentence they support

A four-letter notation can name where a transformation starts and where it ends.

It cannot name the two molecules in between, it cannot say which of them is a gate and which is a poison, it cannot record that a base is

present in forty-one percent of copies in one tissue and none in another, and it cannot distinguish a mimic from the thing it mimics.

All four of those are measurable, and this volume has now measured them.

PART SEVENTY-FOUR · THE ORIGIN

Part Seventy-Four of the evidence volume, sections 493 to 505

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Meijer, Beck, Hansen, Bergmans, Messer, von Meyenburg and Schaller, Proceedings of the National Academy of Sciences, 1979. The first origin of replication of a cellular organism ever sequenced. Four hundred and twenty-two base pairs, built preferentially from the pair with fewer hydrogen bonds, carrying twenty-four inverted repeats, and spelling almost no protein at all.

---

493. The First Cellular Origin Ever Sequenced ↩

What was new in 1979

Previously determined nucleotide sequences of replication origins had all been from phages. This was the first from a cellular organism.

The method was Maxam and Gilbert chemical sequencing — the technique published two years earlier, in which the DNA is cleaved base-specifically and the fragments read off a gel.

This paper is where the four letters were first written down for the place a chromosome begins to copy itself. It is a foundational document of the notation this volume is about.

The object

the organism	**Escherichia coli K-12**
where on the map	82.5 minutes, between the uncB and asn genes
the vehicle	minichromosomes — plasmids carrying only chromosomal DNA, copy number twenty or more per chromosome equivalent

the organism	Escherichia coli K-12
the plasmid	pCM959, molecular weight 2,650,000, 4.0 kilobase pairs

494. What Was Located, and How Precisely ↩

The boundaries

the segment	422 base pairs, flanked by a BamHI site at position 1 and an XhoI site at position 422
total sequence reported	519 base pairs
determined from both strands	positions 39 to 333 — 295 bases, no mistakes
determined from one strand only	−51 to +38, and 334 to 470 — may contain 1 to 2 percent mistakes

Fifty-seven percent of the reported sequence was read twice. The rest was read once and the paper says so.

And the core

Deletion analysis of nineteen constructs showed that no clone survived in which the chromosomal context at the BamHI site at position 92 or the HindIII site at position 249 had been disrupted.

at least 158 base pairs positions 92 to 249\nat most 422 base pairs positions 1 to 422

A 2.7-fold uncertainty in the size of the thing itself. The paper states both bounds and declines to choose, which is the correct behavior and not a common one.

Two plasmids derived by entirely different routes from two different transducing phages gave identical sequences over the region where both were read.

495. The Origin Is Built from the Weaker Pair ↩

The composition

GC content of the 422-base-pair origin	42 percent
therefore A-T content	58 percent
extended GC-rich regions	none

The four A-T blocks

positions	length	A-T content
10 to 35	26 bp	89%
101 to 123	23 bp	74%
198 to 223	26 bp	72%
286 to 307	22 bp	86%

Ninety-seven base pairs — twenty-three percent of the origin — sit in blocks running from seventy-two to eighty-nine percent A-T.

Why that matters to this volume

Part Seventy established the hydrogen-bond count: guanine with cytosine forms three hydrogen bonds, adenine with thymine forms two.

Replication begins by pulling the two strands apart. And the place where a chromosome pulls itself apart is built preferentially out of the pair that holds with two bonds rather than three. The origin of replication is the weakest place in the molecule, by construction.

And the paper notes the arrangement is not uniform: in some cases blocks of a few G-C pairs sit adjacent to blocks of A-T — at positions 100, 185, 308 and 400.

Strong clamps flanking weak openings. The volume records that shape and offers no mechanism beyond the bond count.

---

496. The Origin Is Almost Not a Gene ↩

What the authors found when they looked for reading frames

"Most of the origin segment is probably not translated into proteins."

initiation codons with no in-frame termination codon	**one, at position 361**
potential ribosome-binding site	positions 345 to 356
longest possible polypeptide in any other frame	49 amino acids

Forty-nine amino acids is one hundred and forty-seven nucleotides — thirty-five percent of the segment, and that is the longest possible, not an observed protein.

The statement this supports

The first origin of replication ever sequenced in a cellular organism is a stretch of DNA that does not spell a protein. Its four letters are not a message. They are a shape and a melting temperature.

This volume has argued from Part One that the notation records what it was built to record. Here is a functional, essential, four-hundred-base stretch of a chromosome whose entire function is invisible to the reading the notation was built for.

And the field knew it in 1979. The sentence is in the paper.

---

497. Twenty-Four Inverted Repeats, and an Axis ↩

What the sequence figure carries

Figure 3 of the paper marks inverted repeats with numbered arrows. There are twenty-four numbered pairs across 519 bases.

The authors describe the origin as "characterized by a high degree of repetitiveness," and they include in the figure inverted repeats that are probably too distant for successful folding of the single strands into secondary structure.

And two blocks of direct repeats

Beyond the inverted repeats, two extended stretches of direct — though not perfectly matching — repeats.

These repeated sequences are arranged approximately symmetrically around the HindIII site at position 244. The homology is interrupted

at several sites by inserted sequences, two of which themselves contain inverted repeats.

The authors' own reading

"The high degree of symmetry, direct and inverted repeats, in this DNA segment is indicative of the presence of several similar sequences which may represent repetitive sites for interaction with proteins involved in the initiation of replication."

That is Part Sixty-One's argument — repeated sequence as a recruitment platform for a protein — stated for DNA in 1979, thirty-five years before it was stated for RNA and Alu.

The volume records the parallel and claims nothing from it. Repeats attract proteins. It is not a surprising principle. What is worth recording is how early it was written down.

---

498. The Lambda Homology, Twice and Antiparallel ↩

Where it sits

Portions of the origin show homology with the replication origin of phage lambda. That region of homology is present twice.

occurrence	strand	base pairs	span
first	upper, reading 5′ to 3′	160 to 258	99 bases
second	complementary, reading 3′ to 5′	430 to 326	105 bases

The same homologous sequence, twice, on opposite strands, oriented in an antiparallel way, and arranged roughly symmetrically around the central part of the origin.

And the same region matches a phage primer site

The homologous segment is the same region in which the lambda replication origin — and thus also oriC — shows homology to the origin of complementary strand synthesis in phage G4.

No homologies were found with the replication origins of ColE1 plasmids, phage fd, or phage φX174.

499. Two Primase Sites ↩

The speculation the authors offer

Sequence homology between the G4 and lambda replication origins has been taken to indicate recognition sites for identical or homologous initiation factors — in that case for primase, the

By extension, the authors write, it is tempting to speculate that there are two primase interaction sites in the E. coli replication origin, implying that the dnaG gene product is responsible for origin-RNA synthesis.

And they immediately qualify it: the involvement of RNA polymerase in the initiation of replication may be an indirect one — for example through transcriptional activation, as suggested for lambda.

The experimental support they do have

Replication of oriC plasmids ceases rapidly after inhibition of transcription by rifampicin, or after a shift to nonpermissive temperature in dnaC and dnaA mutants.

The origin depends on functional RNA polymerase. DNA replication begins with an RNA. That is established here by drug and by mutant, and it is worth stating plainly: the copying of DNA starts with the synthesis of the other nucleic acid.

500. Thirty-Five Years, No Change ↩

The stability measurement hidden in the methods

The accompanying paper sequenced the same region from a different line of E. coli K-12.

the two lines	W208 and W3110
separate since	at least 1944
the sequences across the origin	identical

Thirty-five years of independent laboratory culture, in two laboratories, and not one base differs across four hundred and twenty-two positions.

A stretch of DNA that spells almost no protein, whose function is a shape and a melting temperature, held to the letter across thirty-five years of separation. That is what strong selection on a non-coding sequence looks like.

---

501. What the Paper Could Not Settle ↩

Printed because the paper prints it

"The precise limits of the DNA segment comprising oriC have not yet been established."

open at the time of writing	
whether positions 1 to 92 form part of the origin	not established
whether positions 249 to 422 form part of the origin	not established
whether the two primase sites are real	speculation, and labeled as such
whether RNA polymerase acts directly or indirectly	may be indirect

A paper reporting the first cellular replication origin ever sequenced states in its discussion that it does not know where the thing begins or ends within a factor of nearly three. The volume records that as good practice and notes it is the same practice this volume follows.

---

502. What This Volume Takes from It ↩

Three things, and only three

First. The origin is A-T rich, with four blocks running to eighty-nine percent, and no GC-rich region anywhere. The place a chromosome opens is built from the pair with two hydrogen bonds rather than three. That is Part Seventy's descent, applied to a location rather than to a biosynthetic order.

Second. The origin is not a gene. One initiation codon without a stop, and a longest possible polypeptide of forty-nine residues. The four letters here specify a physical property, not a message, and the paper says so in 1979.

Third. Twenty-four inverted repeats and two blocks of direct repeats, symmetric about one restriction site, read by the authors as protein interaction sites. Repetition as a recruitment platform, in DNA, decades before the same argument was made for Alu in RNA.

And one thing it does not take

The volume does not claim that oriC's A-T richness supports any thesis about sulfur. It supports a thesis about hydrogen bonding, which Part Seventy states and which this Part confirms in an independent system.

---

503. What Is Claimed and What Is Not ↩

Claimed

That oriC was located within 422 base pairs between a BamHI site at position 1 and an XhoI site at position 422, that 519 base pairs were reported, that positions 39 to 333 were determined from both strands with no mistakes and the remainder from one strand with a stated 1 to 2 percent error rate.

That deletion analysis of nineteen constructs bounded the functional core between positions 92 and 249 — 158 base pairs — and that the paper states the origin is at least 158 and at most 422 base pairs.

That the GC content of the segment is 42 percent, that four A-T rich blocks run at 89, 74, 72 and 86 percent at positions 10-35, 101-123, 198-223 and 286-307, and that no extended GC-rich regions exist in the segment.

That the paper states most of the origin is probably not translated, that there is one initiation codon without an in-frame termination codon at position 361, and that the longest possible polypeptide is 49 amino acids.

That twenty-four inverted repeats are marked, that two blocks of direct repeats are arranged approximately symmetrically about the HindIII site at position 244, and that the authors read these as possible protein interaction sites.

That the lambda homology occurs twice, at upper-strand 160-258 and complementary-strand 430-326, oriented antiparallel and roughly symmetric about the center; that the same region is homologous to the G4 origin; and that no homology was found with ColE1, fd or φX174.

That oriC plasmid replication ceases after rifampicin or a temperature shift in dnaC and dnaA mutants, and that two K-12 lines separate since at least 1944 gave identical sequences.

Not claimed

That there are two primase interaction sites. The authors call it tempting to speculate and the volume uses their words.

That the A-T richness of oriC was selected for melting temperature. It is a composition, and the inference to function is the obvious one and is not demonstrated in this paper.

That the repeat-as-recruitment-platform parallel between oriC and Alu is more than a parallel. Section 497 states it as a parallel.

---

504. What Would Show This Part Is Wrong ↩

— Show that the origin region is not A-T rich relative to the genome average, and section 508's central observation fails.

— Show an essential protein coded within positions 1 to 422, and section 496's claim that the origin is not a gene is wrong.

— Show that deletions crossing position 92 or position 249 yield functional origins, and the 158-base-pair core of section 494 is not a core.

— Show that the lambda homology occurs once rather than twice, and section 498's antiparallel symmetry has no exhibit.

— Show that the W208 and W3110 origin sequences differ, and section 500's stability measurement is wrong.

505. The Sentence from 1979 ↩

Recorded because of when it was written

Nine words, in the discussion of a paper published in February 1979:

"Most of the origin segment is probably not translated into proteins."

The four-letter alphabet was two years old as a readable technology when that sentence was printed. The first cellular sequence anyone obtained with it, at the place where a chromosome begins, turned out to be a stretch that the alphabet's primary use — reading codons — could not account for.

The volume's argument is that a notation determines what gets counted. This paper is where that problem was first met in a cellular genome, and the authors met it honestly: they printed the composition, printed the repeats, printed the symmetry, and said the segment probably does not code for anything.

PART SEVENTY-FIVE · THE MODIFIED RIBOSOME

Part Seventy-Five of the evidence volume, sections 506 to 518

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Tran, Brown and Maxwell, Trends in Biochemical Sciences, 2004. The machine that reads the four-letter code carries about two hundred chemically modified nucleotides, and the alphabet writes none of them. One class of modification is a methyl from a sulfonium. The other is a base turned around in its own backbone.

506. Two Hundred Modified Nucleotides in the Machine That Reads the Code ↩

The count

modification	number in mature vertebrate ribosomal RNA
2′-O-methylated nucleotides	about one hundred
pseudouridylated nucleotides	about one hundred
together	about two hundred

The ribosome is the apparatus that reads the genetic code. It carries roughly two hundred nucleotides that have been chemically altered after transcription, and the four-letter alphabet has a symbol for none of them.

Each modification is installed by a dedicated guide RNA — a small nucleolar RNA in eukaryotes, a small RNA in archaea — that base-pairs with the target and positions an enzyme over it.

The eukaryotic nucleolus holds numerous of these guides, with predictions of a full complement numbering several hundred. They have become one of the largest classes of small stable RNA in the eukaryotic cell.

507. Two Classes of Guide ↩

What each does

class	the reaction it guides	the enzyme
box C/D	2′-O-methylation — a methyl onto the ribose oxygen	Fibrillarin, a methylase
box H/ACA	pseudouridylation — uridine to pseudouridine	Cbf5p, or dyskerin in humans, a pseudouridine synthase

And both are present in archaea

Archaea use the same two classes, called sRNAs rather than snoRNAs. The presence of both in a second domain of life, distinct from eukarya, strongly suggests that the use of guide RNAs for nucleotide modification is an evolutionarily ancient mechanism.

	archaea	eukarya
box C/D core proteins	three — L7, Nop56/58p, Fibrillarin	four — 15.5kD, Nop56p, Nop58p, Fibrillarin
distribution on the RNA	symmetric	asymmetric
box H/ACA core proteins	four	four

The eukaryotic asymmetry arose by gene duplication — a single archaeal Nop56/58p became two separate eukaryotic proteins, Nop56p and Nop58p, which then specialized.

---

508. The N Plus Five Rule ↩

The counting rule that places the methyl

The guide RNA base-pairs with the target. The nucleotide that gets methylated is fixed by position, not by identity.

the fifth nucleotide of the target RNA\nupstream of box D\nand within the guide-target duplex\nis the one that is modified

A counting rule, in a nucleic acid, that specifies a chemical operation five positions from a landmark. The sequence of the guide decides which target it finds. The arithmetic decides which atom gets the methyl.

Many box C/D RNAs carry two such motifs — the terminal C and D boxes and the internal C′ and D′ boxes — and can therefore guide two methylations from one molecule.

---

509. The Methyl Comes from a Sulfonium ↩

What Fibrillarin is doing

2′-O-methylation places a methyl group on the 2′ hydroxyl of the ribose sugar.

Every biological methyl transfer of this kind takes its methyl from S-adenosylmethionine — a sulfonium, and the volume's molecule since Part Forty-Five.

What that means here

About one hundred positions in vertebrate ribosomal RNA carry a methyl group delivered from a sulfur.

the volume's prior encounters with this donor	
Part Forty-Five	the sulfonium as the methyl donor of the amino acid panel
Part Fifty-Nine	snoRNA HBII-52 blocking ADAR editing by 2′-O-methylation
Part Sixty-Two	METTL6 and METTL10, methyltransferases, edited by ADAR
Part Sixty-Four	m^1I37 — the deaminase acts first, the methyltransferase second
Part Sixty-Five	DNMT1, carrying an Alu-derived peptide
this Part	about one hundred 2′-O-methyls on the ribosome itself

Six Parts, six systems, one donor. The methyl that decorates the ribosome, the methyl that blocks the editor, and the methyl that marks DNA all come off the same sulfur.

And the 2′-O position is worth naming

Part Forty-Seven established that the whole chemical difference between RNA and DNA is the presence or absence of an oxygen at the 2′ position, and that ribonucleotide reductase — the only sulfur system on the nucleotide panel — exists to remove it.

2′-O-methylation caps that same oxygen with a methyl from a sulfur.

The 2′ position is where a sulfur enzyme removes an oxygen to make DNA, and where a sulfur donor decorates the same oxygen to tune the ribosome. One carbon, two sulfur operations, and the alphabet writes neither.

510. Pseudouridine Is Not a Substitution ↩

What the other hundred modifications are

Pseudouridine is uridine with the base rotated. The link to the sugar moves from the ring nitrogen to a ring carbon — a carbon-carbon glycosidic bond in place of the usual carbon-nitrogen one.

	uridine	pseudouridine
formula	identical	identical
molecular weight	identical	identical
the bond to the sugar	N-glycosidic	C-glycosidic
extra hydrogen-bond donor	no	yes — the freed ring nitrogen

Pseudouridine is an isomer, not a substitution. Nothing is added and nothing is removed. The base is turned around. And a four-letter notation, which records identity, cannot express a rotation.

The guide places an unpaired uridine in a pocket within the guide-target duplex, and the synthase converts it.

511. One Protein, Three Jobs ↩

Archaeal ribosomal protein L7

where L7 works	as what
the ribosome large subunit	a structural protein
the box C/D methylation guide complex	a core protein
the box H/ACA pseudouridylation guide complex	a core protein — the functional homolog of eukaryotic Nhp2p

The same protein is a component of the ribosome and a component of both machines that modify the ribosome. That is the observation from which the whole evolutionary argument of this paper is built.

Why it matters

The fact that this common core element is also found in ribosomes suggests that the origin of the progenitor guide complex lies in the primitive translation apparatus.

The L7 family extends further: it includes the ribosomal proteins L30, L4 and S12, and the snoRNP proteins Snu13p and Nhp2p — one family, spanning the ribosome and both modification machines.

---

512. The Kink-turn Predates the Last Common Ancestor ↩

The motif

The kink-turn, or K-turn, is an RNA secondary structure motif consisting of two stems flanking an internal loop that bends the helix sharply. It is what L7 and its eukaryotic homologs bind.

The dating argument

K-turns have now been found in bacterial RNAs, including ribosomal RNA.

Since bacteria lack the guide RNA system entirely, the presence of K-turns in bacterial rRNA makes it plausible that this fundamental RNA motif was present in the translation apparatus of organisms before the last common ancestor.

And the motif is not rigid. In the archaeal 50S subunit, one variant uses a base triple for folding while another requires three separate RNA strands. The K-turn shows great variation in folded structure.

What bacteria do instead

	bacteria	archaea and eukarya
how rRNA is modified	specific protein enzymes, one per site	RNA-guided complexes, one guide per site
number of modified rRNA nucleotides	limited	greater — more 2′-O-methyls and pseudouridines

A protein enzyme must be evolved for each site. A guide RNA needs only a new complementary sequence. The archaeal and eukaryotic route is cheaper per site, and they have more sites.

And thermophilic archaea have higher numbers of modified nucleotides than mesophiles — consistent with a need to stabilize ribosomal RNA in extreme environments.

513. Moonlighting ↩

Core proteins doing second jobs

protein	first job	second job
15.5kD / Snu13p	core protein of the box C/D methylation guide	structural protein of the U4 splicing complex
ribosomal protein L30	structural protein of the ribosome	binds K-turns in 25S rRNA and in its own pre-messenger RNA, regulating its own splicing
61K protein of U4	splicing	shares significant sequence similarity with the box C/D core proteins

L30 is the striking one. A ribosomal protein that binds a bend in RNA, and that uses the same binding to recognize a bend in its own transcript, so controlling how much of itself gets made.

A protein regulating its own production by binding a shape in its own messenger RNA. The shape is not in the sequence in any way the four letters express — it is a fold.

514. The snoRNA That Blocks the Editor ↩

The connection to Part Fifty-Nine

Part Fifty-Nine recorded, from the 2016 review, that the small nucleolar RNA HBII-52 blocks adenosine deamination by 2′-O-methylation — a methyl, from a sulfonium, preventing an edit.

the review states	
snoRNA species expressed in a tissue-specific manner in the brain	

the review states	
one such species shows complementarity to serotonin receptor messenger RNA	
and has been suggested to regulate messenger RNA maturation	
brain-specific and imprinted	

A brain-specific, imprinted guide RNA, complementary to a serotonin receptor transcript, placing a methyl that prevents an inosine from being installed. Part Fifty-Nine had the mechanism. This is where it sits in the taxonomy — and the taxonomy is a class of RNA whose other several hundred members decorate the ribosome.

Part Sixty-Seven recorded that in Alzheimer's hippocampus the unedited form of the serotonin 2C receptor rises from 45 to 58 percent. The same receptor, in the same tissue, appears in three Parts of this volume through three different modification systems.

---

515. The Pseudouridine Synthases, and the One ADAR Edits ↩

The family relationship

Cbf5p, the pseudouridine synthase of the box H/ACA complex, is related to the bacterial transfer RNA pseudouridine synthase TruB.

enzyme	substrate
Pus4p	transfer RNA
Cbf5p	ribosomal RNA

One ancestral enzyme, one duplication, two substrates. And the volume has already met a third member of the family.

Part Sixty-Two found PUS1 — a pseudouridine synthase — carrying three adenosine-to-inosine edits in its own coding sequence.

The enzyme that installs one RNA modification is itself modified by the enzyme that installs another. Two modification systems, writing on each other.

---

516. Intronic Guides and Retroposons ↩

Where the guide RNA genes live

Most snoRNA genes in metazoans — particularly in animals — are encoded in the introns of protein-coding genes, and are processed out of the pre-messenger RNA introns.

And how they may have got there

The identification of a box H/ACA pseudogene possessing a poly-A tail suggests that intronic snoRNAs might be a consequence of retroposon events.

A guide RNA reverse-transcribed and reinserted into an intron. That is the same mechanism that placed a million Alu elements in the primate genome — Parts Sixty and Sixty-One.

And the questions the authors leave open

"What insertion mechanism has resulted in the intronic snoRNAs becoming predominantly positioned in pre-messenger RNA introns of proteins that function in the ribosome or protein biosynthetic pathway? Does this biased positioning have a role in coordinating messenger RNA synthesis with ribosome biogenesis?"

The guides that decorate the ribosome are preferentially hidden inside the introns of genes that build the ribosome. The authors state the observation and ask whether it is coordination. Nobody has answered.

---

517. What Is Claimed and What Is Not ↩

Claimed

That mature vertebrate ribosomal RNAs carry about one hundred 2′-O-methylated and about one hundred pseudouridylated nucleotides. That box C/D guide RNAs direct 2′-O-methylation through the methylase Fibrillarin and box H/ACA guides direct pseudouridylation through Cbf5p or dyskerin.

That box C/D methylation follows the N+5 rule — the fifth nucleotide upstream of box D within the guide duplex. That archaeal box C/D complexes carry three core proteins symmetrically and eukaryotic complexes four asymmetrically, and that the difference arose by duplication of Nop56/58p.

That archaeal ribosomal protein L7 is a structural protein of the ribosome large subunit and a core protein of both the box C/D and box H/ACA guide complexes, being the functional homolog of eukaryotic Nhp2p. That the L7 family includes ribosomal proteins L30, L4 and S12.

That K-turns occur in bacterial RNAs including ribosomal RNA, and that the authors state this makes it plausible the motif was present before the last common ancestor. That bacteria modify rRNA with specific protein enzymes and have fewer modified nucleotides, and that thermophilic archaea have more.

That the 15.5kD protein is also a structural protein of the U4 splicing complex, and that ribosomal protein L30 binds K-turns in 25S rRNA and in its own pre-messenger RNA. That Cbf5p is related to bacterial TruB and that duplication produced Pus4p for transfer RNA and Cbf5p for ribosomal RNA. That most metazoan snoRNA genes are intronic and that a poly-adenylated box H/ACA pseudogene suggests a retroposon origin.

Not claimed

That the guide complexes definitely originated in the primitive translation apparatus. The paper's title ends in a question mark and the volume keeps it.

That the shared L7 core proves a single progenitor complex. The authors call it reasonable to suggest, and the volume uses their words.

That the sulfonium connection of section 509 is a finding of this paper. It is not. The paper does not mention S-adenosylmethionine. The identification of the methyl donor is the volume's, and it is chemistry so standard that it is a statement rather than a claim.

That the intronic positioning of guides in ribosome-related genes is coordination. Section 516 quotes the authors asking, and records that nobody has answered.

518. What Would Show This Part Is Wrong ↩

— Show that vertebrate ribosomal RNA carries substantially fewer than one hundred of either modification, and the headline count of section 506 is wrong.

— Show that 2′-O-methylation of ribosomal RNA uses a methyl donor other than S-adenosylmethionine, and section 509's six-Part convergence loses this member.

— Show that archaeal L7 is not a core protein of both guide classes, and section 511 — the observation the paper's whole argument rests on — fails.

— Show that K-turns are absent from bacterial ribosomal RNA, and the dating argument of section 512 has no basis.

— Show that pseudouridine differs from uridine in molecular formula, and section 510's claim that it is an isomer rather than a substitution is wrong. It cannot be shown; the condition is printed because it is the point.

— Count the modified nucleotides of the ribosome against the four letters, in any published ribosome structure. Two hundred modifications and four symbols is the whole of this Part in one arithmetic, and it has never been printed that way.

PART SEVENTY-SIX · THE THREE-DOMAIN CENSUS

Part Seventy-Six of the evidence volume, sections 519 to 531

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Tan and Tomkins, Answers Research Journal, 2015. A twenty-one page molecular census of DNA replication, transcription and translation across bacteria, archaea and eukarya. The volume takes the census. It does not take the conclusion, and it says so in the same Part.

519. What the Paper Is, and How the Volume Will Use It ↩

Stated at the front, not buried

This paper was published in the Answers Research Journal, a creationist journal, and it argues for design and against a prokaryote-to-eukaryote transition. Its concluding sentence says the molecules are "crying out loudly that eukarya did not evolve from archaea."

What the volume carries is the census — which is compiled from the mainstream primary literature, cited paper by paper, and is largely checkable against those sources. Table 2 alone draws on El Yacoubi, Grosjean, Jackman and Alfonzo, Phillips and de Crécy-Lagard, and the genomic tRNA database at UCSC.

Why the volume prints the ruling in the same section

The volume's falsification rule, stated in Part Sixty-Three and applied to the author's own strongest claim in Part Seventy, is that a claim which cannot be shown wrong does not go in.

A design inference over a molecular census cannot be falsified by counting molecules. The counts themselves can be — every one of them, by going to the databases.

So the volume takes the counts, marks their provenance, and declines the inference. That is the same treatment the author gave his own conspiracy claim in Part Seventy, and it is applied here for the same reason.

What follows is what the census contains that this volume did not already have.

---

520. The Molecular Census: Three Domains, Not Two ↩

The trait table, reproduced

trait	bacteria	archaea	eukarya
carbon linkage of lipids	ester	ether	ester
phosphate backbone of lipids	glycerol-3-phosphate	glycerol-1-phosphate	glycerol-3-phosphate
metabolism	bacterial	bacterial-like	eukaryotic
nucleus	no	no	yes
organelles	no	no	yes

trait	bacteria	archaea	eukarya
spliceosomal introns	no	no	yes
telomeres	no	no	yes
chromosome shape	mostly circular	circular	linear
DNA replication	bacterial	eukaryotic-like	eukaryotic
transcription	bacterial	eukaryotic-like	eukaryotic
translation	bacterial	eukaryotic-like	eukaryotic

The two rows that matter to this volume

The lipid rows are the ones nobody argues about. Archaea build their membranes on ether linkages and glycerol-1-phosphate; bacteria and eukarya both use ester and glycerol-3-phosphate.

Glycerol-1-phosphate and glycerol-3-phosphate are the same molecule at opposite handedness. The domain that sits in the middle on information processing sits on the mirror image on membrane chemistry. The volume records the chirality split and takes nothing further from it.

---

521. Sulfur at the Wobble Position, Printed as a Table ↩

What Table 2 and Figure 8 carry

Part Sixty-Nine established the wobble position — base 34 of the anticodon — and established that a sulfur there restricts reading while an inosine expands it. This paper prints the domain-by-domain table.

amino acid	codon	anticodon	bacteria	archaea	eukaryotes
Glu	GAA	UUC	ynm^{5}s^{2}U	?U	zcm^{5}s^{2}U
Gln	CAA	UUG	ynm^{5}s^{2}U	?U	zcm^{5}s^{2}U
Lys	AAA	UUU	ynm^{5}s^{2}U	?U	zcm^{5}s^{2}U

Three amino acids, two domains, and a sulfur at position 2 of the uracil ring in every one.

And the figure draws the swap explicitly

Figure 8, panels G and H, draw the modified U_{34} structure. In both panels the ring position carries the annotation:

$$s^2U \qquad S <> O$$

The sulfur and the oxygen are drawn at the same ring position with a double-headed arrow between them. In a 2015 review of tRNA modification, in a figure adapted from Grosjean, the sulfur-for-oxygen substitution at the wobble base is printed as an interchange.

That is Part Thirty-Eight's conjugate pair — sulfur and oxygen at the same position, doing the same structural job with different strength — drawn by another hand, in another decade, for another purpose.

The volume records the figure. It claims nothing beyond what the figure shows.

---

522. Inosine in the Eukaryotic Column ↩

The count nobody has printed as a count

Reading down the Eukaryotes column of Table 2 for base 34, the symbol I — inosine — appears at the following anticodons:

amino acid	codon read	anticodon	box
Ala	GCU	AGC	four-codon
Arg	CGU	ACG	four-codon
Ile	AUU	AAU	three-codon
Leu	CUU	AAG	four-codon
Pro	CCU	AGG	four-codon
Ser	UCU	AGA	four-codon
Thr	ACU	AGU	four-codon
Val	GUU	AAC	four-codon

eukarya 8 inosine anticodons at base 34\nbacteria 1 inosine anticodon (Arg, ACG, only)\narchaea 0 inosine anticodons

And the enzymes explain the zero

The deamination of A_{34} is carried out by homodimeric tadA in bacteria and by heteromeric tad2 and tad3 in eukarya. The paper states plainly:

"No archaeal homologues of tadA/tad2/tad3 genes have been found."

Archaea do not make inosine at the wobble position because they do not have the enzyme that makes it.

Why the volume prints this

Part Fifty-Seven established that inosine has three wobble partners — U, C and A — and excludes G. Part Sixty-Nine established that the wobble position is where the reading rule lives.

Here is the domain distribution. The domain with a nucleus, linear chromosomes, spliceosomal introns and telomeres is also the domain with eight inosine anticodons. The domain with none of those has none. The volume records the correlation and offers no mechanism.

Eight. The number this volume has been arguing for since Part Seventy, arrived at from a different direction, in a table that was not built to make that point.

---

523. Three Domains, Three Modifications of One Base ↩

G_{34}, and what each domain does to it

domain	what happens to G_{34}	the modified base
bacteria	modified	preQ1
eukarya	modified	queuosine
archaea	not modified at position 34	—

Archaea instead modify G_{15}, a base in the D loop, into archaeosine — a modification that has not been identified in bacteria or eukarya.

One base, three domains, three different chemistries, and one domain that declines to modify it at the reading position at all and modifies a different position instead.

The general rule the paper states

"Even the same modification is normally accomplished by different enzymes in bacteria, archaea, and eukarya. This makes it impossible to predict the presence of a specific modification in an organism based on the presence in its genome of an enzyme that is homologous to an experimentally characterized enzyme in another organism."

"Though the effect of missing single modifications may be small on translation, missing multiple tRNA modifications is lethal."

The alphabet writes A, G, C and U. The reading depends on preQ1, queuosine, archaeosine, hydroxyuridines, aminomethyluridines, carbamoylmethyluridines, thiouridines and inosine, and losing enough of them kills the cell.

---

524. Forty-Six TRNAs for Sixty-Four Codons ↩

The arithmetic of degeneracy

codons	64
amino acid coding codons	61
anticodons that would be required, naïvely	61
kinds of tRNA actually used by almost all archaea and some eukarya	46

How the gap is closed

By using either a G_{34} or an A_{34} anticodon to read both the U_3-ending and the C_3-ending codons of a box — and A_{34} is deaminated to inosine.

The genetic code as printed has sixty-four cells. The machinery that reads it has forty-six readers. The nineteen-cell shortfall is closed by chemistry the printed code does not name.

And the three domains close it differently: archaea and bacteria group together on the choice of anticodon, with eukarya on the other side.

---

525. The S12 Figure — the Protein Is the Least Informative Part ↩

The comparison, as the paper draws it

S12 is the most conserved universal ribosomal protein and is assumed to be the oldest.

organism	protein identity to H. sapiens	gene size, bp	coding sequence, bp
H. sapiens	—	2289	432
S. cerevisiae	78%	758	438
M. jannaschii (archaea)	53%	447	447
E. coli K-12	35%	375	375

The arithmetic

human gene 2289 bp\nhuman coding sequence 432 bp\n---------- \nnot translated 1857 bp = 81 percent of the gene\nE. coli gene 375 bp\nE. coli coding sequence 375 bp\n----------\nnot translated 0 bp = 0 percent of the gene

The coding sequences are 432 and 375 base pairs — within fifteen percent of each other. The genes are 2289 and 375 — a factor of six. Every bit of that difference is in material the notation does not translate.

The human S12 carries three spliceosomal introns; the yeast S12 carries one; M. jannaschii and E. coli carry none. Splicing them out requires over a hundred different proteins that only eukarya have.

And the paper says the thing out loud

"When one wishes to study the differences of genes using sequences of genomic DNA, RNA transcripts, or proteins, the protein sequences are the least informative."

"Protein sequence comparisons minimize the differences between the compared genes because it ignores the differences in promoters, 5′ untranslated regions, 3′

untranslated regions, and introns — all integral parts of eukaryotic genes and often much longer in total sequence than the protein coding regions."

This volume has argued from Part One that a notation determines what gets counted. Here is the most conserved protein in biology, and the sequence comparison that makes it look conserved is looking at eighteen percent of the gene.

526. The Ribosomal Protein Census ↩

From sixty-six complete genomes

	families
total ribosomal protein families identified	102
found in archaea	68
found in bacteria	57
found in eukarya	78
universal — in every genome analyzed	32
shared by archaea and eukarya, absent from bacteria	33
unique to archaea	1
unique to bacteria	23
unique to eukarya	11

Confirmed by a later study across 995 bacteria, 87 archaea and ten eukarya, with three additional archaea-specific proteins added from proteomics.

And the mitochondrial ribosome

Eukarya carry more than one hundred mitochondrial-specific ribosomal proteins with no homologs in bacteria or archaea.

Mitochondrial ribosomes have been found to be very different from those of bacteria, archaea or eukarya. The paper states that this has "made the endosymbiotic origin theory of mitochondria more questionable than ever." The volume records the count of over one hundred proteins and does not carry the inference about

endosymbiosis, which is a live and technical dispute the volume has no exhibit for.

Thirty-two of one hundred and two families are universal. Fewer than a third of the ribosome's protein parts are shared by everything alive.

---

527. The Heptad Repeat: Ysptsps, Twenty-Six and Fifty-Two ↩

The C-terminal domain of Rpb1

The largest subunit of eukaryotic RNA polymerase II carries a tail made of a repeated seven-residue motif.

Y S P T S P S\n1 2 3 4 5 6 7

organism	number of repeats
yeast	26
humans	52

The number of repeats typically correlates with the complexity of the organism. The non-conserved repeats deviate at positions 2, 3, 4, 5 and 7 — mostly at position 7.

What it does

Each residue can be post-translationally modified in a transcription-cycle-dependent manner. Without any phosphorylation of the CTD, Pol II is inactive in initiating transcription, although the initiation complex can only form when the CTD is not phosphorylated.

Different combinations of these modifications — called the CTD code — control the binding of hundreds of factors.

Deletion of the CTD is lethal in yeast, flies and mice. Archaea have no CTD: it is boxed with dashed lines in the paper's alignment figure, marked as the missing region.

Why the volume prints it

A seven-residue unit, repeated twenty-six or fifty-two times, whose chemical marking state constitutes a second code layered on the first, and which is not in the four-letter sequence at all.

Part Seventy-Five counted about two hundred chemical modifications on the ribosome that the alphabet cannot write. This is the same phenomenon on the polymerase: a tail of 182 or 364 residues, each markable, none of it expressible in A, G, C and T.

528. What Archaea Lack That Eukarya Cannot Do Without ↩

The list the paper compiles

system	archaeal status
telomere synthesis	absent
spliceosomal intron splicing	absent
Orc1 N-terminal BAH extension	absent
Cdc45 homolog	not identified
GINS homolog	absent in many archaea
cyclin-dependent kinase CDK, Dbf4, DDK	absent
DNA polymerase α	absent
Rpb1 C-terminal domain	absent
TAFs, TFIIA, TFIIEβ, TFIIF, TFIIH, Mediator	no homologs identified
tadA/tad2/tad3	absent
eIF3, eIF4F	no homologs

And what archaea have that nobody else does

DNA polymerase families D and E	unique to archaea
RNAP subunit Rpo13	no eukaryotic homolog
archaeosine at G_{15}	not in bacteria or eukarya
one ribosomal protein family	not in bacteria or eukarya

And Pol D, not Pol B, is essential for viability in Methanococcus maripaludis — a family found in no other domain doing the domain's central job.

The functional-prediction warning

Homologs of bacterial DnaG have been found in archaea, but instead of functioning as a primase they function in RNA degradation in Thermococcus kodakarensis and Sulfolobus solfataricus.

Archaeal PriS synthesizes long DNA fragments in vitro, and PriL decreases its DNA polymerase activity and increases its RNA polymerase activity.

Two named cases in which a molecule identified by sequence homology turned out to be doing a different chemistry. The volume records both as a caution about inferring function from name, which is a caution this volume needs and has used since Part Three.

---

529. The Paper's Own Conclusion, and What the Volume Does with It ↩

What the authors conclude

1	**molecular machines are employed as modules — a process is either bacterial-like or eukaryote-like**
2	each machine is a mosaic of modules fine-tuned to the unique need of an organism
3	the machines are unique and specific for each domain and cannot be exchanged
4	functional annotation from sequence homology can be misleading because it takes only isolated parts of proteins
5	organism-specific protein extensions, such as the CTD of Rpb1, can be the determinant factor of life versus death

Then: "the molecules... are crying out loudly that eukarya did not evolve from archaea."

What the volume takes

Findings one through five are statements about molecules that can be checked against databases. The volume takes all five, and finding five in particular — that an organism-specific extension can be the difference between life and death — is a statement this volume has been making about the notation since Part One, arrived at independently.

What the volume declines

The final inference. Not because the volume has a position on eukaryogenesis, but because the volume's own rule is that it carries what can be shown wrong.

A design inference is not falsified by any count of molecules, which is exactly what makes it unavailable to this volume. The author applied that rule to his own strongest claim in Part Seventy. It is applied here in the same way and for the same reason.

And the volume notes one thing in the author's favor: the census stands whether or not the inference does. The eight inosine anticodons, the three sulfur-carrying wobble bases, the 81 percent untranslated fraction of human S12 and the fifty-two heptad repeats are facts about molecules. They belong to nobody's argument in particular.

---

530. What Is Claimed and What Is Not ↩

Claimed

That the paper appears in a creationist journal and argues for design, and that the volume takes its molecular census and declines its concluding inference — stated in section 519 before any figure is used.

That archaea use ether lipids on glycerol-1-phosphate while bacteria and eukarya use ester lipids on glycerol-3-phosphate; that archaea lack nuclei, organelles, spliceosomal introns and telomeres and have circular chromosomes.

That Table 2 lists ynm^{5}s^{2}U at the wobble base for Glu, Gln and Lys in bacteria and zcm^{5}s^{2}U at the same positions in eukarya, and that Figure 8 panels G and H annotate the ring position "S <> O."

That the Eukaryotes column of Table 2 carries inosine at base 34 for Ala, Arg, Ile, Leu, Pro, Ser, Thr and Val — eight anticodons — that the Bacteria column carries inosine only at Arg, and that the paper states no archaeal homologues of tadA, tad2 or tad3 have been found.

That G$_{34}$ is modified to preQ1 in bacteria and queuosine in eukarya but is not modified in archaea, which instead modify G$_{15}$ to archaeosine; and that the paper states missing multiple tRNA modifications is lethal.

That almost all archaea and some eukarya use only 46 kinds of tRNA for 61 coding codons.

That human S12 is a 2289 bp gene with a 432 bp coding sequence while E. coli S12 is 375 bp with a 375 bp coding sequence, that protein identity to human runs 78 percent for yeast, 53 for M. jannaschii and 35 for E. coli, and that the paper states protein sequences are the least informative comparison.

That 102 ribosomal protein families were identified across 66 genomes, with 68 in archaea, 57 in bacteria, 78 in eukarya, 32 universal and 33 shared by archaea and eukarya only; and that eukarya carry more than 100 mitochondrial-specific ribosomal proteins with no prokaryotic homologs.

That the Rpb1 CTD is made of YSPTSPS repeats, 26 in yeast and 52 in humans, that its deletion is lethal in yeast, flies and mice, and that archaea have no CTD.

That archaeal DnaG homologs function in RNA degradation rather than priming in T. kodakarensis and S. solfataricus, and that P. furiosus PriS synthesizes long DNA fragments in vitro.

Not claimed

That eukarya did not descend from an archaeal lineage. The volume takes no position and says so in section 529.

That the eight eukaryotic inosine anticodons of section 522 have anything to do with the eight symbols of Part Seventy. It is a coincidence of number until somebody shows a mechanism. The volume prints it because it is a count in a table nobody has printed as a count, not because it proves anything.

That the "S <> O" annotation in Figure 8 was drawn to make the volume's conjugate-pair argument. It was drawn to show a modification interconversion. The volume records the figure and the coincidence of framing.

That the endosymbiotic origin of mitochondria is questionable. The volume takes the count of over one hundred mitochondrial-specific ribosomal proteins and not the inference.

531. What Would Show This Part Is Wrong ↩

— Show archaeal tadA, tad2 or tad3 homologs, or archaeal inosine at anticodon position 34, and section 522's zero is wrong.

— Show that the eukaryotic inosine-34 anticodons number other than eight in a current build of the genomic tRNA database, and the count of section 522 fails. The volume names the database — gtrnadb.ucsc.edu — so this is checkable in an afternoon.

— Show that s^2U is absent from the Glu, Gln or Lys wobble base in bacteria or eukarya, and section 521's sulfur census fails.

— Show a human S12 gene substantially shorter than 2289 bp, or a coding sequence substantially longer than 432, and section 525's arithmetic — the volume's best single exhibit for the notation argument — is wrong.

— Show a viable CTD deletion in yeast, flies or mice, and section 527's lethality claim fails.

— Show that fewer or more than 32 of the 102 ribosomal protein families are universal, and section 526 needs recounting.

PART SEVENTY-SEVEN · THE HEPTAD

Part Seventy-Seven of the evidence volume, sections 532 to 544

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Beck, Thoms, Perera, Schütte, Unnikrishnan, Knezevic, Kinston, Wilson, O'Brien, Göttgens, Wong and Pimanda, Blood, 2013. Seven transcription factors, twenty-eight thousand seven hundred and ninety-three binding sites, one hundred and nineteen possible combinations, and the finding that the combination the cell prefers is all seven at once.

---

532. Seven Factors and One Cell Identity ↩

The set

Seven transcription factors, measured together in primary human CD34-positive hematopoietic stem and progenitor cells:

FLI1 ERG GATA2 RUNX1 SCL/TAL1 LYL1 LMO2

Purified to ninety-eight percent or better from granulocyte-colony-stimulating-factor mobilized apheresis samples. Chromatin immunoprecipitation with more than twenty million mappable reads for each factor, against an immunoglobulin G background.

Approximately one hundred and sixty million pooled human CD34-positive cells in total, across seven factors and the control.

Why the paper exists

A combination of three of these factors — FLI1, GATA2 and SCL/TAL1 — was already known to form a densely interconnected circuit during stem cell specification in the aorta-gonad-mesonephros. But factors required during specification are no longer essential for maintenance.

The question was which combination maintains the state, rather than which one creates it. The answer turned out to be a set of seven, and the finding was that the set behaves as a set.

---

533. The Counts ↩

Peaks per factor

factor	binding sites
FLI1	16,597
RUNX1	13,993
GATA2	9,311
ERG	4,803
LMO2	2,588
LYL1	1,929
SCL/TAL1	1,315
total distinct binding sites	28,793

A range of nearly thirteen-fold between the most and least prolific factor in the same cells at the same time.

Where the peaks sit

Taken as a whole, sixty to seventy-five percent of binding peaks for each factor fell within a region ten kilobases upstream of the transcription start site. Binding within one kilobase of the start ranged from five to fifteen percent — LYL1 and GATA2 at the low end, SCL/TAL1 and RUNX1 at the high end.

The majority of the binding is not at the promoter. It is upstream, intragenic and intergenic — at enhancers, in the material between and inside genes that the reading frame does not touch.

---

534. The Full Set Is Favored; the Pairs Are Not ↩

The distribution across combination size

number of factors at a site	regions
1	17,393
2	6,070
3	2,720
4	1,255
5	644
6	374
7 — all of them	337

Against a lower-end estimate of eighty thousand regions potentially available for binding, the expected frequency of each of the one hundred and nineteen patterns was calculated and compared to what was observed.

The finding

"In general, binding of only 2 TFs was not favored… In general, multi-TF combinations were favored, with overlapping binding of all 7 TFs being the most prevalent pattern in HSPCs."

The least likely pattern of all was the two closely related ETS-family members FLI1 and ERG together in the absence of any other member of the set.

The one exception

the only favored pairwise combination	
FLI1 with RUNX1	3,284 of 28,793 regions

Previously unrecognized. Eleven percent of all binding sites in these cells are that one pair.

Why this matters to the volume

Part Forty-Eight established the closure rule: four closes under complement, and the reading set and the manufacturing set differ because they close under different operations.

Here is a closure argument in a different system. Of one hundred and nineteen possible subsets of seven, the one the cell statistically prefers is the whole set. Partial occupancy is disfavored; complete occupancy is favored. The set is the unit, not the members.

The volume records the shape of the argument and claims no connection to the nucleotide case. Seven factors are not eight symbols and the operations are not the same. What is shared is that in both systems the meaningful object turned out to be a closed collection rather than an inventory of parts.

---

535. Four Motif Classes ↩

De novo motif discovery on the 337 seven-factor regions

motif	E-value	the factors that read it
ETS	6.6×10^{-125}	FLI1, ERG
GATA	1.6×10^{-30}	GATA2
E-box	4.8×10^{-13}	SCL, LYL1, LMO2
RUNX	1.2×10^{-05}	RUNX1

These four were not only the most significantly enriched motifs. They were the only significantly enriched motifs.

seven proteins\nread\nfour classes of sequence

Seven readers, four things to read. The volume records the pair of numbers and nothing more: a set of seven whose recognition alphabet has four letters is a structure this volume has met before, in a different molecule, and the coincidence is stated as a coincidence.

The motif fractions across combinations

At regions bound by all seven factors, the fraction of regions carrying each motif was:

ETS	GATA	E-box	RUNX
0.85	0.83	0.82	0.48

Three of the four classes present at more than four regions in five. RUNX in fewer than half.

---

536. One Factor Marks the Site for Another ↩

The observation the paper calls striking

FLI1-bound regions showed a higher likelihood for the presence of RUNX motifs than RUNX1 binding per se.

And RUNX1, in contrast with the other six members of the set, was bound more often at sites

The feature was not replicated by ERG, an ETS factor closer to FLI1 than any other member.

The test

Genome-wide binding profiles of FLI1 and RUNX1 were taken from primary megakaryocytes cultured from human CD34-positive cells — a later, more committed state.

megakaryocyte-specific RUNX1 peaks were more likely to be acquired at	significance
sites of prior FLI1 binding in HSPCs	P < .00001
versus random promoters and enhancers	—

megakaryocyte-specific RUNX1 peaks were more likely to be acquired at	significance
versus prior GATA2-bound regions	P < .0001
versus prior SCL-bound regions	P < .0045

FLI1 peaks in megakaryocytes that are FLI1/RUNX1 pairs	18%
GATA2 peaks	1.8%
SCL peaks	2.7%

What this is

A factor binding a site that carries the recognition sequence for a different factor, at a stage before that factor arrives, at a site that factor will later occupy. The first binding event is not reading its own motif. It is marking a position.

The volume records this as the clearest published instance of anticipatory occupancy in a human primary cell, and connects it to nothing. It is a finding in its own right.

---

537. The Density of the Active Mark Tracks the Number of Factors ↩

H3K27 acetylation against occupancy

H3K27ac distinguishes active enhancers from inactive or poised elements containing H3K4me1 alone. The paper overlapped its binding data with H3K27ac and H3K4me1 from the Human Epigenome Atlas.

regions bound by	H3K27ac
1 factor	approximately 10 percent show no detectable H3K27ac; only about 8 reads in up to half
all 7 factors	more than 90 percent of regions have more than about 8 reads

A progressive increase across every intermediate step — one, two, three, four, five, six, seven — with no plateau and no reversal.

And the nucleosome-free region widens

The average distance between the H3K27ac peak densities flanking the factor peak maximum increases with the number of overlapping factors. As the number of factors within a peak increased, there was progressive expansion of the linker region between nucleosomes.

More factors, more acetyl, more space. The physical opening of the chromatin scales with the count of proteins standing on it.

The volume's note on the acetyl

Part Fifty-One established that the acetyl group of histone acetylation arrives on acetyl coenzyme A — a thioester, a sulfur-carbon bond.

Every H3K27 acetyl counted in this figure was delivered by a sulfur. The paper does not say so, because the paper is not about sulfur and had no reason to. The volume says so because it is the volume's business, and marks it as a statement of standard biochemistry rather than a finding of this paper.

---

538. The Heptad Regulates Itself ↩

Where the seven factors bind

The set is enriched at known hematopoietic stem cell enhancers, and most such loci were bound by all seven factors:

locus	factors bound
ERG +85	7
RUNX1 +23	7
GATA2 +3.5	7
FLI1 −15	7
TAL1 +40	5
LMO2 −25	5
LYL1 promoter	6

Every one of the seven genes encoding a member of the set is bound at its own regulatory element by five, six or seven members of the set. Four of the seven are bound by all seven.

All of these regions, with the exception of FLI1 −15, were already known hematopoietic regulatory elements. FLI1 −15 was tested in transgenic assay: the mouse sequence drove expression selectively in endothelial cells along the ventral surface of the dorsal aorta — the place blood stem cells emerge from — and in a small proportion of fetal liver blood cells.

The circuit

A set of seven proteins in which every member's gene is a target of the set. The paper calls this a dense autoregulatory core, and Figure 7A draws it as a complete or near-complete directed graph on seven nodes with self-loops.

And the ERG locus is not bound once. It carries the +85 enhancer plus four additional binding sites at approximately +70, +84, +120 and +175.

genes bound by the whole set	median additional bound regions
heptad-associated	4
bound by only 1 factor	1

539. Thirty MICRORNAs, and Five Feedback Loops ↩

The noncoding half of the paper

Binding peaks were mapped to the putative start sites of primary microRNA transcripts.

factor	miRNAs with an associated peak
FLI1	571
RUNX1	537
GATA2	402
ERG	239
LMO2	140
SCL	100
LYL1	91

factor	miRNAs with an associated peak
all seven together	30

More than half of these microRNAs lie within a coding gene. Of the thirty regulated by the whole set, nine had their own start site rather than sitting inside another gene — and all nine carried active H3K4me3 marks overlapping the binding.

The statistics come out the same way

Combinations of fewer than four factors at a microRNA start site were not favored. The combination of all seven was the most favored.

The same result as for coding genes, in an independent measurement on a different class of transcript. Partial occupancy disfavored; complete occupancy preferred.

And the loops close

microRNAs analyzed with at least ten normalized reads	24 to 216,936 reads
of ten such microRNAs, how many form negative feedback loops with their transcriptional drivers	5

ERG, FLI1 and GATA2 are each targeted by multiple microRNAs in the network.

Three microRNAs are highly expressed in human HSPCs and form incoherent feed-forward loops with genes also regulated by the set: miR-126, miR-146a and miR-223 — all three functionally validated as having a potent impact on stem cell self-renewal or differentiation.

Incoherent feed-forward

A regulator exerting both positive and negative effects on the same target.

The seven proteins activate a gene directly, and simultaneously activate a microRNA that represses the same gene. The paper cites Alon: this provides a mechanism to fine-tune steady state levels and activation kinetics of target proteins.

The volume records it because it is a control structure the four-letter notation cannot express at all. The same sequence is being both switched on and damped, and which happens depends on timing rather than on letters.

540. Bivalent Marks: the Gene Is Poised Before It Is Read ↩

The histone quartiles

Heptad target genes were ordered into quartiles by expression, lowest to highest, and the histone marks at their promoters assessed.

	with expression
fraction carrying active marks — H3K4me3 and H3K27ac	increases
fraction carrying the inactive mark H3K27me3	highest in the lowest-expressed quartile, diminishing as expression rises

And then the finding

Genes that are targets of the set, carrying bivalent histone marks at their promoters — both the active H3K4me3 and the repressive H3K27me3 at once — are:

in CD34-positive cells	lowly expressed
in one or another lineage-committed cell type	upregulated

The seven factors are standing on genes that are not being read yet, at promoters carrying both marks simultaneously, and those are the genes that turn on later when the cell commits.

"The heptad is not only associated with genes that are highly expressed in HSPCs, but it also appears to prime gene loci for subsequent expression."

And the enrichment test

Genome-wide expression profiles for thirty-eight distinct purified human hematopoietic populations were used to build a ranked gene list. One hundred and nineteen gene sets were constructed, one for each combinatorial pattern, and tested.

"The only occupancy pattern with a gene set that was enriched in CD34+ HSCPs was the heptad."

One pattern out of one hundred and nineteen. P = .042.

541. The Arithmetic Checks ↩

The volume verified the counts

The seven occupancy classes reported in the text sum exactly:

1 TF 17,393\n2 TF 6,070\n3 TF 2,720\n4 TF 1,255\n5 TF 644\n6 TF 374\n7 TF 337\n----------\ntotal 28,793 exactly the reported number of binding sites

And the per-factor peaks are consistent with the overlaps

$$16{,}597 + 13{,}993 + 9{,}311 + 4{,}803 + 2{,}588 + 1{,}929 + 1{,}315 = 50{,}536$$

Fifty thousand five hundred and thirty-six factor-site events distributed over twenty-eight thousand seven hundred and ninety-three distinct regions — a mean of 1.76 factors per bound region, which is consistent with a distribution in which sixty percent of regions carry one factor.

One discrepancy, printed because it is there

The legend to Figure 4B gives the class sizes as 17,393 / 6,070 / 2,721 / 1,256 / 645 / 375 / 337, which sums to 28,797 — four more than the stated total.

The text figures sum exactly to 28,793; the figure-legend figures are each one higher for the three-, four-, five- and six-factor classes. The volume uses the text figures and records the discrepancy rather than silently choosing.

It is four counts in twenty-eight thousand. It changes nothing. It is printed because this volume prints what it checked.

542. What the Volume Takes from It ↩

Four things

First. Of one hundred and nineteen possible combinations, the favored one is the complete set, and small subsets are actively disfavored. That is a closure result in a system of seven proteins, established

statistically against an eighty-thousand-region null. Part Forty-Eight's argument has the same shape in a different molecule.

Second. Seven proteins recognizing four and only four significantly enriched classes of sequence. The volume prints the pair of numbers and marks the resemblance to its own four-and- eight structure as a coincidence, because that is what it is until somebody finds a mechanism.

Third. Anticipatory occupancy, measured. FLI1 binds sites carrying RUNX motifs more reliably than RUNX1 does, and RUNX1 arrives at those sites later, at ten times the rate seen for GATA2 or SCL. A protein marking a position for a protein that is not there yet.

Fourth. Bivalent promoters. The set stands on genes that carry both the active and the repressive mark at once and are not being read, and those genes turn on when the cell commits. A four-letter notation cannot express "both, and not yet." This is the same gap Part Seventy-Five found on the ribosome, in a different layer.

And one connection to the volume's own thread

Every H3K27 acetyl in section 537 came from acetyl coenzyme A, a thioester. Every H3K4 and H3K27 methyl in section 540 came from S-adenosylmethionine, a sulfonium.

The entire chromatin readout of this paper — the mark that tracks factor count, the mark that tracks expression, and the mark that makes a promoter bivalent — is written in two chemistries, and both of them are carried by sulfur.

The paper does not mention sulfur once. It had no reason to. The volume states the biochemistry and marks it as standard, not as a finding of this paper.

---

543. What Is Claimed and What Is Not ↩

Claimed

That genome-wide binding profiles for FLI1, ERG, GATA2, RUNX1, SCL/TAL1, LYL1 and LMO2 were generated in primary human CD34-positive cells of at least ninety-eight percent purity, using more than twenty million mappable reads per factor and approximately one hundred and sixty million pooled cells in total, deposited as GSE45144.

That the peak counts are FLI1 16,597, RUNX1 13,993, GATA2 9,311, ERG 4,803, LMO2 2,588, LYL1 1,929 and SCL/TAL1 1,315, over 28,793 distinct binding sites; and that occupancy by 1 through 7 factors accounts for 17,393, 6,070, 2,720, 1,255, 644, 374 and 337 regions respectively.

That binding of only two factors was not favored, that multi-factor combinations were favored, that all seven was the most prevalent pattern, that FLI1 with ERG alone was least likely, and that FLI1 with RUNX1 at 3,284 regions was the only favored pairwise combination.

That de novo motif discovery on the 337 seven-factor regions returned ETS, GATA, E-box and RUNX as the only significantly enriched motifs, at the E-values stated in section 535.

That FLI1-bound regions showed a higher likelihood of RUNX motifs than RUNX1 binding itself, that RUNX1 was bound more often at sites without a RUNX motif at P < .001, that this was not replicated by ERG, and that megakaryocyte-specific RUNX1 peaks were more likely at prior FLI1-bound sites than at random elements (P < .00001), prior GATA2 (P < .0001) or prior SCL (P < .0045); and that 18 percent of megakaryocyte FLI1 peaks are FLI1/RUNX1 pairs versus 1.8 percent of GATA2 and 2.7 percent of SCL.

That H3K27ac density and the internucleosomal linker width both increase progressively with the number of overlapping factors, with about 10 percent of single-factor regions showing no detectable H3K27ac and more than 90 percent of seven-factor regions exceeding about eight reads.

That ERG +85, RUNX1 +23, GATA2 +3.5 and FLI1 −15 are bound by all seven factors, TAL1 +40 and LMO2 −25 by five, and the LYL1 promoter by six; that FLI1 −15 drove expression in the ventral dorsal aorta endothelium in transgenic assay; and that heptad-associated genes carry a median of four additional bound regions versus one for single-factor genes.

That thirty microRNAs are bound by all seven factors, that nine of these have their own start site and all nine carry overlapping H3K4me3, that combinations of fewer

than four factors at microRNA start sites were not favored, that five of ten analyzed microRNAs form negative feedback loops with their drivers, and that miR-126, miR-146a and miR-223 form incoherent feed-forward loops.

That heptad target genes with bivalent promoter marks are lowly expressed in CD34-positive cells and upregulated in at least one lineage-committed cell type, and that of 119 gene sets tested by GSEA the heptad set was the only one enriched in CD34-positive cells at P = .042.

That the text-reported occupancy classes sum exactly to 28,793 while the Figure 4B legend figures sum to 28,797, and that the volume uses the text figures.

Not claimed

That the seven factors of this paper have any relationship to the eight symbols of Part Seventy. Section 534 and section 542 both state the resemblance as a coincidence of shape.

That four motif classes and four base pairs are connected. Section 535 prints two numbers and says so.

That sulfur has any causal role in this paper's findings. Section 542 states that the acetyl comes from a thioester and the methyls from a sulfonium because that is standard biochemistry, and marks explicitly that the paper does not mention sulfur.

That FLI1 binding causes subsequent RUNX1 binding. The paper establishes a strong statistical association across two cell states and calls the question of permissiveness one it evaluated, not one it settled.

That the CD34-positive population is homogeneous. The authors state plainly that it is not, and list this first among their limitations, together with the absence of replicate experiments due to cell-number constraints.

544. What Would Show This Part Is Wrong ↩

— Re-analyze GSE45144 and recover occupancy class sizes materially different from 17,393 / 6,070 / 2,720 / 1,255 / 644 / 374 / 337, and sections 534 and 541 fail. The accession is public; this is the most directly checkable claim in the Part.

— Show that partial occupancy is favored over complete occupancy against a corrected null, and the closure result of section 534 — the reason this Part is in the volume — is wrong.

— Show a fifth significantly enriched motif class in the 337 seven-factor regions, and the four-class count of section 535 fails.

— Show that RUNX1 binds preferentially at sites carrying RUNX motifs in these cells, and section 536's anticipatory-occupancy finding is wrong.

— Show that H3K27ac density does not increase monotonically with factor count, and section 537 fails.

— Show that heptad targets with bivalent promoters are not upregulated in any committed lineage, and section 540's priming claim fails.

— Show that the seven-factor pattern is not the only GSEA-enriched occupancy pattern among the 119 tested, and section 540's central statistical result fails.

PART SEVENTY-EIGHT · THE MAN WHO BROKE IT

Part Seventy-Eight of the evidence volume, sections 545 to 557

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Marshall Nirenberg, Trends in Biochemical Sciences, January 2004. The first-hand account of how the genetic code was deciphered, written by the man who did it. Read here for one sentence in particular: that the residue in the third position of the first anticodon ever sequenced is hypoxanthine.

---

545. A First-hand Account, and Why It Belongs in This Volume ↩

What the document is

An autobiographical review of the events that led to the breaking of the genetic code, published by Nirenberg forty-three years after the poly(U) experiment and five years before his death.

the period covered	1961 to 1966
stage one	base compositions of codons, from randomly ordered RNA
stage two	nucleotide sequences of codons, from trinucleotide-directed tRNA binding
the total elapsed time	about five years

Why this volume prints it

This volume has spent seventy-seven Parts arguing about a notation. This is the account of the notation being written, by the hand that wrote it, and it should be read by anyone who intends to argue with the result.

It is also the most human document in the volume. It records that the man who broke the code was told the project was suicidal, that he had no experience in the field he switched into, that his first success depended on a solvent one person in the world knew about, and that the United States Customs Service confiscated one of his fifteen dinucleotides and used it up testing for drugs.

The volume takes the facts. It also takes the tone, which is the tone of somebody who did the work and does not need to inflate it.

---

546. The Road In: a Pseudomonad and Three Enzymes ↩

Where he started

arrived at NIH	1957, as a post-doctoral fellow with DeWitt Stetten Jr.
doctorate	biochemistry, University of Michigan, Ann Arbor
the next year, with William Jakoby	isolated a Pseudomonad by enrichment culture that grew on γ-butyrolactone, and purified three enzymes in the catabolism of γ-hydroxybutyric acid

That work is reference 1 of the paper: Nirenberg and Jakoby, 1960, Journal of Biological Chemistry 235, 954–960 — "Enzymatic utilization of γ-hydroxybutyric acid."

What he had not done

In his own words: he had no experience with either gene regulation or protein synthesis, having previously worked on sugar transport, glycogen metabolism and enzyme purification.

"After thinking about this for a considerable time, I finally decided to switch fields."

The man who broke the genetic code came to the problem as an outsider, three years into a career spent on something else, and said so in print.

And who opened the door

Gordon Tomkins replaced Herman Kalckar as head of the Section of Metabolic Enzymes in 1958 and offered Nirenberg a position as an independent investigator. The other independent investigators were Elizabeth Maxwell and Victor Ginsberg, carbohydrate biochemists, and Todd Miles, a nucleic-acid biochemist.

Of Tomkins, whose photograph is Figure 1 of the paper: brilliant, a wonderful associative memory, a magnificent sense of humor, and he encouraged exploration.

"I decided then that if I was going to work this hard I might as well have the fun of exploring an important problem."

---

547. What Everyone Told Him Not to Do ↩

The warning

Bruce Ames, working in his laboratory, "just looked at me and said 'It is suicidal'."

Nirenberg's own assessment, printed in the paper	
"I knew this was a risky problem to work on"	
"I estimated it would take me two years to set up a cell-free system"	
"I thought that it was a dangerous project to work on"	
"I found that it was a little extreme"	

Nirenberg's own assessment, printed in the paper	
"Although we both agreed that it was a little extreme, I wanted to explore an important problem, and the wish to explore was much greater than the fear of failure."	

The last clause is the sentence the volume takes: the wish to explore was greater than the fear of failure. It is the operating principle of the archive this book is built from.

What the field already knew

Volkin and Astrachan	**a fraction of RNA in E. coli infected with T2 differed in base composition from the bacteriophage and had the base composition of the DNA of E. coli**
Hershey and colleagues	RNA was rapidly synthesized and degraded in E. coli infected with T2
Monod and Jacob, 1959	regulation of the gene encoding β-galactosidase in E. coli
Zamecnik and colleagues	de novo synthesis of penicillinase following addition of RNA or DNA

"If mRNA did exist, I thought that it might be contained in ribosomes because these organelles were known to be incorporated into protein on these organelles."

---

548. The Three Trivial Technical Advances ↩

Named as trivial by the man who made them

"We made three trivial technical advances that had a tremendous effect on our work."

first	**conditions that enabled E. coli extracts to be frozen and thawed with little or no loss in the ability to incorporate amino acids into protein**
second	DNase. Endogenous incorporation was high; extracts were incubated with DNase I for 40 minutes until endogenous incorporation had almost stopped, so the increase caused by added mRNA was relatively small against a low background
third	the extracts were divided into small portions and frozen for use later

And one more, which he treats as a fourth: replacing the standard method of washing radioactive protein precipitates by repeated centrifugation — which took eight to ten days — with washing through Millipore filters, which took one day.

Freeze-thaw, a forty-minute DNase incubation, aliquoting, and a filter. Four pieces of bench housekeeping, and the man who used them to break the genetic code calls three of them trivial.

Figure 2 of the paper shows the result: incorporation of ^{14}C-valine into protein in E. coli extracts, three curves — minus DNase, plus messenger RNA, plus DNase — over eighty minutes, against counts per minute per milligram of protein.

---

549. Poly(u), and the Month of Waiting ↩

The set-up

Heinrich Matthaei came to the laboratory as a post-doctoral fellow — a plant physiologist from Germany, then at Cornell, who wanted to work on protein synthesis. He came to the NIH because it is a big institution, stopped in Roy Vagelos's laboratory, and Vagelos sent him to Nirenberg.

"I was the only person at the NIH who was studying cell-free protein synthesis."

Matthaei insisted on preparing twenty ^{14}C-labeled amino acids himself, by growing algae in the presence of ^{14}C-bicarbonate, hydrolyzing the protein and purifying the amino acids.

The experiment

Before going to Heinz Fraenkel-Conrat's laboratory in Berkeley, Nirenberg obtained some poly(U) and instructed Matthaei to make twenty different solutions, each with nineteen cold amino acids and one radioactive amino acid, to detect poly(U)-dependent incorporation of a single amino acid into protein.

"After working in Fraenkel-Conrat's laboratory for about a month, Heinrich called me very excitedly to tell me that poly(U) was

extraordinarily active in stimulating the incorporation of only phenylalanine into protein."

Figure 3: counts per minute per milligram of protein rising to sixty-four thousand over ninety minutes with poly(U), against a flat line without it.

The arithmetic of that moment

One synthetic polymer of a single base. One amino acid out of twenty. The first codon assignment in history, and the man who designed the experiment was two thousand five hundred miles away when it worked.

Note the composition, because this volume has an interest in it. Poly(U) is uracil — the pyrimidine that Part Sixty-Nine and Part Seventy-Six both place at the wobble position, and the one whose 2-position carries sulfur in three amino acids across two domains.

The genetic code was opened with a homopolymer of the base this volume has spent the most time on. The volume records the coincidence and takes nothing from it.

---

550. The First Antisense Experiment, 1961 ↩

What they did next

They showed that single-stranded poly(U) functions as messenger RNA, but double-stranded or triple-stranded poly(U)–poly(A) helices do not.

Figure 4: addition of poly(A) completely inhibits the messenger activity of poly(U) by forming double-stranded and triple-stranded helices. By contrast, addition of poly(C) has little effect.

addition	effect on phenylalanine incorporation
poly(U) alone	100 percent
poly(U) + poly(A)	abolished
poly(U) + poly(C)	little effect

What Nirenberg calls it

"This experiment, done in 1961, was the first the anti-sense RNA experiment."

The sentence is printed with that stumble in the original. The volume prints it as written.

Why it matters here

Part Sixty and Part Sixty-One established that an inverted repeat forming a double-stranded RNA is what recruits the adenosine deaminase, and that Alu pairs work as antennas by exactly this mechanism.

In 1961, before anyone knew what an editor was, the code laboratory established that a double-stranded RNA does not get read. Forty years later the field established that a double-stranded RNA gets edited. Same structure, two different consequences, discovered four decades apart.

---

551. The Solvent Nobody Knew ↩

The problem

They had to prove the radioactive product was polyphenylalanine. Table 1 of the paper lists what they put it through:

treatment	product of reaction	authentic poly-L-phenylalanine
6 N HCl, 8 h at 100°	partially hydrolyzed	partially hydrolyzed
12 N HCl, 48 h at 120–130°	completely hydrolyzed	completely hydrolyzed
33% HBr in glacial acetic acid	soluble	soluble
water, benzene, nitrobenzene, chloroform, N,N-dimethylformamide, ethanol, petroleum ether, concentrated phosphoric acid, glacial acetic acid, dioxane, phenol, acetone, ethyl acetate, pyridine, acetophenone, formic acid	insoluble	insoluble

Where the one came from

Michael Sela was the only person in the laboratory at the time who knew that Nirenberg had asked whether he knew anything about the solubility of polyphenylalanine.

"He said 'I do not know much, but I can tell you two things: one, polyphenylalanine is insoluble in most solvents; and second, it does dissolve in 15% hydrobromic acid dissolved in concentrated acetic acid.'"

Nirenberg had never heard of such a solution. Fifteen years later he learned that Michael Sela was the only person in the world who knew that polyphenylalanine dissolved in this esoteric solution, because Sela had mistakenly added it while looking at C-termini of proteins.

A single piece of accidental knowledge, held by one person on the planet, arrived by conversation in a corridor, and it is what let them characterize the product of the first codon assignment. Recorded here because this volume is a record of an archive assembled the same way.

---

552. Moscow, and the Audience of Thirty-Five ↩

The talk

Nirenberg was scheduled to give a talk in 1961 at the Fifth International Congress of Biochemistry in Moscow. Just before leaving, he married Perola Zaltzman, a biochemist from Rio de Janeiro who worked with Sidney Udenfriend at the NIH, and they planned to meet for a leisurely two-week vacation after the meeting.

He gave his talk to an audience of about thirty-five people.

Then Francis Crick, who was chairing a large symposium on nucleic acids, invited him to give the talk again — "which I did to an extraordinarily enthusiastic audience."

What happened at MIT

A few years earlier Severo Ochoa had been awarded the Nobel Prize with Marianne Grunberg-Manago for the discovery of polynucleotide phosphorylase, which catalyzes the synthesis of randomly ordered polynucleotides.

Nirenberg gave a talk at MIT. Peter Lengyel came up to the podium and told him that Ochoa's laboratory had used randomly ordered synthetic polynucleotides.

"While I was answering questions from the audience, Peter Lengyel came up to the podium and told me that he and others in Ochoa's laboratory had used randomly ordered synthetic polynucleotides."

Nirenberg's response to the competition, printed in full because it is the ethical center of the document:

"I found that I enjoyed competing, and I focused on solving the problems that we were investigating and on working more effectively, rather than on winning or losing. The competition stimulated me to become more focused and I accomplished far more than I would have in its absence. From the beginning I vowed never to cut corners or reduce the rigor with which experiments were done to win the competition. Therefore, the quality of our work remained high throughout the deciphering process."

And: "Ochoa was very gracious. He invited me to his laboratory and introduced me to his post-doctoral fellows, and we had tea in the library. Therefore, there was no way we could collaborate."

---

553. The Base Compositions, Before the Sequences ↩

Stage one

Between 1961 and 1964, Bill Jones, Bob Martin and Nirenberg determined the base compositions of RNA codons by directing amino acid incorporation using many randomly ordered polynucleotide preparations containing different combinations and proportions of bases.

Figure 6 gives the minimum number of kinds of bases necessary for template activity:

kinds of bases required	amino acids
one	PHE, PRO, LYS
two	LEU, LEU, HIS, ARG, ARG, ASP, ASP, SER, TYR, VAL, THR, ALA, GLU, MET, SER
three	ILE, CYS, TRP, GLN, ASN, ASN

And the proof that the code is a triplet code

Five poly(A-C) preparations were used. The observed codon frequencies were compared with the theoretical frequencies calculated from the base composition determined for each preparation.

result	
histidine	a triplet containing one A and two Cs
asparagine and glutamine	triplets containing two As and one C
threonine	two triplets or a doublet

The code was shown to be a triplet code by curve-fitting — plotting observed amino acid incorporation against theoretical codeword frequency as the ratio of A to C was varied, and seeing which curve the data lay on. Figure 7 of the paper.

The two laboratories that failed at it first

Mirko Beljansky told Nirenberg that during a year's sabbatical in Ochoa's laboratory, Ochoa had suggested he test whether synthetic polynucleotides could direct cell-free protein synthesis. Beljansky spent a year trying with poly(A) and was unsuccessful — because the polylysine product is a basic protein and is not precipitated by trichloroacetic acid. Tissières, in Jim Watson's laboratory, also tried with poly(A) and failed for the same reason.

Two laboratories tried the right experiment with the wrong homopolymer and missed the genetic code because the product would not precipitate. Nirenberg's laboratory used poly(U), and polyphenylalanine precipitates.

554. Sixty-Four Trinucleotides, and Fifteen Doublets ↩

The second stage

Trinucleotides had been neither synthesized previously nor isolated. The two enzymatic methods used are shown in Figure 10 of the paper:

(1) ApApG + UDP polynucleotide phosphorylase, Mg++\n(2) ApG + uridine 2',3'-cyclic phosphate RNase A

Leon Heppel had reported, in a single sentence in one of his papers, that in the presence of a high concentration of methanol, pancreatic RNase A catalyzes the synthesis of trinucleotides and higher homologs from oligoribonucleotide primers and pyrimidine 2′,3′-cyclic phosphates.

Marianne Grunberg-Manago was visiting Maxine Singer at the time. Both were experts on polynucleotide phosphorylase. Phil Leder and Richard Brimacombe joined them in optimizing the conditions.

The doublets, and the Customs Service

Phil Leder saw an advertisement offering 0.5 g of each of the 16 doublets for $1500 per doublet.

"Although expensive (a few years earlier my salary for 6 months was $1500), we brought the lot. However, we received only 15 doublets because the US Customs Service confiscated one and used it all to test for drugs."

doublets ordered	16
doublets received	15
price per doublet	$1500
Nirenberg's salary for six months, a few years earlier	$1500

One sixteenth of the raw material for deciphering the genetic code was consumed by a drug test.

The binding assay

Leon Heppel gave Nirenberg a doublet, a triplet and a hexanucleotide consisting only of U residues.

"I thought that the ternary complex, ³H-phenylalanine-tRNA–UUU trinucleotide–ribosome complex, would be retained by Millipore filters, whereas ³H-phenylalanine-tRNA would be washed through the filter. The first experiment worked beautifully; the trinucleotide, UUU, stimulated binding of ³H-phenylalanine-tRNA to ribosomes, but the doublet, UU, was without effect."

addition	¹⁴C-Lys-tRNA bound to ribosomes, µmoles
ApA	0.01
ApApA	1.92
ApApApA	1.92
ApApApApApA	1.92
ApApApApApApApA	2.71

Two bases: nothing. Three bases: everything. A hundred and ninety-two-fold step between the doublet and the triplet, and a flat line from three to six. The triplet nature of the code, in five numbers.

The labor

"It took my colleagues Philip Leder, Sid Pestka, Fritz Rottman, Richard Brimacombe, Charles O'Neal, French Anderson, Don Kellogg, Ty Jaouni, Merton Bernfield, Joel Trupin and myself about a year to synthesize the 64 trinucleotides and test each against about 20 different radioactive aminoacyl-tRNA preparations."

Fifty-four of the sixty-four codon sequences were published from this laboratory. Gobind Khorana and colleagues reported sequences determined using chemically synthesized trinucleotides.

---

555. Hypoxanthine in the Third Position ↩

The sentence

Robert Holley gave Nirenberg's laboratory a highly purified preparation of yeast alanine-tRNA —

Philip Leder and Nirenberg showed that this species recognizes the codons GCU, GCC and GCA.

And then, in the legend to Figure 13 and again in the body of the paper:

"Philip Leder and I showed that this species of alanine-tRNA recognizes the codons GCU, GCC and GCA, and that the nucleotide residue in the third position is hypoxanthine."

And in the figure legend: "Hypoxanthine in the tRNA anticodon recognizes U, C or A in the third position of RNA codons."

What that is

hypoxanthine	the base of inosine
the position	anticodon base 34 — the wobble position
what it reads	U, C or A
what it does not read	G

Part Fifty-Seven of this volume established, from the modern literature, that inosine has three wobble partners — U, C and A — and excludes G. Part Sixty-Nine placed it at the reading position. Part Seventy-Six counted eight such anticodons in eukarya.

Here is the same fact, in the first anticodon ever sequenced, printed by the man who broke the code, and printed by him again in 2004 in his own summary of what he did.

Why this is the center of the Part

The author of this volume has argued since September 2000 that hypoxanthine belongs in the genetic code as a letter and not as a footnote.

The record shows that hypoxanthine was in the first anticodon sequence anyone obtained. It was in the paper. It was in Nirenberg's own account of the paper forty-three years later. It reads three of the four third-position bases, which is more than any canonical base does.

Figure 14 of this paper is the genetic code as printed — sixty-four cells, four bases, three stop codons in red and AUG in green. Hypoxanthine does not appear in it.

The volume states this as a fact about the table and not as an accusation. A table of codons is a table of codons; the anticodon that reads them is a different object. But the man who built the table knew

what was in the third position of the first anticodon he sequenced, and this volume's argument is about what a notation leaves out.

And Francis Crick's word

"We soon found that the third bases of synonym RNA codons varied, and using purified aminoacyl-tRNA fractions we found four patterns of degeneracy. Francis Crick coined the term 'wobble' to describe the third-base degeneracy of RNA codons."

---

556. The Code Is Not Random, and It Is Universal ↩

The arrangement

class	second base	amino acids
hydrophobic	U	Phe, Leu, Ile, Met, Val
hydrophilic	A	Tyr, His, Gln, Asn, Lys, Asp, Glu

And chemically similar side chains have chemically similar codons — Asp with Glu, Asn with Gln.

"Clearly, the arrangement of codons and amino acids is not random."

This volume has argued the same thing from Part Twelve onward, on different grounds — that the table has structure, that the structure is chemical, and that a notation which records only identity cannot express it.

Universality

Thomas Caskey and Richard Marshall purified tRNA fractions from Xenopus embryos and hamster liver. Comparing the genetic code of E. coli with that of Xenopus and hamster, they found the code is essentially universal.

"These results had a profound philosophical impact on me because they indicate that all forms of life on this planet use essentially the same language. Some dialects have been reported subsequently in some organisms, but all are modifications of the same genetic code."

The group

Table 2 of the paper lists the post-doctoral fellows in the laboratory from 1961 to 1966. There were nine or fewer at any one time, and not all worked on the code.

Among the names: Heinrich Matthaei, Philip Leder, Sidney Pestka, Merton Bernfield, Fritz Rottman, Brian Clark, Joel Trupin, Richard Brimacombe, Richard Marshall, Thomas Caskey, Joseph Goldstein, Edward Scolnick, French Anderson, Arthur Beaudet, Michael Wilcox, Judith Levin, Frank Portugal — and Dolph Hatfield.

The name this volume stops on

Dolph Hatfield did his post-doctoral training with Nirenberg and appears on the 1966 Cold Spring Harbor paper "The RNA code and protein synthesis." He then spent his career at the National Cancer Institute on the biosynthesis of selenocysteine — the twenty-first amino acid in the genetic code, which has its own transfer RNA, its own codeword and its own specialized translational machinery.

A man trained in the laboratory that wrote the sixty-four-cell table spent the rest of his life on the amino acid the table does not contain. The volume records the line of descent and claims nothing more from it.

Part Twenty-Five of this volume dealt with the twenty-second amino acid and the selenium question. The connection runs through one person, and his name is in Table 2.

---

557. What Is Claimed, What Is Not, and What Would Show This Part Wrong ↩

Claimed

That Nirenberg came to NIH in 1957 with DeWitt Stetten Jr. after a biochemistry doctorate at Michigan, worked the next year with William Jakoby isolating a Pseudomonad on γ-butyrolactone and purifying three enzymes of γ-hydroxybutyric acid catabolism, and was offered an independent position by Gordon Tomkins in 1958.

That Bruce Ames told him the project was suicidal, and that Nirenberg wrote that the wish to explore was greater than the fear of failure.

That the three named technical advances were freeze-thaw conditions, a forty-minute DNase I pre-incubation, and aliquoting extracts for later use; and that Millipore filtration replaced an eight-to-ten day centrifugation protocol with a one-day one.

That Heinrich Matthaei prepared twenty ^{14}C amino acids by growing algae on ^{14}C-bicarbonate, that Nirenberg instructed him to test twenty solutions each with one radioactive amino acid, that Nirenberg was in Fraenkel-Conrat's laboratory in Berkeley at the time, and that after about a month Matthaei telephoned to report poly(U) stimulating incorporation of phenylalanine only.

That single-stranded poly(U) functions as messenger RNA while poly(U)–poly(A) double and triple helices do not, that poly(C) had little effect, and that Nirenberg describes this 1961 experiment as the first antisense RNA experiment.

That polyphenylalanine was insoluble in sixteen listed solvents and soluble in 33 percent HBr in glacial acetic acid, that Michael Sela supplied this fact, and that Nirenberg learned fifteen years later Sela was the only person in the world who knew it.

That Nirenberg married Perola Zaltzman, a biochemist who worked with Sidney Udenfriend, just before the 1961 Moscow congress; that he first spoke to about thirty-five people; and that Francis Crick invited him to repeat the talk to a large symposium.

That between 1961 and 1964 Bill Jones, Bob Martin and Nirenberg determined codon base compositions from randomly ordered polynucleotides; that poly(A-C) data established histidine as one A and two Cs and asparagine and glutamine as two As and one C; and that Beljansky in Ochoa's laboratory and Tissières in Watson's both failed with poly(A) because polylysine is not precipitated by trichloroacetic acid.

That sixteen doublets were offered at $1500 each, that fifteen were received because US Customs confiscated and consumed one testing for drugs, and that Nirenberg's salary for six months a few years earlier had been $1500.

That ApA bound 0.01 µmoles of ^{14}C-Lys-tRNA to ribosomes while ApApA bound 1.92, and that the sixty-four trinucleotides were synthesized and tested against about twenty aminoacyl-tRNA preparations in about a year, yielding fifty-four published codon sequences.

That Robert Holley supplied the yeast alanine-tRNA that was the first nucleic acid ever sequenced; that Leder and Nirenberg showed it reads GCU, GCC and GCA; and that Nirenberg states the residue in the third position of that anticodon is hypoxanthine, recognizing U, C or A.

That Crick coined "wobble"; that hydrophobic amino acids have U and hydrophilic amino acids have A as the second codon base; that Caskey and Marshall established universality against Xenopus and hamster; and that Table 2 lists the fellows, nine or fewer at a time, including Dolph Hatfield.

That Dolph Hatfield trained with Nirenberg and subsequently worked at the National Cancer Institute on selenocysteine, the twenty-first amino acid.

Not claimed

That the genetic code table is wrong. This Part records what the man who built it wrote, and what the table does and does not contain. Section 555 states plainly that a codon table and an anticodon are different objects.

That the field concealed hypoxanthine. It is printed in Nirenberg's own review. Part Seventy already ruled that the concealment claim does not go in this volume, and that ruling stands here.

That poly(U) being a uracil polymer has any bearing on the sulfur argument. Section 549 states the coincidence and takes nothing from it.

That Dolph Hatfield's later career on selenocysteine was caused by his training in the code laboratory. Section 556 records a line of descent, not a cause.

What would show this Part is wrong

— Show that the third-position residue of the Holley yeast alanine-tRNA anticodon is not hypoxanthine, and section 555 — the reason this Part is in the volume — fails. The primary reference is Nirenberg's citation 40, and the sequence is public.

— Show that inosine at the anticodon wobble position reads G, and both this section and Part Fifty-Seven fail together.

— Show that ApA stimulates lysyl-tRNA binding to ribosomes, and the triplet demonstration of section 554 fails.

— Show that poly(A) added to poly(U) does not abolish phenylalanine incorporation, and section 550 fails.

— Show that Dolph Hatfield was not a post-doctoral fellow in Nirenberg's laboratory, and section 556's line of descent is wrong. His name is in Table 2 of the paper and on the 1966 Cold Spring Harbor authorship.

PART SEVENTY-NINE · THE PROVENANCE

Part Seventy-Nine of the evidence volume, sections 558 to 570

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The dated record of the author's own position, from the archive: a 2012 ranking, a 2013 professional profile written in his own words, a family connection to the laboratory that broke the genetic code, and a page of margin arithmetic. Printed because a claim of priority needs a date, and these carry dates.

---

558. Why This Part Exists ↩

The problem every long project has

This volume argues a position about the genetic code that its author has held for a long time. How long is a question a reader is entitled to ask, and the answer needs to come from documents that were not written to answer it.

A dated professional profile, written years before this volume existed and for an entirely different purpose, is better evidence of what somebody believed and when than any statement made afterward.

What is printed here

document	date
LinkedIn notification: top one percent most viewed profiles for 2012	7 February 2013
the professional profile itself, with summary, projects and publications	captured 2013
project start date stated on that profile	September 2000
NovagonDNA start date stated on that profile	September 2001

document	date
the marked-up Nirenberg review with the family annotation	undated, in hand
the margin arithmetic and the selenium note	undated, in hand

And what this Part will not do

It will not use any of it as scientific evidence for the six-base or eight-base claim.

A profile is a record of a position, not a demonstration of it. The demonstrations are in Parts One through Seventy-Eight and stand or fall on their own. This Part establishes dates and nothing else, and says so before printing a single line.

---

559. The 2012 Ranking ↩

The notification, in full

from	LinkedIn
to	drjab699
dated	7 February 2013, 2:20 PM
subject	Congratulations! You have one of the top 1% most viewed LinkedIn profiles for 2012
stated platform size at that date	200 million members
the profile headline it was addressed to	John Berger (Triplex Genetic Code Developer)

What the number means

200,000,000 members\n× 0.01\n----------\n2,000,000 profiles in the top one percent

Two million is a large band, and the volume states that plainly rather than letting the percentage do work it cannot do.

What the notification establishes is narrower and more useful: that in 2012, a profile whose stated occupation was Triplex Genetic Code

Developer was among the most viewed on a professional network of two hundred million people. People were reading it.

The headline itself is the finding. In 2012 the author was already describing his occupation, in public, as the development of a revised genetic code.

---

560. The Family Connection, and What Could Not Be Verified ↩

What the author states

On the marked-up first page of the Nirenberg review, in the author's hand beneath Nirenberg's name:

"1st cousin — Shelby Berger — mar[ried] to..."

The annotation continues past the edge of the page and the remainder is not legible in the copy supplied.

The author's stated relationship: Shelby Berger is his first cousin, and she was married to a laboratory head who was a colleague of Nirenberg's at the National Institutes of Health.

What the volume was able to verify independently

verified	
Shelby L. Berger existed and worked at the National Institutes of Health	yes
her institute	National Cancer Institute, Bethesda, Maryland
her field	molecular biology, nucleic acid methodology

What the volume could not verify

not verified	
the cousin relationship	no independent source located
the identity of her husband	the annotation is cut off at the page edge; the volume will not guess a name

The volume records the author's statement as the author's statement, records what could be confirmed, and records what could not. It does not fill the gap. If the author supplies the rest of the annotation the volume will run the check and print the result either way.

This is the same standard applied to every other claim in seventy-eight Parts, and it is applied here to the author's own family because a volume that relaxes its rule for its author is not worth reading.

---

561. Shelby L. Berger and the Big Book ↩

The book

title	Guide to Molecular Cloning Techniques
series	Methods in Enzymology, Volume 152
editors	Shelby L. Berger and Alan R. Kimmel
series editors	John N. Abelson and Melvin I. Simon
publisher	Academic Press
year	1987
extent	xxvi + 812 pages
contributors	87
her affiliation on the volume	National Cancer Institute, National Institutes of Health, Bethesda, Maryland

What it is

Methods in Enzymology is the standard methods series of twentieth-century biochemistry. Volume 152 is a self-contained manual of recombinant DNA technique, running from the basic methods underlying the technology through a series of sections on commonly encountered problems, with editors' notes, overviews and cross-referencing throughout.

Eight hundred and twelve pages, eighty-seven contributing experts, and one of the two names on the spine is Berger. It was for a generation the book you went to in order to obtain a clone.

Why the volume prints it

Because the author asked for it to be looked up, and because it is worth having on the record that the surname appears on a standard reference of the field this volume is arguing with.

The volume claims nothing scientific from a family name. It records the bibliographic fact.

---

562. The 2013 Summary, Printed as Written ↩

The five numbered objectives, verbatim

1. Validate new 6 nucleotide triplex genetic code primer. Comparison validation study current 5 vs. 6 nucleotide DNA/RNA genetic code primer

2. Develop RNAi editing primer using proprietary 18-36 mer codon & anti-codon sequences to repair selected SNPs (Single Nucleotide Polymorphic Mutations).

3. Reveal the atomic genetic code primer; progenitor of current molecular level genetic code which is incorrect i.e. see above

4. Develop atomic organic crystalline enzyme catalysts to control gene regulation both suppression (switch off) and activation (switch on).

5. Have over 1 million "visioneering" context rich pictures/images (color coded) tracing functional side groups from interstellar space (comets, meteors) to current atomic molecular macromolecular compounds i.e. proteins, lipids, carbohyrdates, nucleic acids. Use polyhedral bravais (14 types molecular crystalline structures with symmetry operations) to specify exact 3 dimensional space coordinates of 230 lattice space (230/10) = 23 chromosomes, chromatin thermodynamics, string theory optical sequence strands and much much more.

And the stated objective

"My objective for the past 12 years is to gain enough knowledge to emulate nature, not try to improve on metabolic fractal non-linear algorithms which have developed over 3.6 billion years."

"Ultimate goal: replace the current watson-crick 5 nucleotide genetic code with Novagon DNA's six nucleotide; purine+pyrmidine (base pairs)."

"Use addition not substitution as the mathematical operator of the ~3.2 billion base pairs genome. Determine functionality of introns, inverted repeats, reverse transcriptase, alternative splicing and gene-quantum packets."

What this establishes

Twelve years, stated in 2013, places the start at 2001. The Novagon DNA entry on the same page gives September 2001 and eleven years six months, which agrees.

The addition-not-substitution operator, the six-nucleotide code, the inclusion of the inosine family, and the demand that introns and inverted repeats be assigned a function are all on a public profile page dated 2013 — years before the field's Alu and A-to-I literature that Parts Sixty through Sixty-Eight of this volume are built on had reached its present shape.

The volume records the date. It does not use the date as an argument for correctness.

---

563. The Dated Priority Claims ↩

Novagon DNA, from September 2001

"Add inosine family do not substitute thymine for uracil since both are necessary and sufficient for nucleotide, nucleic acid genetic code, codons, anti-codons, sulfur atomic organic isotopic alleles i.e. genes"

"Have developed a new nucleotide Rdna integrated genetic code with six nucleotides: 3 pyrmidines (U,T,C) and 3 purines (IAG). Can correct

RNA editing A to I deaminase SNPs, modulate glutamate & serotonin exposure to toxic NH3, and correct all the missense mutations in cDNA genomic arrays, servers"

"New integrated six nucleotide genetic code uses mathematical operator addition not substitution as primary genome growth process i.e. one male, one female, one new life form (baby new born). 2 + 1 = 3. Thymine is included in new Rdna code while Uracil remains and Inosine family is added. Three pairs of purine-pyrmidines pairings emerge (A+T), (U+I) C+G). Crick wobble anti-codons and mRNA editing (A to I) and (C to U) deamination (spontaneous equilibrium entrophic changes occurr in and by nature)."

The three pairs, as stated in 2013

$$A + T\nU + I\nC + G$$

Part Forty-Eight of this volume ruled on exactly this set — six as the reading set, closing under complement. The three pairs printed on a 2013 profile page are the three pairs the volume arrived at independently by a group-theoretic argument in 2026.

The Missing Purine Genetic Code, from September 2000

"Final Proof the hypoxanthine and xanthine family bases are not toxic to dna or rna synthesis, salvage, or elimination. The final study finding a new endonuclease Gene which repairs the hypoxanthine and xanthine families just as the deoxyglycolytic glycoprotein is releashed. The dITPase senior catalyst has the functional power to forestall hydrolysis and deamination so the correct transversal…"

Hypoxanthine and xanthine named together, as a family, as non-toxic, with dITPase named as the controlling enzyme — on a page dated to a start in September 2000.

Part Sixty-Four of this volume was built on the multiple-substrate dITP/dXTPase literature the author supplied. Part Seventy-Eight, section 555, records Nirenberg's own statement that hypoxanthine sits in the third position of the first anticodon ever sequenced.

The claim on the profile predates the volume by twenty-six years.

564. The Margin Arithmetic: Thirty-Six Over One Thousand and Seventy ↩

What is written in the margin

36\n------ = .03333\n1070\n1070\n36\n------\n1070\n.03364486

What the volume can check

36 ÷ 1070 = 0.033644859813…\nrounded to eight places: 0.03364486 ← the second computation, correct\nthe first line reads: .03333 ← this is 36 ÷ 1080, not 36 ÷ 1070

The author computed it once, got a figure that is what you obtain if you divide by 1080, wrote the divisor down again on its own line as if checking it, and recomputed. The second answer is correct to eight decimal places.

The volume records this because it is the working of somebody who caught his own arithmetic error and fixed it on the page, and that is the habit this whole volume runs on.

What the ratio is of

Not stated on the sheet. The volume does not know what thirty-six and one thousand and seventy count, and will not invent an interpretation.

Three point three six percent of something. The number is recorded, the arithmetic is checked, and the referent is left open until the author supplies it.

565. Chaos: the Seven-word Sequence ↩

What is written

Down the left margin, the word CHAOS set vertically, with a sequence of terms beside it:

C\nH Random\nA Reorder\nO Identity\nS
Seed\nRemix\nRestart\nReact

What the volume takes from it

Seven operations, written as a cycle rather than a list.

the term	the operation it names
Random	disorder introduced
Reorder	a permutation applied
Identity	the operation that changes nothing
Seed	an initial condition set
Remix	recombination
Restart	return to the initial condition
React	chemistry

Six of the seven are operations on a set. Identity is in the middle of the list, and identity is the element every group must contain. Part Forty-Eight and Part Fifty-Seven of this volume are built on group structure — complement, transversion, transition, and the identity that closes them into a Klein four-group.

The volume records that the author wrote "Identity" in a list of transformations in a margin, and claims nothing about when or why. It is a note, not a proof. But it is the right word in the right company.

---

566. Selenium Sensors, and the Man in Table 2 ↩

What is written, circled

Sensers\neyes eye\neyes ear\ndevelop space volume\nwalion membrane salt\n(SELENIUM SENSORS)

The two words at the bottom are circled in the author's hand.

Why the volume stops here

Part Twenty-Five of this volume dealt with selenium and the twenty-first and twenty-second amino acids. Part Seventy-Eight, section 556, records that Dolph Hatfield —

a post-doctoral fellow in Nirenberg's laboratory during the deciphering, listed in Table 2 of Nirenberg's own account — spent his subsequent career at the National Cancer Institute on the biosynthesis of selenocysteine, the twenty-first amino acid in the genetic code.

selenocysteine	has its own transfer RNA
	has its own codeword
	has its own specialized translational machinery
and it is not in the sixty-four-cell table	

A margin note circling the words "selenium sensors," in a private archive in Illinois, and a career at the National Cancer Institute on the amino acid the printed code omits, begun by a man who trained in the laboratory that printed it. The volume records both and connects them only as a matter of record.

Selenium sits directly below sulfur in the periodic table. Part Thirty-Eight of this volume is about the sulfur-oxygen conjugate pair; selenium is the next step down the same column. The author's note is in the volume's territory.

---

567. The Endorsement Census ↩

Most endorsed, as of the 2013 capture

skill	endorsements
Genomics	39
Genetics	25
Bioinformatics	22
DNA	19
Protein Chemistry	12
Genetic Algorithms	11
Computational Biology	11
Sequence Analysis	9
Microarray Analysis	9
Molecular Biology	8

The long tail, and what is in it

Below the top ten, at counts of one or two, the profile lists subjects that this volume has spent seventy-nine Parts on:

subject	endorsements
Nucleic Acid Metabolism	1
Sulfur Quantum…	1
Purine & Pyrimidine…	1
RNA editing	1
Bravais Crystalline…	1
Genetic Mutations (SNPs)	1
Optical Thermodynamic…	1
Visioneering Compressed…	1
Fractal Geometry	1
dRNA primer design	1
Triplex Genetic Code	1
Genetic Code Evolution	5

And connections: 500+, with a stated profile strength of All-Star.

Thirty-nine people endorsed him for genomics. One endorsed him for the triplex genetic code. One for sulfur quantum. One for RNA editing.

The volume prints the distribution without comment on what it means, except this: the subjects at a count of one are the subjects this volume is made of. That is what a position ahead of its audience looks like in a table of endorsements.

---

568. Nobody, and Dr Know It All ↩

What the record says about the team

The Missing Purine Genetic Code, September 2000 to present, lists two team members:

John Berger	Triplex Genetic Code Developer
Nobody	—

The publication entry, Triplex Genetic Code, lists two authors:

John Berger	Triplex Genetic Code Developer
DrKyia (Dr Know It All)	"was coauthor bu..."

What the volume records

The author entered a second team member into a structured field and typed the word Nobody.

That is a fact about a thirteen-year project on a public professional record, and the volume prints it without decoration. From September 2000 to the 2013 capture, the stated team was one person.

Part Seventy-Eight, section 556, records Nirenberg's Table 2: nine or fewer post-doctoral fellows at any one time, over five years, plus Robert Martin, Leon Heppel, Maxine Singer and Marianne Grunberg-Manago, plus Fritz Lipmann's transfer enzyme, plus Michael Sela's solvent, plus Robert Holley's tRNA preparation.

The genetic code was broken by a group. The proposal to revise it was carried for thirteen years by one man and an entry that says Nobody. Both facts are in the record, and the volume puts them on facing pages because the contrast is the point.

---

569. What the Provenance Establishes and What It Does Not ↩

Established

First. That by 2012 the author's publicly stated occupation was Triplex Genetic Code Developer, and that the profile carrying that headline was among the most viewed on a network of two hundred million.

Second. That claims dated to September 2000 and September 2001 name hypoxanthine and xanthine as a non-toxic family, name dITPase as the controlling enzyme, name A-to-I and C-to-U deamination as the editing channels, and print the three base pairs A+T, U+I and C+G.

Third. That the operator is stated as addition rather than substitution, and that this is the distinguishing formal move of the whole program, stated in 2013 and unchanged since.

Fourth. That the author's margin working shows an arithmetic error caught and corrected on the same sheet.

Not established

A date is not a demonstration. Priority is not correctness. A person can hold a position for twenty-six years and be wrong for twenty-six years, and this volume has said so about specific claims in Part Seventy and again in Part Seventy-Six.

What the dates do is dispose of one specific counter-argument — that the position was assembled after the fact to fit the literature. It was not. The literature of Parts Sixty through Sixty-Eight arrived after the profile, not before it.

That is a narrow finding and the volume states it narrowly.

---

570. What Is Claimed and What Would Show This Part Wrong ↩

Claimed

That a LinkedIn notification dated 7 February 2013 states the recipient held one of the top one percent most viewed profiles for 2012 on a platform of 200 million members, addressed to John Berger (Triplex Genetic Code Developer).

That the 2013 profile capture states five numbered objectives, a twelve-year duration, the goal of replacing a five-nucleotide code with a six-nucleotide code, and the use of addition rather than substitution as the operator; and that it lists Novagon DNA from September 2001 (eleven years six months), drJab & Associates from September 1986 to September 2001, Assistant Professor at Roosevelt University September 1989 to September 1992, and the Missing Purine Genetic Code project from September 2000.

That the Novagon DNA entry names the inosine family, three pyrimidines U, T, C and three purines I, A, G, the pairs A+T, U+I and C+G, A-to-I and C-to-U deamination, and Crick wobble anticodons.

That the Missing Purine entry names hypoxanthine and xanthine as non-toxic families and names dITPase.

That education is listed as Illinois Institute of Technology PhD 1979–1982, University of Dayton Masters 1973–1975, and Vanderbilt University BS 1969–1972; and that endorsement counts are as listed in section 567 with 500+ connections.

That the margin arithmetic reads 36/1070 with a first result of .03333 and a second of .03364486, and that the volume computed 36 ÷ 1070 = 0.033644859813 and 36 ÷ 1080 = 0.03333, confirming the second and identifying the first as division by 1080.

That the margin carries the vertical word CHAOS beside the terms Random, Reorder, Identity, Seed, Remix, Restart, React; and that "SELENIUM SENSORS" is circled.

That the author states in his own hand that Shelby Berger is his first cousin and was married to a laboratory head and colleague of Nirenberg's, and that the annotation is cut off at the page edge.

That Shelby L. Berger co-edited Methods in Enzymology Volume 152, Guide to Molecular Cloning Techniques, with Alan R. Kimmel, published by Academic Press in 1987, xxvi + 812 pages, 87 contributors, with her affiliation given as the National Cancer Institute, NIH, Bethesda.

That the project record lists "Nobody" as the second team member and "DrKyia (Dr Know It All)" as the second author.

Not claimed

That the cousin relationship is verified. Section 560 states that it could not be independently confirmed and that the volume will not guess the husband's name.

That any family connection bears on the science. Section 561 states this outright.

That a top-one-per-cent ranking is evidence of correctness. Section 559 computes the band at two million profiles and says so.

That priority is correctness. Section 569 states the opposite in as many words.

That the volume knows what 36 and 1070 count. Section 564 states that it does not.

What would show this Part is wrong

— Produce the profile with a different date, or the Missing Purine entry with a start date later than September 2000, and the priority finding of section 563 fails.

— Show that Shelby L. Berger did not edit Methods in Enzymology Volume 152, or was not at the National Cancer Institute, and section 561 is wrong.

— Show that 36 ÷ 1070 is not 0.03364486, and section 564's verification is wrong. It is checkable on any calculator, which is why it is printed.

— Produce a dated document from before September 2000 in which another party states the A+T, U+I, C+G pairing with addition as the operator, and the priority claim of section 563 belongs to somebody else. The volume would print that and say so.

PART EIGHTY · TWO MUTATIONS IN ONE GENE

Part Eighty of the evidence volume, sections 571 to 583

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

PSEN2, presenilin 2, chromosome 1q42.13. Its two commonest pathogenic mutations do two different things to this volume's argument. One swaps a queuosine reader for an inosine reader without moving the wobble base. The other is, at the level of chemistry, an adenosine-to-inosine edit written into the DNA.

---

571. One Gene, Two Mutations, Two Different Lessons ↩

What is on the table

At least eleven mutations in PSEN2 cause early-onset Alzheimer's disease. They account for fewer than five percent of all early-onset cases. Two of them are the common ones.

	N141I	M239V
amino acid change	asparagine → isoleucine	methionine → valine
cDNA change	c.422A>T	c.715A>G

	N141I	M239V
class	transversion	transition
first reported	Levy-Lahad and colleagues, 1995	Rogaev and colleagues, 1995
founder population	seven Volga German families	an Italian kindred, FL010
reference SNP	rs63750215	rs28936379

The two findings, stated before the arithmetic

First. N141I changes the second base of the codon, not the third. The wobble base is untouched. And yet the transfer RNA that reads that codon changes from one carrying queuosine at position 34 to one carrying inosine at position 34. Two hypermodified purines, neither in the four-letter alphabet, on either side of the most studied mutation in the Volga German pedigrees.

Second. M239V is an adenosine-to-guanosine transition at the first position of the codon. That is precisely the chemistry an adenosine deaminase acting on RNA performs, and the protein product is identical whether the change is written into the DNA permanently or into the messenger RNA transiently.

One of these is a mutation the editor could never make. The other is a mutation the editor makes for a living.

---

572. The Gene, and Its Eleven Names ↩

What it is

locus	chromosome 1q42.13
product	presenilin 2, a membrane protein
complex	the γ-secretase complex
substrate	amyloid precursor protein
products of cleavage	soluble APP (sAPP) and amyloid beta peptide

Presenilin 2 also processes proteins that carry chemical signals from the cell membrane into the nucleus, where those signals activate genes governing cell growth and maturation.

Soluble APP has growth-promoting properties and may have a role in the formation of neurons both before and after birth. The same enzyme complex makes the peptide that builds plaques and the peptide that appears to help build the brain.

The names it goes by

PSEN2 presenilin 2 (Alzheimer disease 4)\nAD3L AD3-like protein\nAD3LP\nAD4\nAD5\nE5-1\nPS2 PS2 protein (Alzheimer-associated) \nPSN2_HUMAN\nPSNL2\nSTM2\nCMD1V

Eleven designations for one gene, of which the oldest — AD3-like protein — records that it was first recognized by resemblance to something else. The volume notes this without comment beyond observing that a naming system carrying eleven aliases is not a naming system that has settled.

---

573. The Codon Arithmetic ↩

Locating the codons from the cDNA coordinates

codon number = ceiling(cDNA position / 3)\nposition in codon = cDNA position - 3 x (codon number - 1)

	c.422	c.715
codon number	141	239
codon spans	c.421 to c.423	c.715 to c.717
position within the codon	2 of 3	1 of 3
exon	6	—

The codons themselves

N141I A A C --> A U C asparagine --> isoleucine\n^ position 2, A to T (DNA) / A to U (RNA)\ntransversion: purine --> pyrimidine\nM239V A U G --> G U G

methionine --> valine\n^ position 1, A to G\nTRANSITION: purine --> purine

The wild-type codon at 141 is AAC and the mutant is AUC, confirmed against the ALZFORUM record. The third base is C before the mutation and C after it. It does not move.

---

574. N141i: the Reader Changes, the Wobble Base Does Not ↩

What reads asparagine in a human cell

codon	anticodon	base 34	tRNA gene copies	share
AAC	GUU	queuosine	1859	0.95
AAU	AUU	—	92	0.05

Asparagine is read overwhelmingly by a single transfer RNA species whose wobble base has been replaced by queuosine.

What reads isoleucine

codon	anticodon	base 34	tRNA gene copies	share
AUU	AAU	inosine	953	0.74
AUC	GAU	G	42	0.03
AUA	UAU	pseudouridine	300	0.23

The mutant codon AUC has only forty-two dedicated transfer RNA genes of its own.

But inosine at position 34 pairs with U, C and A. The inosine-bearing anticodon IAU reads AUU, AUC and AUA alike.

So the AUC codon created by the mutation is read chiefly by the inosine transfer RNA — nine hundred and fifty-three gene copies against forty-two.

The result stated plainly

before the mutation A A C read by queuosine · C\nafter the mutation A U C read by inosine · C\nthe wobble base of the codon: C before, C after — unchanged\nthe modified base doing the reading: Q --> I

A single substitution at codon position two, nowhere near the wobble, and the identity of the chemically modified base that performs the reading changes from queuosine to inosine. The pairing partner on the codon side never moves.

The volume records this as an observation about the reading apparatus and offers no mechanism by which it contributes to disease. It is stated because the four-letter notation cannot express any part of it.

---

575. Queuosine and Inosine: Two Modified Purines, One Pairing Partner ↩

What the two bases are

	queuosine	inosine
derived from	guanosine — a 7-deazaguanosine	adenosine — by deamination
the operation that makes it	ring carbon substituted for nitrogen, plus a cyclopentene side chain	loss of the exocyclic amine
who can synthesize it	bacteria	the cell itself, by ADAT2/ADAT3
how humans obtain it	salvage, from diet and gut bacteria	made in place
pairs at the wobble with	C	U, C and A
symbol in the four-letter alphabet	none	none

The symmetry

The wild-type reader carries a modified guanine. The mutant reader carries a modified adenine. Both are purines, both are hypermodified, both pair with the same cytosine, and the notation writes neither.

Part Seventy-Six recorded, from the three-domain census, that G_{34} is modified to preQ1 in bacteria and to queuosine in eukarya, and is not modified at all in archaea. Part Fifty-Seven established that inosine reads U, C and A and excludes G. Part Sixty-Nine placed both at the reading position.

This section is where those three facts meet a named human disease mutation.

And the dietary line

Humans do not make queuosine. The base in ninety-five percent of the transfer RNA that reads asparagine in every cell of the body arrives from gut bacteria and from food.

The volume records that as a fact about the reading machinery and draws no clinical inference from it. It is stated because a codon whose reading depends on a nutrient obtained from another organism is not a codon that a four-letter table describes completely.

---

576. M239v Is a Transition, and It Is the Editor's Own Chemistry ↩

The change

c.715 A --> G position 1 of codon 239\nA U G --> G U G\nMet Val

What adenosine deaminase acting on RNA does

ADAR removes the exocyclic amine from adenosine, producing inosine. The ribosome reads inosine as guanosine. The net effect on the protein is an A-to-G substitution.

Therefore

the genomic mutation A U G --> G U G --> valine\nan A-to-I edit at c.715 A U G --> I U G --> valine\n^\ninosine, read as G

The two routes produce the same amino acid at the same position in the same protein. The ribosome cannot distinguish them. The difference between them exists only in where the change was written and how long it lasts.

	the genomic mutation	an edit at the same position
where written	DNA	messenger RNA
heritable	yes, autosomal dominant	no
duration	permanent, every cell, every transcript	transient, transcript by transcript
visible to DNA sequencing	yes	no
protein produced	presenilin 2 with valine at 239	presenilin 2 with valine at 239

The genomic version was found by Rogaev and colleagues in 1995 in all four affected members of an extended Italian pedigree with pathologically confirmed familial Alzheimer's disease and onset at or before fifty years of age.

577. Methionine Has One Codon and One Modified Reader ↩

The residue the mutation removes

methionine codons	one — AUG
the anticodon that reads it	CAU
base 34	2′-O-methylcytidine (Cm)
tRNA gene copies	1486

Methionine is the only amino acid besides tryptophan with a single codon, and that codon is read by a transfer RNA whose wobble base carries a methyl on the ribose oxygen — a methyl delivered by S-adenosylmethionine, which is itself made from methionine.

The amino acid that donates the methyl is read by a transfer RNA that carries one.

And what the mutation moves it into

codon	anticodon	base 34	tRNA gene copies	share
GUU	AAC	inosine	758	0.41
GUC	GAC	G	52	0.03
GUG	CAC	C, unmodified	611	0.33
GUA	UAC	ncm⁵U	432	0.23

M239V moves the residue out of a 2′-O-methylated reading box and into the one valine codon read by a plain, unmodified cytidine. Of the four valine codons, GUG is the only one whose reader carries nothing at position 34.

Part Seventy-Five recorded roughly one hundred 2′-O-methyl groups on vertebrate ribosomal RNA, all of them from a sulfonium. This is the same chemistry on a transfer RNA, and losing it is what the mutation does at the level of the reading apparatus.

---

578. What the Notation Cannot Distinguish ↩

The four objects

Consider four molecules of presenilin 2 messenger RNA, all carrying G at the first position of codon 239 as the ribosome sees it:

	how the G got there	what a DNA sequencer sees	what a protein assay sees
1	inherited genomic mutation	A>G at c.715	valine at 239
2	somatic mutation in one cell	A>G in that cell only	valine at 239
3	A-to-I edit by ADAR	nothing	valine at 239
4	transcription error	nothing	valine at 239

Four different events, three of which the four-letter notation cannot record at all, and one protein. This is the volume's central claim reduced to a single codon in a single named gene with a named disease attached.

The general form

Part One argued that a notation determines what gets counted. Here is the cost of that, priced:

the alphabet records: identity of the base in the DNA\nthe alphabet cannot record: whether that base was edited\nwhether it was modified\nwhich modified base read it\nwhether the change was permanent or transient

And every one of those four unrecorded properties is chemically real, is measurable by a different assay, and changes nothing about what comes off the ribosome.

579. The Complication, Printed Because It Runs Against This Part ↩

The direction problem

Part Sixty-Seven recorded, from the published Alzheimer's data, that protein recoding by adenosine-to-inosine editing is reduced in Alzheimer's disease — the unedited form of the serotonin 2C receptor rising from forty-five to fifty-eight percent in hippocampus.

If editing at PSEN2 c.715 produced the pathogenic M239V substitution, then less editing would be protective, and Alzheimer's brains — which edit less — would be expected to carry less of the harmful valine form, not more.

That runs opposite to the direction the volume would want. The volume prints it here rather than in a footnote, because a Part that only lists the evidence pointing its way is not evidence.

What the complication does and does not damage

It does not damage section 576, which is a statement about chemistry: an A-to-I edit at c.715 would produce valine at 239. That is arithmetic and it holds regardless of biology.

It does damage any claim that editing at this site contributes to sporadic Alzheimer's disease. This Part makes no such claim, and section 582 says so.

A reader who wants the direction to work would need editing at c.715 to be protective in the wild-type context, or would need the site to matter in some tissue or stage where the global editing picture is different. Neither is established and neither is asserted here.

580. The Experiment This Part Generates ↩

Experiment: is PSEN2 c.715 an editing site?

The volume searched and found no published evidence that PSEN2 c.715 is a substrate for adenosine deaminase acting on RNA. That is not a finding. It is an unopened question, and it is cheap to open.

tissue	human brain, prefrontal cortex and hippocampus; matched Alzheimer's and control
material	total RNA and matched genomic DNA from the same subject
method one	amplicon sequencing of PSEN2 exon 7 across c.715 from cDNA, compared against the same subject's genomic DNA
the signal sought	A in the DNA, mixed A and G in the cDNA, at c.715
method two	ICE-seq — acrylonitrile cyanoethylation of inosine N1, which blocks reverse transcription and marks inosine positions directly
control	a known edited site in the same library, and a known unedited adenosine
negative result	c.715 shows no A-to-G discrepancy between DNA and cDNA in any subject

What each outcome would mean

If the site is edited: a pathogenic familial Alzheimer's substitution is being produced transiently, by enzyme, in ordinary brains, and no DNA-based diagnostic would ever see it.

If the site is not edited: section 576 stands as a statement about chemistry and coincidence, the volume records the negative, and this Part loses its clinical edge while keeping its notational one.

The volume states in advance that it expects the second outcome. AUG codons in coding sequence are not common editing substrates, because the enzyme requires a double-stranded structure and most coding adenosines do not sit in one.

The prediction is recorded before the experiment so that a negative result cannot afterward be described as expected all along.

581. Why Psen2 and Not Some Other Gene ↩

The reason this gene carries the argument

Three properties, none of which the volume selected for:

the two commonest mutations sit in different chemical classes	**one transversion, one transition**
the transition is exactly the editor's product	A to G, first codon position
the transversion crosses a modification boundary	queuosine reader to inosine reader

The volume did not go looking for a gene with these properties. The two mutations are the two the public reference materials name as the common ones, and they turned out to be a matched pair.

And the founder histories

N141I was carried out of the Hesse region of Germany by families who emigrated to the Volga River region of Russia in the 1760s, and it is present today in the United States, Germany and Argentina. It is absent from the gnomAD control databases and is the most common PSEN2 mutation worldwide.

A single adenosine, changed once before 1760, at the second position of the one hundred and forty-first codon of a gene on chromosome one, tracked across two and a half centuries and three continents by the disease it causes.

The volume records the history because it is a demonstration of what the four letters do well. They are an excellent instrument for tracking a heritable change through a pedigree. That is what they were built for, and Part Seventy-Eight records the men who built them.

The argument of this volume is not that the notation fails at its own job. It is that its job is narrower than the use it has been put to.

---

582. What Is Claimed and What Is Not ↩

Claimed

That PSEN2 lies at chromosome 1q42.13, encodes presenilin 2 as part of the γ-secretase complex, cleaves amyloid precursor protein into soluble APP and amyloid beta peptide, and carries the aliases AD3L, AD3LP, AD4, AD5, E5-1, PS2, PSN2_HUMAN, PSNL2, STM2 and CMD1V.

That at least eleven PSEN2 mutations cause early-onset Alzheimer's disease and account for fewer than five percent of early-onset cases; and that N141I and M239V are named as the two commonest.

That N141I is c.422A>T in exon 6, changing codon AAC to AUC — an A to T transversion at the second position of codon 141 — reported by Levy-Lahad and colleagues in 1995 in seven Volga German families, cataloged as rs63750215, absent from gnomAD controls, and present in the United States, Germany and Argentina.

That M239V is c.715A>G, changing codon AUG to GUG — an A to G transition at the first position of codon 239 — reported by Rogaev and colleagues in 1995 in four affected members of an Italian pedigree with onset at or before fifty, and cataloged as rs28936379.

That in eukaryotes asparagine codon AAC is read by anticodon GUU carrying queuosine at position 34, with 1859 transfer RNA gene copies against 92 for AAU; that isoleucine codons AUU, AUC and AUA are read by anticodons AAU (inosine, 953 copies), GAU (G, 42 copies) and UAU (pseudouridine, 300 copies); that inosine at position 34 pairs with U, C and A; and that the mutant AUC codon is therefore read chiefly by the inosine-bearing transfer RNA.

That the third base of codon 141 is C before the mutation and C after it.

That methionine has a single codon AUG read by anticodon CAU carrying 2′-O-methylcytidine at position 34 with 1486 gene copies; and that valine codon GUG is read by anticodon CAC carrying unmodified cytidine, 611 copies, the only one of the four valine codons whose reader carries no modification at position 34.

That adenosine deaminase acting on RNA converts adenosine to inosine, that the ribosome reads inosine as guanosine, and that an edit at PSEN2 c.715 would therefore yield valine at residue 239 — the same protein product as the genomic mutation.

That queuosine is a 7-deazaguanosine derivative synthesized by bacteria and obtained by humans through salvage, and that inosine is produced from adenosine by deamination.

Not claimed

That PSEN2 c.715 is an editing site. Section 580 states that no published evidence was found, records the experiment, and states in advance that the volume expects a negative result.

That A-to-I editing contributes to Alzheimer's disease through PSEN2. Section 579 prints the directional argument against it in the body of the Part rather than in a footnote.

That the queuosine-to-inosine crossing of section 574 contributes to the pathogenicity of N141I. It is an observation about the reading apparatus and no mechanism is offered.

That the dietary origin of queuosine has any clinical bearing here. Section 575 states the fact and declines the inference.

That the four-letter notation fails at tracking heritable variants. Section 581 states the opposite: that is the job it does well and the job it was built for.

---

583. What Would Show This Part Is Wrong ↩

- Show that PSEN2 N141I is not c.422A>T, or that the wild-type codon is not AAC, and the transversion classification and the whole of section 574 fail. Both are in ClinVar and ALZFORUM under rs63750215.
- Show that PSEN2 M239V is not c.715A>G, and section 576 — the reason this Part exists — fails completely. It is in ClinVar under rs28936379 and VCV000008846.
- Show that inosine at anticodon position 34 does not pair with C, and the AUC codon is not read by the inosine transfer RNA, and section 574 fails.
- Show that human asparagine transfer RNA does not carry queuosine at position 34, and the crossing of section 574 has no boundary to cross.
- Show that the ribosome does not read inosine as guanosine, and section 576's equivalence collapses. This one cannot be shown; it is the basis of wobble decoding and of Part Fifty-Seven.
- Run the experiment of section 580 and find PSEN2 c.715 edited, and this Part becomes a great deal more consequential than it currently claims to be. The volume has recorded its expectation of the opposite result in advance.
- Show that the transfer RNA gene counts differ materially from 1859, 953, 42, 300, 1486 and 611 in a current build of the genomic transfer RNA database, and the quantitative claims of sections 574 and 577 need recounting. The database is named — gtrnadb.ucsc.edu — so this is checkable in an afternoon.

PART EIGHTY-ONE · THE CROSSED GRAPHS

Part Eighty-One of the evidence volume, sections 584 to 596

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The purine and pyrimidine biosynthetic routes are two squares on the same eight symbols. They do not line up. The gatekeeper sits inside one square and outside the other, and the branch that makes adenine is the same operation as the branch that makes cytosine — which are the two bases that do not pair with each other.

584. The Question This Part Answers ↩

The author's own objection to his own scheme

This volume orders the purines I X G A and the pyrimidines U O C T, and colors xanthine and orotate alike because both are gatekeepers.

The author raised the following objection against his own arrangement:

"IMP generates XMP and XMP is the gatekeeper to GMP, while OMP is the gatekeeper to UMP. Somehow the one-to-one correspondence order does not match. XMP follows IMP but UMP follows OMP. Both are colored indigo in my color scheme. Something is amiss."

The objection is correct

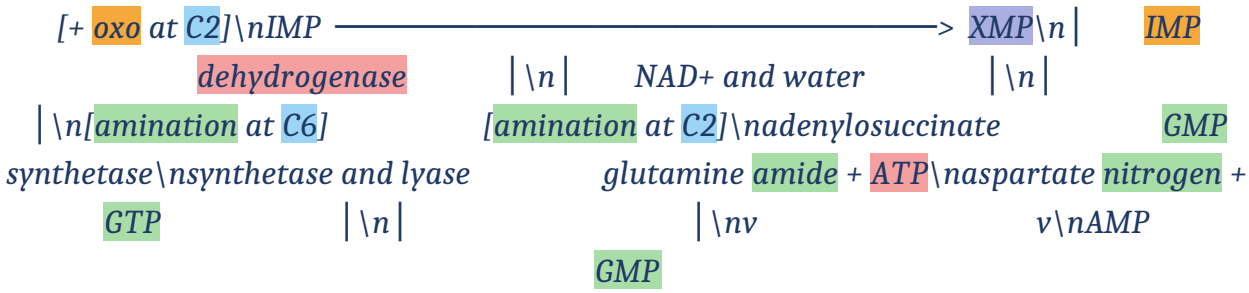
Something is amiss, the author found it, and this Part establishes exactly what it is.

The mismatch is real and it is not a defect in the notation. It is a genuine asymmetry between the two biosynthetic routes, it has a chemical cause that can be named atom by atom, and working it out produces a result about base pairing that this volume did not previously hold.

A volume that prints an author's objection to his own scheme, and then finds the objection sound, is behaving the way this volume has claimed to behave for eighty Parts. This section exists to say so before the argument begins.

585. The Purine Square ↩

The route, drawn as it is



What each corner is

	base	ring substituents
IMP	hypoxanthine	6-oxo
XMP	xanthine	2-oxo, 6-oxo
AMP	adenine	6-amino
GMP	guanine	2-amino, 6-oxo

Ten enzymatic steps assemble the purine ring directly on the ribose, and the first complete purine nucleotide the cell makes is inosine monophosphate.

The branch point of purine biosynthesis is a nucleotide whose base is hypoxanthine. Every adenine and every guanine in every organism passes through it.

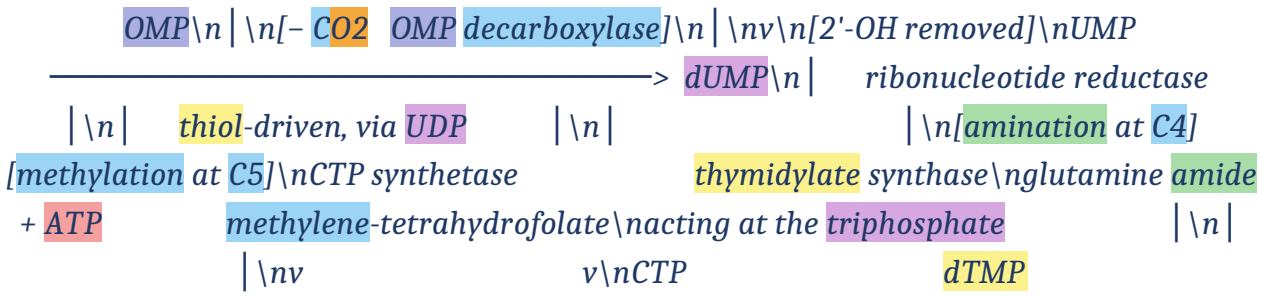
And the reciprocal requirement

making AMP from IMP requires	**GTP**
making GMP from XMP requires	ATP

Each branch is paid for in the currency of the other. The pathway cannot run away toward one purine without depleting the fuel for that branch.

586. The Pyrimidine Square ↩

The route, drawn the same way



What each corner is

	base	ring substituents
OMP	orotate	2-oxo, 4-oxo, 6-carboxyl
UMP	uracil	2-oxo, 4-oxo
CTP	cytosine	2-oxo, 4-amino
dTMP	thymine	2-oxo, 4-oxo, 5-methyl

The route is built the other way round

The pyrimidine ring is assembled free, from carbamoyl phosphate and aspartate, and the ribose is attached afterward by orotate phosphoribosyltransferase.

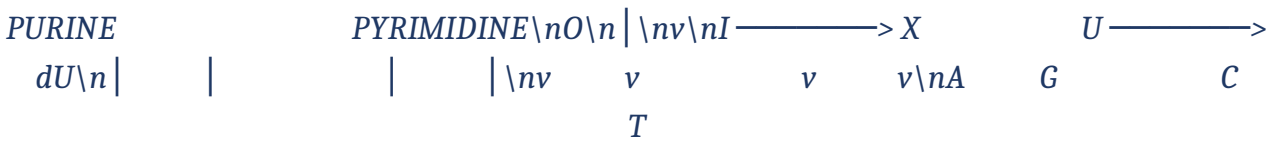
SEE PART NINETY-SEVEN. The ribose attached here is PRPP, and it is the same activated sugar the purine ring of this section is grown upon. Section 799 sets the two assembly orders side by side; this sentence is where the volume first recorded half of it.

	purines	pyrimidines
where the ring is built	on the sugar	free, then attached
the first complete nucleotide	IMP	OMP
the branch-point nucleotide	IMP	UMP

In the purine route the first nucleotide made and the branch point are the same molecule. In the pyrimidine route they are not. That single difference is the whole of the mismatch.

587. Where the Correspondence Fails: X Is Inside, O Is Outside ↩

The two squares laid against each other



XMP is a corner of the purine square. It sits on the branch from the branch-point nucleotide to guanine.

OMP is not a corner of the pyrimidine square at all. It sits upstream of the branch point, and its only function is to become uridine monophosphate.

Therefore

the positional counterpart of XMP	**dUMP, not OMP**
the positional counterpart of OMP	nothing

OMP is the only member of the eight-symbol set with no counterpart in the other series. There is no purine that stands upstream of inosine monophosphate in the way that orotidine monophosphate stands upstream of uridine monophosphate.

And that is why the arrows run opposite ways

In the purine string I X G A, the flow runs forward from position one to position two: I becomes X.

In the pyrimidine string U O C T, the flow runs backward from position two to position one: O becomes U.

The author observed exactly this and called it amiss. It is not an error in his ordering. It is a fact about the two pathways, and the next section says why.

588. What Each Gatekeeper Carries: an Atom Kept, an Atom Discarded ↩

The chemical cause of the directional mismatch

Both gatekeepers differ from their downstream product by one substituent. What happens to that substituent is opposite.

	XMP	OMP
the extra substituent	an oxo at C2	a carboxyl at C6
what happens to it	converted to an amino group by GMP synthetase	released as carbon dioxide by OMP decarboxylase
is the atom kept?	yes — it becomes part of guanine	no — it leaves the molecule entirely
the step is therefore	constructive	subtractive

The purine gatekeeper carries an atom forward. The pyrimidine gatekeeper carries an atom that must be thrown away. That is why one is a step into the square and the other is a step that has to be undone before the square can begin.

And it names the operator

The author's own formulation, stated on a public record in 2013 and recorded in Part Seventy-Nine section 563: use addition not substitution as the mathematical operator.

The purine route runs by addition. The pyrimidine route reaches its branch point by subtraction. The two halves of the nucleotide panel are built by opposite operations, and the two gatekeepers are where that shows.

The enzyme that does the throwing away

Orotidine monophosphate decarboxylase is the most catalytically proficient pure protein catalyst known.

half-life of the uncatalyzed decarboxylation	78 million years
rate enhancement by the yeast enzyme	1.4×10^{17}
cofactors required	none
metal ions required	none

Removing that carboxyl is the hardest single-step reaction the cell performs on a nucleotide, and it takes seventy-eight million years without help. In humans the enzyme is fused with orotate phosphoribosyltransferase into one bifunctional protein, UMP synthase, whose deficiency is hereditary orotic aciduria.

---

589. The Third Hydrogen Bond Is Installed by the Detour Through Xanthine ↩

Counting the bonds

pair	hydrogen bonds	the atoms
A-T	two	A N6–H ··· O4 T; A N1 ··· H–N3 T
G-C	three	G O6 ··· H–N4 C; G N1–H ··· N3 C; G N2–H ··· O2 C

The third bond of the guanine-cytosine pair is contributed by the amino group at guanine C2.

Where that amino group comes from

IMP 6-oxo purine no substituent at C2\n/\n/ IMP dehydrogenase adds an oxo at C2\nv\nXMP 2,6-dioxo purine oxygen at C2\n/\n/ GMP synthetase replaces it with an amide nitrogen from glutamine\nv\nGMP 2-amino-6-oxo purine NITROGEN at C2 <-- the third bond

The two-enzyme detour through xanthosine monophosphate exists to place the atom that makes guanine-cytosine a three-bond pair rather than a two-bond pair.

Why this volume cares

Part Seventy's descent argument rests entirely on the two-versus-three hydrogen bond count. Part Seventy-Four found the E. coli replication origin built preferentially from the two-bond pair, with four A-T blocks running to eighty-nine percent and no extended GC-rich region anywhere.

XMP is the enzymatic step that creates the difference those two Parts are built on. The gatekeeper the author colored indigo is the reaction that manufactures the third hydrogen bond.

The volume states this as a description of the biosynthesis and claims no purpose behind it.

---

590. The Methyl on Thymine Is Not a Hydrogen Bond ↩

The other branch, and what it installs

UMP 2,4-dioxo pyrimidine\n|\n| ribonucleotide reductase removes the 2'-OH (at the diphosphate level)\nv\ndUMP same base, deoxyribose\n|\n| thymidylate synthase adds a methyl at C5 from methylene-tetrahydrofolate\nv\ndTMP 2,4-dioxo-5-methyl pyrimidine

What the methyl does for pairing

hydrogen bonds in A–U	**two**
hydrogen bonds in A–T	two
contribution of the C5 methyl to pairing	none

The C5 methyl sits in the major groove. It is a recognition feature and a chemical marker. It is not a bonding atom.

So the two right-hand branches are not the same operation at all. The purine detour adds a hydrogen bond. The pyrimidine detour adds a group that contributes nothing to pairing.

And what it is for

Uracil arising in DNA by spontaneous deamination of cytosine is excised by uracil-DNA glycosylase. That repair only works if uracil is foreign to DNA.

The methyl that distinguishes thymine from uracil exists so that a deamination event can be recognized as damage. Thymine is uracil made unmistakable.

Part Forty-Seven established that ribonucleotide reductase, the only sulfur system on the nucleotide panel, removes the 2′ oxygen. This branch runs through that enzyme.

The route from uracil to thymine passes through the volume's sulfur enzyme and ends in a methyl from folate. The route from hypoxanthine to guanine passes through xanthine and ends in a nitrogen from glutamine. Neither route resembles the other.

---

591. The Left Branch of Both Squares Is the Same Operation ↩

What the two single-step branches do

	I → A	U → C
the change	6-oxo becomes 6-amino	4-oxo becomes 4-amino
enzyme	adenylosuccinate synthetase and lyase	CTP synthetase
nitrogen donor	aspartate	glutamine amide
energy	GTP	ATP
ring position	purine C6	pyrimidine C4

And those two ring positions are the same position

In a Watson-Crick pair, the purine C6 substituent faces the pyrimidine C4 substituent directly across the helix axis.

A 6-amino --H···O-- 4-oxo T\nG 6-oxo --O···H-- 4-amino C

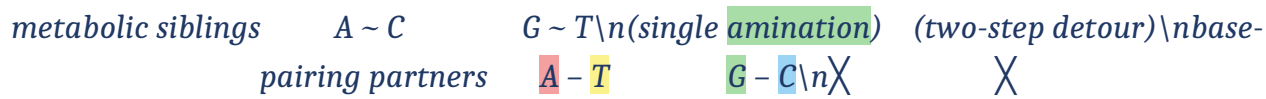
Purine C6 and pyrimidine C4 are reciprocal. Whichever carries the amine, the other carries the oxygen. That is the first hydrogen bond of every canonical pair.

Therefore

The single-amination branch of each square installs an amine at the reciprocal face position. Adenine and cytosine are made by the same operation, at facing positions, from the branch-point nucleotide of their own series.

592. The Crossing ↩

Put the two facts together



Stated plainly

The base a nucleotide is made alongside is never the base it pairs with.

base	its metabolic sibling	its pairing partner
A	C	T
G	T	C
C	A	G
T	G	A

Four bases, four siblings, four partners, and not one of them coincides.

Is this a coincidence?

The volume does not know and says so. Two readings are available and neither is demonstrated:

The first reading is that it is arbitrary. The pathways evolved for chemical reasons and the pairing rules for geometric reasons, and there is no cause for them to agree.

The second reading is that it could not be otherwise. A pair must be a purine with a pyrimidine, so a base's partner is necessarily in the other series, while its metabolic sibling is necessarily in its own. On that reading the crossing is forced and carries no information.

The volume records the second reading as the more likely and prints it as the deflationary alternative to its own observation, which is what Part Sixty-Three's rule requires.

What survives either reading is the structural fact: the metabolic relation and the pairing relation are different relations on the same

four objects, and no arrangement of four letters can express both at once.

---

593. Two Graphs on Eight Nodes ↩

The formal statement

Take the eight symbols of this volume as vertices. There are two distinct edge sets on them.

THE PAIRING GRAPH THE METABOLIC GRAPH\nA --- T I --> A O --> U\nG --- C I --> X U --> C\nI --- U X --> G U --> dU\nX --- O (absent, both gatekeepers) dU --> T

	pairing graph	metabolic graph
edges	undirected	directed
what an edge means	hydrogen bonding, two or three	an enzymatic step
degree of each vertex	one — a perfect matching	variable
X and O	do not participate	both are internal vertices
the shape	four disjoint edges	two rooted trees

What that means for a notation

A four-letter alphabet encodes the pairing graph, because complementarity is what it was built to record. It encodes nothing whatever about the metabolic graph. The two graphs share their vertices and share no edges.

This is the volume's title, derived rather than asserted. A code adequate to replication is not so adequate to metabolism, because the relations are different relations.

Part Forty-Eight established that four closes under complement and that closure is what makes four the reading set. This Part establishes that the metabolic relation does not close on four at all: it requires X and O, which the pairing graph has no vertices for.

Six is what you need to read. Eight is what you need to build. Part Forty-Eight said so from group theory. This Part says so from two biosynthetic pathways, and arrives at the same place by a road that does not touch the first one.

---

594. What This Settles About the Color Scheme ↩

The ruling

The author's color scheme assigns one color, indigo, to xanthine and orotate together. The question this Part was asked to settle is whether that pairing is sound.

It is sound, but for a different reason than the one implied by position.

the justification that does not hold	the justification that does
X and O occupy corresponding positions in their pathways	X and O are the only two of the eight that never appear in a nucleic acid

The property they actually share

is X ever incorporated into DNA or RNA?	no
is O ever incorporated into DNA or RNA?	no
is either ever free in the cell for long?	no — both are consumed immediately
can guanine be reached without X?	no
can uridine be reached without O?	no

Two obligate, non-incorporated, immediately consumed gatekeepers. Nothing reaches guanine except through xanthosine monophosphate and nothing reaches uridine except through orotidine monophosphate. One color for both is correct.

The correction the volume makes

The scheme should state that the X–O pairing is functional and not positional, and should record that the positional counterpart of xanthosine monophosphate is deoxyuridine monophosphate, which the scheme does not color at all.

The author's ordering IXGA against UOCT is retained. The reason for it is amended: it pairs gatekeeper with gatekeeper by role, not by step number, and the step numbers do not agree because the pathways do not have the same shape.

Recorded here rather than silently adjusted, because a scheme that changes its justification without saying so is not a scheme.

---

595. What Is Claimed and What Is Not ↩

Claimed

That purine biosynthesis assembles the ring on the ribose and yields inosine monophosphate as the first complete purine nucleotide and the branch point of the series; that IMP dehydrogenase converts IMP to XMP by adding an oxo at C2 using NAD and water; that GMP synthetase converts XMP to GMP by replacing that oxo with an amide nitrogen from glutamine, using ATP; and that adenylosuccinate synthetase and lyase convert IMP to AMP by amination at C6 using aspartate nitrogen and GTP.

That AMP synthesis requires GTP and GMP synthesis requires ATP.

That pyrimidine biosynthesis assembles the ring free from carbamoyl phosphate and aspartate, attaches the ribose by orotate phosphoribosyltransferase to give OMP, and that OMP decarboxylase removes the C6 carboxyl as carbon dioxide to give UMP, which is the branch point of the series.

That the half-life of the uncatalyzed OMP decarboxylation is 78 million years, that the yeast enzyme accelerates it 1.4×10^{17}-fold making it the fastest pure protein catalyst known, that it requires no cofactor or metal, and that in humans the activity is fused with orotate phosphoribosyltransferase in the bifunctional UMP synthase whose deficiency is hereditary orotic aciduria.

That CTP synthetase aminates C4 using glutamine amide and ATP; that ribonucleotide reductase removes the 2′ hydroxyl at the diphosphate level; and that thymidylate synthase methylates C5 of dUMP using methylene-tetrahydrofolate.

That hypoxanthine is 6-oxopurine, xanthine is 2,6-dioxopurine, adenine is 6-aminopurine, guanine is 2-amino-6-oxopurine, uracil is 2,4-dioxopyrimidine, orotate is uracil-6-carboxylic acid, cytosine is 4-amino-2-oxopyrimidine and thymine is 5-methyl-2,4-dioxopyrimidine.

That A–T carries two hydrogen bonds and G–C three, that the third is contributed by the guanine C2 amino group installed by the XMP detour, and that the thymine C5 methyl contributes no hydrogen bond, A–U and A–T both carrying two.

That purine C6 and pyrimidine C4 face each other in a Watson-Crick pair, that the I→A and U→C branches are both single aminations at those reciprocal positions, and that consequently the metabolic sibling of each base is not its pairing partner in any of the four cases.

That XMP is a corner of the purine branch topology while OMP lies upstream of the pyrimidine branch point, that the positional counterpart of XMP is dUMP, and that OMP has no purine counterpart.

That neither xanthosine monophosphate nor orotidine monophosphate is ever incorporated into a nucleic acid, and that neither guanine nor uridine can be reached without passing through them.

Not claimed

That the crossing of section 592 carries information. Section 592 prints the deflationary reading — that a pair must be purine with pyrimidine and therefore the crossing is forced — and records it as the more likely of the two.

That the XMP detour exists in order to create the third hydrogen bond. Section 589 describes the biosynthesis and states that no purpose is claimed.

That the author's ordering IXGA and UOCT is metabolically ordinal. Section 594 rules the opposite and prints the correction.

That anything here bears on whether the code should have six symbols or eight. Section 593 records that this Part reaches Part Forty-Eight's conclusion by an independent road, which is a convergence and not a proof.

596. What Would Show This Part Is Wrong ↩

— Show a route to guanine nucleotides that does not pass through xanthosine monophosphate, or a route to uridine nucleotides that does not pass through orotidine monophosphate, and the gatekeeper claim of section 594 fails and the color pairing loses its justification.

— Show xanthine or orotate incorporated into a natural nucleic acid, and section 594's shared property is not shared.

— Show that the guanine C2 amino nitrogen does not derive from the glutamine amide transferred by GMP synthetase onto the XMP C2 oxo, and section 589's account of the third hydrogen bond is wrong.

— Show that A–U carries a different number of hydrogen bonds from A–T, and section 590's claim that the thymine methyl is not a bonding atom fails.

— Show that purine C6 and pyrimidine C4 are not the reciprocal face positions of a canonical pair, and section 591 collapses, and with it the crossing of section 592.

— Show a purine nucleotide standing upstream of IMP in the way OMP stands upstream of UMP, and section 587's asymmetry is not an asymmetry.

— Show that the uncatalyzed OMP decarboxylation half-life is not of order 10^7 to 10^8 years, and the arithmetic of section 588 needs restating. Radzicka and Wolfenden, Science 267, 90–93, 1995.

PART EIGHTY-TWO · THE WOBBLE PAPER

Part Eighty-Two of the evidence volume, sections 597 to 609

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

F. H. C. Crick, Journal of Molecular Biology, 1966, volume 19, pages 548 to 555. Received 14 February 1966. Eight pages, six figures, one table. It establishes that inosine reads three bases and excludes guanine, and it predicts in a footnote that adenosine will be absent from the position because an enzyme will have removed it.

597. The Paper, and What It Proposed ↩

The proposal, in Crick's own summary

"It is suggested that while the standard base pairs may be used rather strictly in the first two positions of the triplet, there may be some wobble in the pairing of the third base. This hypothesis is explored systematically, and it is shown that such a wobble could explain the general nature of the degeneracy of the genetic code."

The occasion

"Now that most of the genetic code is known and the base-sequences of sRNA molecules are coming out, it seems a proper time to consider the possible base-pairing between codons on mRNA and the presumed anticodons on the sRNA."

Part Seventy-Eight recorded the other side of that sentence: Nirenberg's laboratory had by then published the nucleotide sequences of fifty-four of the sixty-four codons, and Holley's yeast alanine transfer RNA was the first nucleic acid ever sequenced.

This paper is what a theorist did with those two results within months of their appearing. It is the moment the code table and the reading machinery were first put into the same argument.

The starting assumption

"The obvious assumption to adopt is that sRNA molecules will have certain common features, and that the ribosome will ensure that all sRNA molecules are presented to the mRNA in the same way. In short, that the pairing between one codon-anticodon matching pair will to a first approximation be equivalent to that between any other matching pair."

From which: if all four bases must be distinguished at a position, the pairing there is highly likely to be the standard one — G with C, A with U — "since this is the only type of pairing which allows all four bases to be distinguished in a strictly equivalent way."

And therefore the first two positions of the codon use standard pairs. The argument for wobble applies only to the third.

598. The Five Candidate Pairs, and the One He Ruled Out ↩

The question he asked

"How many base pairs are there in which the glycosidic bonds occur in a position close to the standard one?"

	pair	Crick's verdict	figure
(1)	G with A	will not occur — "the NH_2 group of guanine cannot make one of its hydrogen bonds, even to water"	Fig. 1
(2)	U with C	possible; "brings the two keto groups rather close together and also the two glycosidic bonds"	Fig. 2
(3)	U with U	possible; "again rather close together"	Fig. 3
(4)	G with U, or I with U	"only require the bond to move about 2.5 Å from the standard position"	Fig. 4
(5)	I with A	"perfectly possible. Poly I and poly A will form a double helix."	Fig. 5

The legend to Figure 4 reads: "The pair guanine-uracil (the pair inosine-uracil is similar)."

The legend to Figure 5 reads: "The pair inosine-adenine."

Two of the five figures in the paper are drawings of inosine pairs. Inosine appears in the published geometry of the wobble hypothesis at its first statement.

The one he ruled out

Guanine with adenine. Not on grounds of distance but on grounds of a hydrogen bond that cannot form even to water.

Part Fifty-Seven established that inosine has three wobble partners — U, C and A — and excludes G. Section 602 below is Crick saying the same thing. The exclusion runs both ways and it is drawn in Figure 1 of this paper.

599. The Geometry: Two Point Five Ångströms ↩

The number the whole hypothesis rests on

the glycosidic bond must move about 2.5 Å from the standard position\nfor the G–U and I–U pairs to form

"I now postulate that in the base-pairing of the third base of the codon there is a certain amount of play, or wobble, such that more than one position of pairing is possible."

Figure 6, and what it shows

The point X marks the position of the C1′ atom of the glycosidic bond in the anticodon. The other points show where the C1′ atom and the glycosidic bond fall for the various base pairs.

possible positions reachable by wobbling	seven
positions used by the suggested wobble code	the four on the right of the diagram
positions not used	the three close positions on the left

The figure legend notes: "Pairs with inosine in the codon have been omitted for simplicity."

A hypothesis about the genetic code, stated as a permitted displacement of two and a half ångströms at one atom. The degeneracy of the entire table is derived from how far one carbon may move.

600. One Hundred and Twenty-Seven Combinations Reduced to Seven ↩

The enumeration

seven possible wobble positions\ncombinations of allowed positions

127\nrequiring that all four codon bases be recognized *51\nrequiring also that the*

code distinguish U/C from A/G included\ntherefore *4 sites\nof which the standard one must be 7 combinations*

The two assumptions that do the cutting

"(b) that the code must in some cases distinguish between U/C and A/G as it appears to do for the pairs"

Phe	Tyr	His	Asn	Asp
Leu	C.T.	Gln	Lys	Glu

Five amino acid pairs, each split by whether the third base is a pyrimidine or a purine. That observation — five rows of a table — is the entire empirical input to the reduction from one hundred and twenty-seven possibilities to seven.

"Then by strictly logical argument it can be shown both that the standard position must be used, and that the three positions on the left of Fig. 6 cannot be used."

And the one he chose

"I shall restrict myself here to the case in which all four positions are used, as this is structurally the most likely and also seems to give the code (called code 4 in the note privately circulated) which best fits the experimental data."

The correct answer was the fourth of seven candidates in a privately circulated note.

---

601. Table One ↩

Pairing at the third position of the codon

base on the anticodon	bases recognized on the codon
U	A, G
C	G
A	U
G	U, C
I	U, C, A

The predictions Crick draws from it

"(1) it is not possible to code for either C alone, or for A alone."

Applied to the then-unassigned codon UGA: it "might either (a) code for cysteine, which has UGU and UGC; or (b) code for tryptophan, which has UGG; or (c) not be recognized."

"However it does not permit UGA to code for any amino acid other than cysteine or tryptophan."

UGA became a termination codon — Crick's option (c), not recognized. And Part Fifty-Nine of this volume records the modern consequence: UGA and UAG are the only two stop codons repairable by a single adenosine-to-inosine edit, and both repair to tryptophan.

"This rule could also explain why no suppressor has yet been found which suppresses only ochre mutants (UAA), although suppressors exist which suppress both ochre and amber mutants (UAA and UAG)."

And the row that matters most

Inosine is the only entry in the table that reads three bases. No canonical base reads more than two.

---

602. Inosine Reads Three and Excludes G — Crick's Own Sentence ↩

Printed in full because it is the center of this Part

"If an sRNA has inosine in the place at the relevant position on the anticodon (i.e. enabling it to pair with the third base of the codon), then it must recognize U, C and A in the third place of the codon. Conversely, those amino acids coded only by XY(U/C) (such as Phe, Tyr, His, etc.) cannot have inosine in that place on their sRNA."

What that sentence contains

inosine recognizes	**U, C and A**
inosine does not recognize	G
the exclusion is stated as a	

inosine recognizes	U, C and A
consequence, not a stipulation	
and it is stated in both directions — an amino acid coded only by U and C cannot use inosine	

Part Fifty-Seven of this volume established the three-partner rule from the modern literature and used it to build the hypoxanthine-quaternion join. Part Seventy-Six counted eight eukaryotic inosine anticodons from a 2015 census. Part Eighty applied it to a named Alzheimer mutation.

Crick stated the rule in 1966, in one sentence, on page 553, and it has not been amended.

The prediction about how many transfer RNAs

"If an amino acid is coded for by all four bases in the third position (as are Pro, Thr, Val, etc.), then wobble theory predicts that there will be at least two sRNA's."

With recognition patterns U/C plus A/G, or U/C/A plus G.

"Note that the sets actually used for any amino acid may well vary from species to species."

The second pattern — U, C and A read by one transfer RNA, G by another — is the inosine pattern. Part Seventy-Six's count of the eukaryotic table found precisely that arrangement for alanine, arginine, isoleucine, leucine, proline, serine, threonine and valine. Eight amino acids, the pattern Crick named as one of two possibilities, fifty years later.

---

603. The Footnote That Predicts Adenosine Will Not Be There ↩

The dagger on Table 1

Table 1 lists A as an anticodon base recognizing U. The dagger footnote reads:

"It seems likely that inosine will be formed enzymically from an adenine in the nascent sRNA. This may mean that A in this position will be rare or absent, depending upon the exact specificity of the enzyme(s) involved."

What is being said

the symbol A appears in the table	yes
Crick expects the molecule A to be present at that position	no
why not	an enzyme will have deaminated it to inosine
was the enzyme known in 1966	no — he writes "the enzyme(s) involved"

A row in a table of the genetic code, annotated by its author with the prediction that the molecule the row names will not be found, because something will have chemically converted it before the ribosome ever sees it.

Why this volume prints it

Part One of this volume argues that a notation records what it was built to record, and that the molecule and the symbol can part company.

Here is the parting, on page 552, in 1966, in a footnote by the man who proposed the wobble rules. The alphabet says adenosine. The cell says inosine. Crick wrote both down and told the reader which one to believe.

And he was right

The enzymes are ADAT2 and ADAT3 in eukaryotes and the homodimeric TadA in bacteria. Part Seventy-Six recorded that archaea have no homolog of either and consequently no inosine at anticodon position 34 at all.

The deamination happens at the precursor transfer RNA level. Crick's "nascent sRNA" was correct as written.

604. The Three Yeast Anticodons, All Beginning with I ↩

The experimental evidence Crick had

Three sequences, from three laboratories, in the section he titles The Anticodons:

source	organism, molecule	sequence given
Holley and colleagues, 1965	yeast alanine sRNA	— pUpUpIpGpCpMeIpΨp —
Dütting, Karan, Melchers and Zachau, 1965	yeast serine sRNA	— pΨpUpIpGpApA⁺pΨp —
Ingram and Sjöquist, 1963	yeast valine sRNA	— pIpApCp — the only inosine in the molecule

Positions 36, 37, 38 are marked under the alanine sequence.

The table he derives

yeast sRNA	anticodon	codon
Ala	I G C	G C (U/C/A)
Ser	I G A	U C (U/C/A)
Val	I A C	G U (U/C/A)

Three anticodons. All three begin with inosine. All three read three codons.

"Holley et al. have already pointed out that IGC is a possible anticodon for alanine, and the additional evidence makes it almost certain to my mind that this is correct."

The prediction that followed

"Thus I confidently predict: the anticodon is a triplet at (or very near) positions 36-37-38 on every sRNA, and that the first two bases in the codon pair with this (in an anti-parallel manner) using the standard base pairs."

And a note added in proof

"Note added 26 April 1966. Drs J. T. Madison, G. A. Everett and H. Kung have completed the sequence of the tyrosine sRNA from yeast. The sequence strongly suggests that the anticodon in this case is GΨA, corresponding to the known codons UA(U/C). Since Ψ can form the same base pairs as U, this is in excellent agreement with the previous data."

Pseudouridine, in an anticodon, in a note added in proof ten weeks after submission. Part Seventy-Five of this volume recorded roughly one hundred pseudouridines in the ribosome and named pseudouridine an isomer rather than a substitution. Here it is at the reading position in 1966, and Crick's remark that it forms the same base pairs as uridine is exactly why a four-letter notation cannot see it.

---

605. Sanger's Letter: Little Inosine in E. Coli ↩

The two exceptions Crick records against himself

"However, inosine does not occur in every sRNA. In particular Holley et al. (1963) (and personal communication) have reported that the tyrosine sRNA has two peaks, neither of which contains inosine."

"Moreover, Sanger (personal communication) tells me that there is rather little inosine in the total sRNA from E. coli."

What later counting found

	inosine anticodons at position 34
bacteria	one — arginine only
archaea	zero — no tadA, tad2 or tad3 homolog exists
eukarya	eight — Ala, Arg, Ile, Leu, Pro, Ser, Thr, Val

Recorded in Part Seventy-Six from the three-domain census.

Sanger was right in a private letter in 1966. Bacteria have one inosine anticodon and eukarya have eight. Nobody printed that as a count for another fifty years.

And Crick's closing instruction

Under Testing the Theory, the second of two obvious tests:

"To discover unambiguously the position of the anticodon on sRNA, and to find further anticodons. This will certainly happen as our knowledge of the base sequence of sRNA molecules develops. The

absence of inosine from any anticodon is obviously of special interest."

"In conclusion it seems to me that the preliminary evidence seems rather favorable to the theory. I shall not be surprised if it proves correct."

---

606. What Crick Did Not Know ↩

Printed because the volume's method requires it

The paper is sixty years old and the following were unavailable to it:

the identity of the deaminating enzymes	**unknown — "the enzyme(s) involved"**
the modified base inventory	almost entirely unknown
queuosine, archaeosine, the thiouridines, lysidine	not yet characterized at the reading position
the existence of archaea as a third domain	twelve years away
adenosine deaminase acting on RNA	twenty-two years away
that the anticodon numbering would settle on 34, 35, 36	he wrote 36, 37, 38

The numbering

Crick placed the anticodon "at (or very near) positions 36-37-38." The modern convention numbers the anticodon 34, 35, 36.

The offset is a convention, not an error, and it arises from how the D loop is counted. The volume notes it so that a reader comparing his page with Part Sixty-Nine is not confused.

What survived unchanged

the wobble at the third position	**stands**
the standard pairs at positions one and two	stands
inosine reads U, C and A	stands
inosine excludes G	stands

the wobble at the third position	stands
A at the wobble position is rare or absent because it is deaminated	stands
the anticodon is a triplet at a fixed position on every transfer RNA	stands

Six of six. On the substance, the 1966 paper has not been amended.

---

607. What the Volume Takes ↩

Three things

First. That the three-partner rule for inosine — U, C and A, excluding G — is Crick's, stated in one sentence in 1966, and that this volume's Parts Fifty-Seven, Sixty-Nine, Seventy-Six and Eighty all rest on it without having said whose it was. This Part says whose it was.

Second. That the footnote to Table 1 is the earliest printed statement the volume has found of its own central claim: that a symbol in the code table may name a molecule the cell has already chemically replaced. Crick wrote A in the table and predicted in the footnote that A would not be there.

Third. That two of the six figures in the paper are inosine pairs, and that all three of the sequenced yeast anticodons available to Crick began with inosine. Inosine is not a late addition to the wobble hypothesis. It is present in the geometry, in the table, in the footnote and in every piece of sequence evidence the paper cites.

And what the volume does not take

Nothing in this paper argues for a six-symbol or eight-symbol code. Crick was describing how four letters are read, not proposing a different set.

The volume records that his rules require inosine to do work no canonical base does, and stops there. Whether that warrants promoting inosine to a symbol is argued in Parts Forty-Eight and

Seventy on independent grounds, and this Part supplies no additional support for that conclusion beyond the fact that the reading rules cannot be stated without naming inosine.

Which is itself worth one sentence: a table of the genetic code can be printed without inosine, and the rules for reading that table cannot.

---

608. What Is Claimed and What Is Not ↩

Claimed

That the paper is F. H. C. Crick, "Codon-Anticodon Pairing: The Wobble Hypothesis," Journal of Molecular Biology 19, 548–555, received 14 February 1966, from the MRC Laboratory of Molecular Biology, Hills Road, Cambridge.

That Crick assumed equivalent presentation of all transfer RNAs by the ribosome, concluded that the first two codon positions use standard pairs, and postulated play only at the third.

That he considered five candidate pairs — G with A, U with C, U with U, G or I with U, and I with A — that he ruled out G with A because the guanine amino group cannot make one of its hydrogen bonds even to water, and that Figures 4 and 5 are drawings of inosine-uracil and inosine-adenine.

That G–U and I–U require the glycosidic bond to move about 2.5 Å from the standard position, and that poly I and poly A form a double helix.

That Figure 6 shows seven reachable positions, that the suggested code uses the four on the right and not the three close positions on the left, and that pairs with inosine in the codon were omitted from that figure for simplicity.

That the enumeration runs 127 combinations, reduced to 51 by requiring all four codon bases be recognized, and to 7 by the further requirement that the code distinguish U/C from A/G as it does for Phe/Leu, Tyr/chain-termination, His/Gln, Asn/Lys and Asp/Glu; and that the case chosen was called code 4 in a privately circulated note.

That Table 1 gives anticodon U reading A and G; C reading G; A reading U; G reading U and C; and

That Crick states inosine at the anticodon must recognize U, C and A, and conversely that amino acids coded only by XY(U/C) cannot have inosine there.

That the dagger footnote to Table 1 predicts inosine will be formed enzymically from adenine in the nascent sRNA and that A in that position will consequently be rare or absent.

That he predicted UGA could code only for cysteine or tryptophan or not be recognized, and offered the rule as an explanation for the absence of ochre-only suppressors.

That the three sequences cited are Holley and colleagues 1965 for yeast alanine, Dütting, Karan, Melchers and Zachau 1965 for yeast serine, and Ingram and Sjöquist 1963 for yeast valine; that the derived anticodons are IGC, IGA and IAC; and that a note added 26 April 1966 reports Madison, Everett and Kung finding GΨA for yeast tyrosine.

That Crick records Holley's tyrosine sRNA as containing no inosine, and Sanger's private communication that there is rather little inosine in total E. coli sRNA.

That he closes by writing that the absence of inosine from any anticodon is obviously of special interest, and that he will not be surprised if the theory proves correct.

Not claimed

That Crick proposed a six-base or eight-base code. Section 607 states outright that he did not.

That this paper supports promoting inosine to a symbol. Section 607 states that the support for that comes from Parts Forty-Eight and Seventy on independent grounds.

That Crick's 36-37-38 numbering was an error. Section 606 records it as a convention that later settled at 34-35-36.

That anyone mistranslated or misrepresented this paper. The author of this volume raised that possibility and then withdrew it on inspection. The volume records the withdrawal rather than the suspicion, because that is what the record shows.

609. What Would Show This Part Is Wrong ↩

— Show that Crick's Table 1 does not give I as reading U, C and A, and section 601 and the whole of section 602 fail. The table is on page 552.

— Show that the dagger footnote does not predict A will be rare or absent through enzymatic deamination, and section 603 — the reason this Part is in the volume — fails. It is on the same page.

— Show that inosine at anticodon position 34 does read G in some organism, and Crick's rule, Part Fifty-Seven and Part Eighty all fail together.

— Show that the yeast alanine, serine and valine anticodons of 1963 to 1965 did not all begin with inosine, and section 604's observation is wrong. The three primary references are named in Crick's bibliography.

— Show a canonical unmodified base that reads three codons at the third position, and section 601's closing claim that inosine is unique in the table fails.

— Show that the wobble displacement for G–U is not of order 2.5 Å, and section 599 needs restating.

PART EIGHTY-THREE · THE BRANCH POINT ENZYME

Part Eighty-Three of the evidence volume, sections 610 to 622

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Three papers on one enzyme, spanning 1990 to 1998, and the annotated reprint that started this volume. Block IMP dehydrogenase and inosine monophosphate accumulates five-fold, guanosine triphosphate falls to a fifth, and twelve out of twelve cancer cell lines stop dividing and begin to differentiate.

---

610. Where the Volume's Inosine Came from ↩

The reprint, and what is written on it

On the first page of Kiguchi, Collart, Henning-Chubb and Huberman, Cell Growth and Differentiation, volume 1, pages 259 to 270, June 1990, in the author's hand:

"My first contact — Argonne Labs — learned about IMP dehydrogenase."

The name Frank R. Collart is highlighted in the author list. So is Argonne National Laboratory in the affiliation.

And down the right margin, a chain in seven steps

purine synthesis de novo\n|\nclosed ring structure\n|\nparent nucleotide\n|\ninosine + wobble\n|\nincomplete\nmisleading\ninadequate\n|\ngenetic code\nWatson and Crick

The argument of this entire volume, written down the margin of a melanoma paper, at the moment the author first walked into a national laboratory. Seven steps from de novo purine synthesis to the inadequacy of the four-letter code.

Part Seventy-Nine dated the author's public claims to September 2000 and September 2001. This reprint sits earlier still, and it is not a claim. It is a note to himself about what he had just learned.

Frank Collart's own contribution

The 1998 paper's reference list, checked in the author's hand, carries four Collart entries:

Collart and Huberman, 1987	amplification of the IMPDH gene in Chinese hamster cells resistant to mycophenolic acid
Collart and Huberman, 1988	cloning and sequence analysis of the human and Chinese hamster IMPDH cDNAs
Glesne, Collart and Huberman, 1991	regulation of IMPDH gene expression by its end products, the guanine nucleotides
Collart, Chubb, Mirkin and Huberman, 1992	increased IMPDH gene expression in solid tumor tissues and tumor cell lines

The scientist who introduced the author to this enzyme is the scientist who cloned it. The volume records the provenance and claims nothing scientific from it.

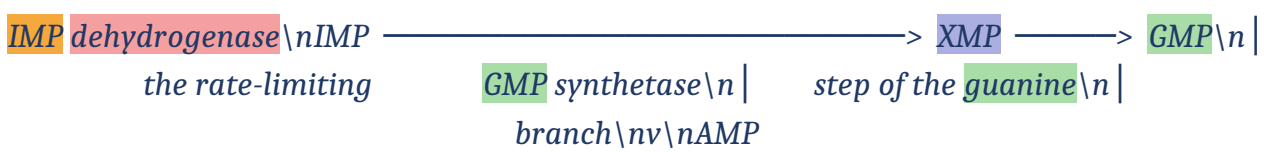
611. The Enzyme at the Branch Point ↩

What IMP dehydrogenase is, in the paper's own words

"IMP dehydrogenase, an enzyme positioned at the branch point in the synthesis of adenine and guanine nucleotides, is the rate-limiting enzyme in the de novo synthesis of guanine nucleotides."

Where it sits

Part Eighty-One drew the purine square. This is the top edge of it.



the substrate	**inosine monophosphate**
the product	xanthosine monophosphate
what it commits	every guanine nucleotide the cell makes de novo
what it competes with	the adenine branch, which begins at the same molecule

Inosine monophosphate is the fork. This enzyme decides how much of it goes toward guanine, and whatever it does not take goes toward adenine. It is the single valve on the purine supply.

The two inhibitors used

	mycophenolic acid	tiazofurin
dose in this study	3 µM	300 µM
relative potency, molar	about two orders of magnitude greater	—
why chosen	specific for IMPDH; does not interfere with nucleotide transport or inhibit other nucleotide-metabolizing enzymes	then in clinical trials for myeloid leukemia
cytotoxicity at these doses	less than 10 percent trypan blue positive after two days	same

612. Twelve Cell Lines, Two Inhibitors, One Result ↩

Table 1 of the paper, recomputed

Twelve human melanoma cell lines, seeded at 2 × 10^5 per dish, inhibitor added at 24 hours, counted and assayed at six days.

cell line	growth under MPA, percent of control	melanin fold-increase, MPA	melanin fold-increase, TZ
SK-MEL-131	8%	3.0×	2.5×
SK-MEL-28	20%	2.0×	1.1×
PI #3	56%	1.7×	1.5×
PA NuT #3	3%	1.8×	1.3×
HO	16%	11.5×	8.2×
HOFF	27%	7.8×	6.1×
SK-MEL-24	30%	2.9×	2.6×
RPMI 7951	12%	2.3×	2.3×
AY-305	26%	3.6×	4.6×
Ebey	29%	5.7×	2.3×
C-32	15%	9.0×	7.5×
SH #1	11%	22.0×	12.0×

The count

cell lines in which mycophenolic acid REDUCED growth *12 of 12\ncell lines in which mycophenolic acid RAISED melanin* *12 of 12*

Twenty-four out of twenty-four. No exceptions in either direction.

And the untreated lines were not alike: melanin content ranged from 0.1 to 6.0 micrograms per million cells — a sixty-fold spread — and every one of them still responded.

A note on the authors' arithmetic

The paper states "up to a 20-fold increase in their melanin content." The largest value in their own Table 1 is SH #1, rising from 0.1 to 2.2, which is 22-fold.

They rounded down. The volume records the direction of the rounding, because rounding a result against yourself is the behavior this volume has spent eighty-three Parts recommending.

And the growth inhibition does not explain it

"The degree of growth inhibition did not necessarily correspond to the increase in melanin content."

PI #3 grew at 56 percent of control and gained 1.7-fold melanin. PA NuT #3 grew at 3 percent and gained 1.8-fold. Nearly the same melanin response from an eighteen-fold difference in growth suppression.

The differentiation is not a side effect of being poisoned. It is a separate consequence of the same intervention.

---

613. What Happens to the Nucleotide Pool ↩

The control cell, measured

Average ribonucleoside triphosphate concentrations in untreated HO melanoma cells, nanomoles per million cells:

	concentration	share of the four
ATP	1.84	72.2%
GTP	0.31	12.2%
UTP	0.22	8.6%
CTP	0.18	7.1%

The adenine nucleotide is present at almost six times the guanine nucleotide.

What the inhibitor does, within six hours

	mycophenolic acid	tiazofurin	phorbol ester	retinoic acid
GTP	falls to about 20 percent	falls to about 20 percent	unchanged	unchanged
UTP	rises to about 175–200 percent	rises	unchanged	unchanged
CTP	rises	rises	unchanged	unchanged
ATP	relatively unchanged	relatively unchanged	unchanged	unchanged

GTP before 0.31 nmol per million cells\nGTP after 0.06 nmol per million cells

Block one enzyme on the purine side and the pyrimidine triphosphates go up by three-quarters. The two halves of the nucleotide panel are coupled, and blocking the guanine branch pushes carbon and ribose into the other series.

Part Eighty-One established that the purine and pyrimidine routes are two squares that do not line up. This is the measurement showing they are nonetheless connected.

And the two non-IMPDH inducers do nothing to the pool

"No disruption of the nucleotide pool was observed after the addition of PMA or RA, with the level of all cellular ribonucleotides remaining relatively constant during the 2-day analysis period."

Phorbol ester and retinoic acid also drive these cells to differentiate. They do it without touching the nucleotide pool. So the pool change is not what differentiation requires in general — it is what this particular route uses.

The volume records that as the paper's own control against its own thesis.

---

614. The Substrate Accumulates Five-fold ↩

The measurement

"Levels of IMP (the substrate of IMPDH) increased approximately 5-fold after 24 h of incubation with MPA or TZ."

What that means for this volume

Part Seventy-Eight recorded Nirenberg's sentence that the third-position residue of the first anticodon ever sequenced is hypoxanthine. Part Fifty-Seven established that inosine reads three bases and excludes guanine. Part Seventy-Six counted eight eukaryotic inosine anticodons.

This is inosine as a quantity. Block the enzyme that consumes it and it piles up five-fold inside a living human cell, and that cell changes what it is.

inosine monophosphate rises	about 5-fold
guanosine triphosphate falls	to about 20 percent
the cell	stops dividing and starts making pigment

The author's margin chain, checked against the data

His seven-step chain reads parent nucleotide → inosine + wobble. The paper supplies the first half of that: inosine monophosphate is the parent nucleotide of both purines, it is the enzyme's substrate, and it accumulates when the enzyme is blocked.

The volume records that the reprint and the margin note agree with the data on the page they are written on. That is not a scientific finding. It is a statement that the note was written by somebody reading carefully.

---

615. Guanosine Reverses It, and Only for the First Two Days ↩

The rescue experiment

One hundred micromolar guanosine added to the medium bypasses the blocked enzyme through the salvage pathway.

guanosine alone, six days	effect
growth rate	20 percent reduction
melanin	about 2-fold increase

Minor changes compared with what mycophenolic acid does on its own.

Added together with the inhibitor

"Addition of guanosine in conjunction with MPA was able to alleviate the MPA-mediated inhibition of cell growth and the induction of differentiation."

And the timing, which is the finding

guanosine added	growth rescue	melanin prevention
day 0, with MPA	full	full

guanosine added	growth rescue	melanin prevention
within 1 day	substantial	full
by day 2	declining, almost linear reduction in rescue with each successive day	only partial
days 3 and 4	little	little

"Most of the cells were already committed to an MPA-mediated increase in the melanin content after 1 day of treatment with this IMPDH inhibitor."

One day of guanine nucleotide depletion and the decision is made. Restoring the supply afterward restores growth on a sliding scale but does not undo the commitment to differentiate.

And the specificity control

Guanosine addition had no effect on the growth or melanogenesis induced by phorbol ester or retinoic acid.

The rescue works only against the route that runs through the enzyme. That is the cleanest control in the paper and it is what makes the guanine nucleotide depletion causal rather than correlated.

---

616. The Compensation: the Cell Makes More of the Enzyme You Are Blocking ↩

The unexpected result

treatment	IMPDH messenger RNA	IMPDH protein	IMPDH activity
mycophenolic acid	increased	markedly increased	inhibited
tiazofurin	increased	markedly increased	inhibited
phorbol ester	decreased	decreased after one day	decreased
retinoic acid	unchanged	decreased after one day	decreased

γ-actin messenger RNA remained constant throughout, as the loading control.

"This pattern may have resulted from cellular compensation for the inhibition of IMPDH activity."

What the authors conclude from the inconsistency

"The lack of a consistent pattern of IMPDH expression in the cells treated with IMPDH inhibitors and phorbol 12-myristate 13-acetate or retinoic acid suggests that the altered expression of IMPDH is not a general requirement for the induction of cell differentiation in these cells."

The paper's own abstract states the negative result. Two routes to the same differentiated phenotype, one raising the enzyme and one lowering it, and the authors decline to claim the enzyme's expression is the common cause.

And the clinical note they attach to it

"The observation of the temporal increase in cellular enzyme in cells treated with IMPDH inhibitors may also have important consequences for the treatment of cancer patients — for example, time and dose scheduling after initial treatment. This observation may be particularly relevant in the treatment of leukemia with tiazofurin."

The volume records the observation and offers no clinical guidance of any kind.

---

617. Hypoxanthine in DNA, and the Enzyme That Removes It ↩

The second paper

Saparbaev and Laval, Proceedings of the National Academy of Sciences, volume 91, pages 5875 to 5876, 1994.

The lesion

"Purines are spontaneously deaminated in DNA at neutral pH. The rate of conversion of adenine to hypoxanthine in DNA is ≈2% of the rate of the conversion of cytosine to uracil."

adenine deaminates to	hypoxanthine
relative rate	2 percent of the C-to-U rate

adenine deaminates to	hypoxanthine
the deoxynucleotide formed	dIMP — deoxyinosine monophosphate
is it mutagenic	yes; "the presence of dIMP residues in DNA has mutagenic potential and should be eliminated by living organisms"

The enzyme

organism	protein
E. coli	AlkA — the 3-methyladenine DNA glycosylase
human	ANPG
rat	ADPG
yeast	MAG

Four lines of evidence identified AlkA as the activity: the same chromatographic behavior on ion exchange and hydrophobic supports, the same molecular weight, correlated induction under the adaptive response, and no detectable activity in an alkA-deleted mutant.

HPLC of the released material showed a single peak eluting at the position of authentic hypoxanthine, with no radioactivity at the deoxyinosine or dIMP positions.

The enzyme cuts the base off and leaves the sugar. It is a glycosylase, and what it releases is free hypoxanthine.

And the substrate requirement

"AlkA protein does not excise hypoxanthine from single-stranded DNA at a detectable rate and does not incise the control duplex DNA in which Hyp/T is replaced by the correct A·T pair."

---

618. The Repair Enzyme Is Bad at Its Job ↩

The kinetics, side by side

	deoxyinosine	3-methyladenine	ratio
apparent Km	420 × 10^{-9} M	5 × 10^{-9} M	84-fold weaker binding
k_cat/Km	2 × 10^{-6} $nM^{-1}{\cdot}min^{-1}$	0.1 $nM^{-1}{\cdot}min^{-1}$	50,000-fold less efficient

Under conditions where one enzymatic unit releases 1 picomole of 3-methyladenine per minute, the same amount of protein liberates 1.2 femtomoles of hypoxanthine.

The enzyme that removes deaminated adenine from DNA is fifty thousand times better at removing a methylated adenine. Hypoxanthine is, kinetically, an afterthought for the protein that handles it.

And the species comparison

Product released per unit of 3-methyladenine glycosylase activity:

origin	Hyp20/T oligonucleotide incised, pmol/min
Human ANPG70	0.146
Human splicing variant ANPG60	0.158
Human truncated ANPG40	0.311
Rat ADPG	0.149
Yeast MAG	0.0004
E. coli AlkA	0.0012

human / E. coli = 122-fold (the paper states "120 times higher")\nhuman / yeast = 365-fold (the paper states ">300-fold")

The volume recomputed both from the table and they check.

Mammals repair hypoxanthine in DNA more than a hundred times better than bacteria do, and nearly four hundred times better than yeast. The organism with eight inosine anticodons is also the organism that works hardest to keep inosine out of its DNA.

Part Seventy-Six counted eight inosine anticodons in eukarya, one in bacteria and none in archaea. The repair capacity runs in the same direction as the reading capacity.

The volume records the parallel and offers no mechanism connecting them.

619. The Human Enzyme Has a Base-pair Preference the Bacterial One Does Not ↩

What E. coli AlkA does

Initial velocity of hypoxanthine excision from duplexes carrying each of the four bases opposite the deoxyinosine, femtomoles per minute:

base pair	rate
I·A	5.8
I·T	5.1
I·C	4.0
I·G	3.8

"All the base pairs are substrates for the AlkA protein. The E. coli enzyme does not show any clear specificity."

What the human enzyme does

Tested on the same oligonucleotide, deliberately, "in order to warrant precise comparison":

I·T recognized best\nI·G next\nI·A next\nI·C recognized rather poorly

"This result is at variance with the specificity of the E. coli enzyme."

Why this belongs in the volume

The bacterial enzyme sees a lesion. The human enzyme sees a lesion and what it is paired against, and treats the four cases differently.

bacterial repair	reads the damaged base
human repair	reads the base pair

Part Fifty-Seven established that inosine pairs with U, C and A and excludes G. Here is a repair enzyme in the human nucleus discriminating among I·T, I·G, I·A and I·C — sorting the same lesion four ways by its partner.

A four-letter notation records the identity of a base. It does not record which base is opposite it, and it cannot express an enzyme whose rate depends on that.

The volume notes one limitation the paper itself flags: the human specificity data are reported without the numerical table given for E. coli, marked "data not shown." The ordering is stated; the magnitudes are not.

---

620. P53 Works Through This Enzyme ↩

The third paper

Liu and colleagues, Molecular Biology of the Cell, volume 9, pages 15 to 28, January 1998, supported by National Cancer Institute grants CA-58619 and CA-06927 and the Pew Scholars Program.

The central claim

"Our studies establish reduced IMPD activity as an essential requirement for p53-dependent cell cycle arrest in the absence of cellular damage."

"Our studies implicate the impd gene as a p53 target whose repression is required for p53-dependent growth suppression."

Why they argue the enzyme is the right target for a tumor suppressor

"IMPD is an ideal choice to play a pivotal role in the function of a cancer gene like p53 that functions to regulate cell growth in diverse tissues. IMPD is an essential, found everywherely expressed enzyme that is rate limiting for the biosynthesis of guanine ribonucleotides, which are universal regulators of diverse processes required for normal cell function and growth."

The proposed mechanism, and its honest status

The authors offer two mechanisms and label both as proposals.

first	**the GTP:ATP ratio may regulate the quality and efficiency of signal transduction, since many signaling proteins can use either nucleotide and bind them in different conformations**
second	direct regulation of cell cycle programs by GTP-sensor proteins

protein	why proposed
Rho GTPases	in the GTP-bound state, promote degradation of the cyclin

protein	why proposed
	kinase inhibitor p27Kip1, required for the G1-to-S transition
Ran GTPase	required for activation of Cdc2/cyclin B complexes in Xenopus egg extracts
CDC6	rate-determining for the initiation of DNA replication; exhibits ATP/GTPase activity; conserved in S. pombe, Xenopus and humans

"CDC6 is an especially attractive candidate, because its substrate specificity qualifies it as a target for single-site, integrated signal regulation by the GTP:ATP ratio as well."

The prediction they make

"They indicate that p53 mutations in human cancers reflect a significant requirement for increased guanine ribonucleotide biosynthesis for tumorigenesis. This requirement may be in effect even in tumors that exhibit wild-type p53 function. Such tumors are predicted to have other alterations that accomplish the same disruption, i.e., increased guanine ribonucleotide levels with accompanying increases in GTP:GDP and GTP:ATP ratios."

A falsifiable prediction, stated in 1998, about tumors the authors did not examine.

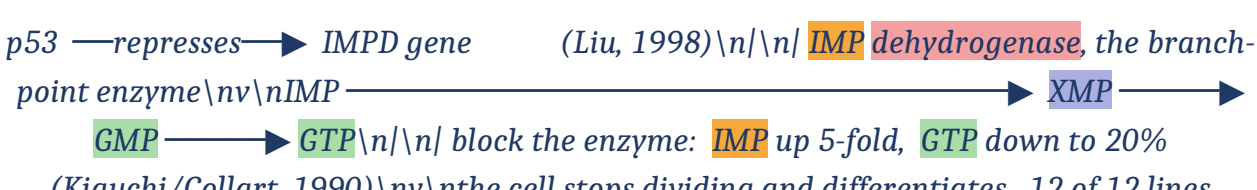
And the caution they attach

"Although the results presented herein are based in cell culture experiments, they have implications for the significance of p53 mutations in human cancers."

---

621. What the Three Papers Say Together ↩

The chain



adenine —spontaneous deamination→ hypoxanthine in DNA\n|\nexcised by ANPG / AlkA\n50,000x less efficiently than 3-MeAde\nhuman 122x better than E. coli\nhuman sorts I·T, I·G, I·A, I·C differently\n(Saparbaev & Laval, 1994)

What the volume takes

First. Inosine monophosphate is not only the reader at anticodon position 34. It is a quantity inside a cell, it is the substrate of a rate-limiting enzyme, and its concentration decides whether a cancer cell divides or differentiates. Twelve lines out of twelve, with a specific rescue and a specific negative control.

Second. The one-day commitment window. Guanine nucleotide depletion for twenty-four hours and the decision to differentiate is made, after which restoring the supply restores growth but not the phenotype. A metabolite concentration, held low for a day, writing something that outlasts it.

Third. Hypoxanthine in DNA is repaired by an enzyme that is fifty thousand times better at its other substrate, and the human version sorts the lesion by which base it is paired against. The notation records neither the lesion nor its partner.

Fourth. The tumor suppressor most frequently mutated in human cancer exerts its growth-arresting function, in the absence of damage, by turning this enzyme down.

What the volume does not take

That any of this argues for a six-symbol or eight-symbol code. These are papers about metabolism, repair and growth control. None of them proposes a change to the code table and the volume does not read one into them.

What they establish is narrower and, for this volume, sufficient: the molecule the four-letter alphabet has no symbol for is the branch point of purine metabolism, the substrate of a chemotherapy target, a repaired DNA lesion, and the lever a tumor suppressor pulls.

622. What Is Claimed, What Is Not, and What Would Show This Part Wrong ↩

Claimed

That Kiguchi, Collart, Henning-Chubb and Huberman published in Cell Growth and Differentiation 1, 259–270, June 1990, from the Biological and Medical Research Division, Argonne National Laboratory, under Department of Energy contract W-31-109-ENG-38; and that the author's annotated reprint carries the note about his first contact with Argonne and a seven-step margin chain from de novo purine synthesis to the inadequacy of the Watson-Crick code.

That the paper describes IMP dehydrogenase as positioned at the branch point between adenine and guanine nucleotide synthesis and rate-limiting for de novo guanine nucleotide synthesis.

That twelve human melanoma cell lines were treated with 3 µM mycophenolic acid or 300 µM tiazofurin, that MPA is about two orders of magnitude more potent on a molar basis, that both reduced growth in all twelve lines and raised melanin in all twelve, that untreated melanin content ranged from 0.1 to 6.0 µg per 10^6 cells, and that the largest increase in the paper's own Table 1 is 22-fold while the text states "up to a 20-fold increase."

That the degree of growth inhibition did not necessarily correspond to the increase in melanin.

That control ribonucleoside triphosphate concentrations in HO cells were ATP 1.84, GTP 0.31, UTP 0.22 and CTP 0.18 nmol per 10^6 cells; that MPA and TZ reduced GTP to about 20 percent within six hours while raising UTP and CTP and leaving ATP relatively unchanged; that IMP increased approximately five-fold after 24 hours; and that phorbol ester and retinoic acid produced no disruption of the nucleotide pool.

That 100 µM guanosine alone caused a 20 percent growth reduction and about a two-fold melanin increase; that added with MPA it prevented both effects; that its rescue of growth declined almost linearly with each day of delay; that by day two it only partially prevented the melanin increase; and that it had no effect on phorbol ester or retinoic acid induced differentiation.

That MPA and TZ increased IMPDH messenger RNA and protein while phorbol ester decreased them, that ɣ-actin messenger RNA was unchanged, and that the authors conclude altered IMPDH expression is not a general requirement for differentiation in these cells.

That Saparbaev and Laval published in PNAS 91, 5875–5876, 1994; that the rate of adenine deamination to hypoxanthine in DNA is approximately 2 percent of the cytosine-to-uracil rate; that E. coli AlkA excises hypoxanthine from duplex but not single-stranded DNA and releases the free base; that its apparent Km for deoxyinosine is 420 × 10^{-9} M against 5 × 10^{-9} M for 3-methyladenine, and its k_cat/Km 2 × 10^{-6} against 0.1 $nM^{-1}{\cdot}min^{-1}$.

That E. coli AlkA excises hypoxanthine at 5.8, 5.1, 4.0 and 3.8 fmol/min from I·A, I·T, I·C and I·G respectively with no clear specificity, and that the human enzyme recognizes I·T best, then I·G, then I·A, with I·C poorly — stated by the authors as at variance with the bacterial enzyme.

That the human ANPG70 enzyme incises 0.146 pmol/min against E. coli AlkA at 0.0012 and yeast MAG at 0.0004, giving ratios of 122 and 365 which match the paper's stated "120 times" and ">300-fold."

That Liu and colleagues published in Molecular Biology of the Cell 9, 15–28, January 1998; that they establish reduced IMPD activity as an essential requirement for p53-dependent cell cycle arrest in the absence of cellular damage; that they propose regulation via the GTP:ATP ratio and via GTP sensor proteins with Rho GTPases, Ran GTPase and CDC6 as candidates; and that they predict tumors with wild-type p53 will carry other alterations raising guanine ribonucleotide levels and the GTP:GDP and GTP:ATP ratios.

That Frank R. Collart is an author on the 1990 paper and, with Huberman and colleagues, cloned and sequenced the human and Chinese hamster IMPDH cDNAs in 1988.

Not claimed

That any of these papers supports a six-symbol or eight-symbol genetic code. Section 621 states that none of them proposes a change to the code table.

That the parallel between eukaryotic inosine reading capacity and eukaryotic hypoxanthine repair capacity has a mechanism. Section 618 states that the volume offers none.

Any clinical guidance whatever. Section 616 quotes the authors' remark about dose scheduling and records that the volume adds nothing to it.

That the personal provenance of section 610 bears on the science. It establishes a date and a source of an idea, nothing more.

That the human ANPG base-pair specificity is quantified. Section 619 records that the ordering is stated and the magnitudes are marked "data not shown" in the source.

What would show this Part is wrong

— Show that mycophenolic acid fails to raise melanin in any of the twelve named lines, and the twelve-of-twelve count of section 612 fails.

— Show that IMP does not accumulate on IMPDH inhibition, and section 614 — the reason this Part is in the volume — fails.

— Show that guanosine rescue is equally effective on day four as on day zero, and the commitment-window finding of section 615 is wrong.

— Show that AlkA's Km for deoxyinosine is comparable to its Km for 3-methyladenine, and section 618's fifty-thousand-fold efficiency gap collapses.

— Show that human ANPG has no base-pair preference, and section 619 fails. The magnitudes were not published, so this is the least secure claim in the Part and is marked as such.

— Show that p53 does not repress the impd gene, or that p53-dependent arrest proceeds normally with IMPD activity unreduced, and section 620 fails.

— Find a tumor with wild-type p53 and normal guanine ribonucleotide levels and normal GTP:ATP ratio, and the 1998 prediction quoted in section 620 is falsified. Twenty-eight years on, the volume has not established whether anyone has looked.

PART EIGHTY-FOUR · THE IMMORTAL STRAND

Part Eighty-Four of the evidence volume, sections 623 to 635

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Two papers, two enzymes, one letter. Sherley's group at MIT shows that a stem cell cannot sort its old DNA strands from its new ones unless IMP dehydrogenase is turned down. Nishikura's group at the Wistar shows that the adenosine deaminase which makes inosine comes in four spliced forms, two of which carry forty amino acids of Alu inside the protein.

---

623. Two Enzymes, Two Papers, One Letter ↩

What is on the table

	Rambhatla, Ram-Mohan, Cheng and Sherley	Lai, Chen, Carter and Nishikura
journal	Cancer Research 65(8), 3155–3161	Molecular and Cellular Biology 17(5), 2413–2424
year	2005	1997
institution	Massachusetts Institute of Technology	The Wistar Institute, Philadelphia
the enzyme	IMP dehydrogenase — makes XMP from IMP	DRADA2 / ADAR2 — makes inosine from adenosine
what it decides	whether a stem cell divides symmetrically or asymmetrically	which adenosines in a glutamate receptor transcript become inosine

One enzyme consumes inosine monophosphate. The other manufactures inosine in RNA. Both are reactions on the base the four-letter alphabet has no symbol for, and both are reactions that decide something about a cell.

Part Eighty-Three established the branch-point enzyme, its inhibitors, and p53's control of it. This Part carries that argument to its endpoint in stem cell kinetics, and then turns to the other enzyme on the same base.

624. The Stem Cell Hypothesis, and the Thousand-fold ↩

The premise

"Because they are long-lived and cycle continuously, adult stem cells are predicted as the most common precursor for cancers in adult mammalian tissues."

	what it does	what it limits
asymmetric self-renewal	each division makes one new stem cell and one non-stem sister	the number of stem cells
immortal DNA strand cosegregation	the oldest template strands are kept, nonrandomly, by the stem cell	the accumulation of replication errors

The number

"The effect of immortal DNA strand cosegregation on ASC mutation rate, compared with their symmetrically renewing progeny, is estimated to be a >1,000-fold reduction."

A stem cell that keeps its original template strands and passes the newly synthesized ones to the daughter destined to differentiate and die accumulates mutations at less than a thousandth of the rate of a cell that segregates randomly.

This is a strategy for handling the errors a four-letter copying process makes: do not repair them, do not detect them — sort them, and give them to the cell that is going to be discarded.

What was demonstrated here

Engineered murine cell lines shift from symmetric to asymmetric self-renewal on conditional expression of wild-type p53 at physiological levels. Under symmetric conditions the cells incorporate bromodeoxyuridine until every chromosome is hemi-labeled; on the shift, the induced cells cosegregate a complement of hemi-labeled chromosomes for as many as six cell divisions.

Not detected in isogenic p53-null lines, which segregate randomly at all times.

---

625. Xanthosine Runs the Switch Backward ↩

The bypass

Xanthosine is converted to xanthosine 5′-monophosphate — the product of the IMP dehydrogenase reaction — in one step, by found everywhere nucleoside kinases.

Adding it therefore restores what the blocked enzyme would have made, without the enzyme.

What it does

"When added to asymmetrically self-renewing cells, xanthosine induces a transition to symmetric self-renewal, which promotes exponential proliferation."

cells self-renewing asymmetrically	one stem daughter, one arrested daughter
add xanthosine	both daughters divide
result	exponential proliferation

Feed a cell the product of the reaction and it stops behaving like a stem cell. The switch between the two kinds of division is operated by the concentration of a purine nucleotide, and the operating handle is the molecule immediately downstream of inosine monophosphate.

Part Eighty-One established that xanthosine monophosphate is a gatekeeper — one of only two members of the eight-symbol set that never enters a nucleic acid. This is the gatekeeper acting as a signal.

---

626. The Transfectant Experiment: Hold the Enzyme Up and P53 Cannot Act ↩

The design

Isogenic zinc-responsive, p53-inducible murine embryo fibroblasts, into which a constitutively expressed IMPDH transgene has been placed. These cells make wild-type p53 on demand, but they cannot lower IMPDH, because the transgene is not under p53 control.

The measurement

Percent Hoechst-bright nuclei — the arrested, non-dividing daughters produced by asymmetric division:

cell line	what it is	noninduced	p53 induced
Con-3	p53-null control	0.0	0.9
Ind-4	p53-inducible parent	0.3	43.0
Ind-8	p53-inducible parent	0.3	46.0
tC-2	vector transfectant of Ind-8	0.2	47.0
tC-4	vector transfectant of Ind-8	0.0	24.0
tI-1	impdh transfectant	0.2	3.0

cell line	what it is	noninduced	p53 induced
	of Ind-8		
tI-3	impdh transfectant	0.2	0.2
tI-5	impdh transfectant	0.2	6.3

vector transfectants, mean 35.5 %\nimpdh transfectants, mean 3.17 %\nratio 11.2-fold\np53-null control 0.9 %

Line tI-3 with p53 fully induced scores 0.2 percent — indistinguishable from its own uninduced state, and below the p53-null control.

What that establishes

"This finding shows that unless IMPDH is reduced below its basal level, p53 cannot initiate an asymmetric self-renewal program."

p53 is present. p53 is active. And it can do nothing, because one enzyme has been pinned at its normal level.

And the second result, from the label-retention assay: impdh-transfectants showed the random segregation pattern of p53-null cells, with anti-BrdUrd fluorescence distributed uniformly between sister nuclei, while the parental p53-expressing cells put the label asymmetrically into one nucleus.

"Thus, this result shows that p53 expression alone is not sufficient for immortal strand cosegregation."

The oldest strands cannot be sorted unless a purine enzyme is turned down.

---

627. The Sensitivity, Recomputed ↩

The method

F_d is the fraction of new daughter cells that divide. For asymmetric lineages it approximates 0.5; for exponential lineages it approaches 1.0. P_ack is the probability that a cell initiates asymmetric kinetics.

	F_d	P_ack
p53-null fibroblasts	0.79	0.09
p53-expressing fibroblasts	0.49	0.72

dPack / dFd = (0.72 - 0.09) / (0.49 - 0.79) = 0.63 / -0.30 = -2.10\ntheoretical value -2

The volume recomputed this and obtains −2.10 exactly, against the paper's stated −2.1 and the theoretical −2.

The chain rule, verified

rate	slope per µmol/L	n	R^2	P
ΔF_d / Δ[Zn]	−0.017	5	0.967	0.007
Δp53 / Δ[Zn]	0.006	8	0.667	0.013
ΔIMPDH protein / Δ[Zn]	−0.003	6	0.765	0.023
ΔIMPDH activity / Δ[Zn]	−0.002	5	0.818	0.035

dPack / d(p53 protein) = -2.1 x 1/(0.006) x -0.017 = 5.95 paper: 6\ndPack / d(IMPDH protein) = -2.1 x 1/(-0.003) x -0.017 = -11.90 paper: -12\ndPack / d(IMPDH activity) = -2.1 x 1/(-0.002) x -0.017 = -17.85 paper: -18\nmean absolute value 11.9 paper: 12

All four reproduce. The volume recomputed every figure in Table 2 from the four regression slopes and obtained the paper's own numbers to within rounding.

What the number means

"A 30% to 50% reduction in IMPDH in response to modest levels of wild-type p53 precipitates a nearly quantitative shift from symmetric to asymmetric self-renewal."

A twelve-to-one lever. Move the enzyme one unit and the probability of asymmetric division moves twelve. And the sign is negative for IMPDH and positive for p53 — they pull in opposite directions on the same outcome, which is what a repressor and its target should do.

628. The Nci60 Result, and the Control That Came Out Backward ↩

The in silico test

Normalized messenger RNA expression for approximately 8,000 gene sequences across 60 human tumor cell lines, stratified by p53 genotype.

stratum	n	regression	R²	P
wild-type p53	18	Y = 49.9 − 16.9X	0.427	0.003
mutant p53	37	Y = 36.9 − 0.85X	0.001	0.868

Where Y is population doubling time in hours and X is normalized type II IMPDH messenger RNA.

slope in wild-type cells is 19.9x steeper\nvariance explained: 42.7 % versus 0.1 %

In cells that still have working p53, higher IMPDH expression predicts faster doubling and accounts for forty-three percent of the variance. In cells whose p53 is mutant, the relationship is gone entirely.

And the control that failed

The authors also regressed wild-type p53 messenger RNA against p21^waf1 messenger RNA — a canonical, strongly p53-induced transcript, included as a positive control.

	n	R²	P	regression coefficient
p53 vs p21^waf1	20	0.117	0.031	−1.15

"Moreover, the regression coefficient from this analysis is negative (−1.15), a result that is contrary to the known positive correlation between wild-type p53 protein expression and p21waf1 mRNA level."

The authors attribute it to the high degree of post-translational regulation p53 undergoes, which would make any messenger-RNA-level relationship hard to detect. That explanation is reasonable and it is also the explanation that would excuse a null result on their own hypothesis.

The volume records the failed control at the same weight as the successful regression, and notes that it weakens the in silico section of the paper without touching the cell-culture experiments of sections 626 and 627, which do not depend on it.

And a further caution the authors supply themselves: type II IMPDH mean normalized expression was 1.1 ± 0.39 in wild-type-p53 lines and 1.1 ± 0.47 in mutant lines — the same. The relationship differs between strata; the level does not.

---

629. Four Editors from One Gene ↩

The second paper

Lai, Chen, Carter and Nishikura, 1997. Four differentially spliced isoforms of the human double-stranded RNA adenosine deaminase DRADA2, now known as ADAR2.

isoform	calculated mass	C terminus	Alu cassette
DRADA2a	77 kD	long, 29 aa	absent
DRADA2b	81 kD	long, 29 aa	present
DRADA2c	78 kD	short, 2 aa	absent
DRADA2d	74 kD	short, 2 aa	present

Two independent binary choices — long or short tail, Alu in or Alu out — giving four proteins from one gene.

How it differs from the other deaminase

	DRADA1 (ADAR1)	DRADA2 (ADAR2)
messenger RNA	7.1 kb	8.6 and 6.0 kb
double-stranded RNA binding motifs	three	two
spacing between the motifs	40 or 41 aa	83 aa — twice as long
Z-DNA binding motif	present, N-terminal	absent
chromosome	1q21	21q22.2

The two enzymes that make inosine in human RNA differ in the number of their RNA-binding modules, in the spacing between them,

in the presence of a Z-DNA binding domain, and in which chromosome they sit on. They are not variants of each other.

---

630. The Alu Cassette Inside the Editor ↩

What is inserted

A forty-amino-acid stretch, encoded by an Alu element, sitting in frame in the middle of the putative deaminase domain of DRADA2b and DRADA2d.

"This Alu segment appears to be recognized as a part of the intron sequence and is spliced out in the mRNA for the DRADA2a and -2c isoforms."

The same forty codons are an exon in half the transcripts and an intron in the other half

ratio of DRADA2 messenger RNAs with and without the Alu cassette insert	approximately 1:4
measured in	HEK 293 and HeLa cells
ratio of short-to-long C-terminal messenger RNAs	3:2

One transcript in five keeps the Alu and translates it into protein. Four in five splice it out and treat the identical DNA as intron.

Why this Part exists

Part Sixty-Five of this volume is titled The Editor Made of Its Substrate, and rests on the observation that the enzymes which act on Alu-derived double-stranded RNA are themselves built in part from Alu-derived sequence.

This is the primary source for that argument, and it is stronger than the volume had it. The adenosine deaminase that converts adenosine to inosine — the enzyme this whole volume is built around — carries forty amino acids of a mobile element inside its catalytic domain, in one transcript out of five.

And Parts Sixty and Sixty-One established that inverted Alu pairs are what recruit these enzymes to their targets.

The element is the antenna, the element is in the protein, and the same forty base pairs are read as coding sequence or as intron depending on how the spliceosome feels about that transcript on that occasion. A four-letter notation records those forty positions once and identically in every cell.

---

631. But the Alu Is Not the Active Part ↩

The authors' own statement, and a correction to this section

"The RNA editing site selectivity of DRADA2b is almost identical to that of DRADA2a for the three editing sites (Q/R, +60, and R/G) examined, suggesting that the presence of an Alu cassette insert in DRADA2b does not alter its RNA editing function, at least in the in vitro RNA editing assay system used in the present study."

A first draft of this section stated that the paper does not print this cross-tabulation. That was wrong. The authors state it directly on page 2419, and again in their discussion on page 2421: "Surprisingly, the presence of an in-frame Alu cassette in the middle of the putative deaminase domain of DRADA2b seems to have essentially no effect on its A-to-I conversion activity or GluR-B RNA editing site selectivity."

The error arose because the volume was working from a partial copy that did not include page 2419. It is printed here rather than silently repaired. The finding is the authors' and the arithmetic below is the volume's.

Figure 6 gives site-specific editing by all four isoforms. The volume laid the Alu status and the C-terminal status against the activity:

isoform	C terminus	Alu	Q/R site	+60 site	R/G site
DRADA2a	long	no	73	17	68
DRADA2b	long	YES	75	13	56
DRADA2c	short	no	1	1	1
DRADA2d	short	YES	2	2	1

Q/R site: long C terminus 74 % vs short 1.5 % = 49-fold\nR/G site: long C terminus 62 % vs short 1.0 % = 62-fold\nAlu present (2b, 2d) = 75 and 2\nAlu absent (2a, 2c) = 73 and 1

The finding

Activity is determined entirely by the C terminus. The Alu cassette makes no measurable difference: 2b with the Alu edits at 75 percent and 2a without it edits at 73; 2d with the Alu is dead at 2 percent and 2c without it is dead at 1.

This cuts against the reading a careless advocate would want, and the authors printed it anyway. The editor carries a mobile element inside its catalytic domain, and as far as this assay can see,

The paper's own general estimate — that short-C-terminus isoforms have five- to tenfold less adenosine-to-inosine conversion activity — is measured by a different assay. On site-specific editing the gap is closer to fiftyfold.

What survives is the fact and not an inference: forty amino acids of Alu are translated into a human RNA-editing enzyme, and the volume knows of no function for them. That is a better sentence than a claim would have been.

---

632. Which Isoform Edits Which Site ↩

The division of labor between the two enzymes

Time course, percent edited, purified recombinant protein:

site	DRADA2a	DRADA1
Q/R	79 → 81	4 → 8
+60	8 → 22	34 → 50
R/G	32 → 53	14 → 32

DRADA2a reaches eighty percent editing at the Q/R site after a thirty-minute incubation. DRADA1 can barely edit the Q/R site at all, even after prolonged incubation.

The reverse holds at the +60 intronic site, which DRADA1 edits about twice as efficiently.

Why the Q/R site matters

The glutamate receptor B subunit Q/R site is the single most consequential recoding event known. Editing changes a glutamine codon CAG to an arginine codon CIG, and the resulting arginine alters calcium permeability of the assembled ion channel.

A glutamine becomes an arginine because one adenosine in one codon became inosine, and the ribosome read the inosine as guanosine. Part Fifty-Seven's rule, doing work in a neuron.

And a salt effect worth recording

DRADA1 was essentially unaffected by sodium chloride up to 0.2 M at the Q/R site. DRADA2a decreased at 0.15 M and above.

And the site selectivity of DRADA2a changed with salt: decreasing sodium chloride from 0.15 to 0.05 M produced a threefold increase in editing at the +60 site.

Which adenosine an enzyme chooses to deaminate depends on the ionic strength of the solution it is working in. Not on the sequence — on the salt.

---

633. Chromosome 21, and Who Paid for It ↩

Where the gene sits

DRADA2 / ADAR2	**chromosome 21, region q22.2**
DRADA1 / ADAR1	chromosome 1, region q21

"In this region, there have been several important genes involved in hereditary diseases, such as Down syndrome, whose molecular bases are not yet identified. It is possible that the pathogenesis of some of these human central nervous system diseases could involve inappropriate RNA editing of certain gene transcripts such as GluR."

21q22.2 is inside the Down syndrome critical region. A gene present in three copies rather than two in trisomy 21 encodes the enzyme that recodes glutamate receptors in the brain.

The volume records the map position and the authors' speculation as a speculation. No dosage measurement is offered in this paper and none is claimed here.

The funder

"This work was supported by grants from the National Institutes of Health (GM40536), and also

The Alzheimer's Association paid, in 1994, for the cloning of the four spliced forms of the adenosine deaminase that edits glutamate receptors.

Part Sixty-Seven of this volume records that protein recoding by adenosine-to-inosine editing is reduced in Alzheimer's disease, with the unedited serotonin 2C receptor rising from 45 to 58 percent in hippocampus. Part Eighty applied the same chemistry to a presenilin mutation.

The connection between this enzyme family and Alzheimer's disease was not made in 2016 when the recoding deficit was published. It was made in a grant application before 1994, by whoever wrote the one that carried number PRG-94-156.

Northern blots in this paper cover cerebellum, cerebral cortex, medulla, spinal cord, occipital pole, frontal lobe, temporal lobe, putamen, amygdala, caudate nucleus, corpus callosum, hippocampus, substantia nigra, subthalamic nucleus and thalamus, plus fetal brain, lung, liver and kidney.

---

634. What the Two Papers Say Together ↩

Two enzymes, one base, two kinds of decision

IMP DEHYDROGENASE ADENOSINE DEAMINASE ACTING ON RNA\nconsumes IMP produces inosine in RNA\n|\np53 represses it four spliced isoforms\n|two carry 40 aa of Alu in frame\n30-50% reduction|\n|activity set by the C

terminus\nasymmetric self-renewal not by the Alu\n| |
\nimmortal strands cosegregate Q/R site: CAG -> CIG -> arginine\n|
|\n>1,000-fold lower mutation rate calcium permeability of a neuron

What the volume takes

First. A cell cannot sort its old DNA strands from its new ones unless a purine enzyme is turned down. The mechanism by which a stem cell avoids a thousand generations of copying error runs through the metabolism of the base the alphabet does not name.

Second. Feeding a cell xanthosine — the gatekeeper nucleoside, which never enters a nucleic acid — switches it from asymmetric to symmetric division. A metabolite operates the switch between two kinds of cell.

Third. The sensitivity is twelve to one, and the volume recomputed all four figures in the paper's Table 2 from its own regression slopes.

Fourth. The enzyme that makes inosine in messenger RNA carries forty amino acids of Alu inside its deaminase domain in one transcript out of five, and the same forty codons are spliced out as intron in the other four.

Fifth. That Alu insert has no detectable effect on editing activity. The volume prints the cross-tabulation showing so.

What the volume does not take

That the in silico NCI60 analysis of section 628 is secure. Its own positive control returned the wrong sign and section 628 says so.

That trisomy of 21q22.2 alters editing in Down syndrome. The authors speculate; no measurement is offered; the volume carries the speculation as theirs.

That the Alu cassette has a function. Section 631 states that this assay finds none.

635. What Is Claimed, What Is Not, and What Would Show This Part Wrong ↩

Claimed

That Rambhatla, Ram-Mohan, Cheng and Sherley published in Cancer Research 65(8), 3155–3161, 15 April 2005, from MIT; that they state the effect of immortal DNA strand cosegregation on adult stem cell mutation rate is estimated at greater than 1,000-fold reduction; and that engineered p53-inducible cells cosegregated hemi-labeled chromosomes for as many as six cell divisions while isogenic p53-null lines did not.

That xanthosine is converted to XMP in one step by found everywhere nucleoside kinases and, added to asymmetrically self-renewing cells, induces a transition to symmetric self-renewal promoting exponential proliferation.

That the percent Hoechst-bright nuclei figures of Table 1 are as printed in section 626; that vector transfectants average 35.5 percent under p53 induction against 3.17 percent for impdh-transfectants, an 11.2-fold difference; that line tI-3 scores 0.2 percent induced; and that the authors conclude p53 cannot initiate asymmetric self-renewal unless IMPDH is reduced below basal.

That impdh-transfectants showed uniform BrdUrd distribution between sister nuclei like p53-null cells, and the authors conclude p53 expression alone is not sufficient for immortal strand cosegregation.

That F_d and P_ack were 0.79 and 0.09 for p53-null and 0.49 and 0.72 for p53-expressing fibroblasts, giving ΔP_ack/ΔF_d = −2.10 against a theoretical −2; that the four regression slopes against zinc are −0.017, 0.006, −0.003 and −0.002 per µmol/L with the stated n, R² and P values; and that the volume recomputed the chain-rule products as 5.95, −11.90 and −17.85 with mean absolute value 11.9, against the paper's 6, −12, −18 and 12.

That the authors state a 30 to 50 percent reduction in IMPDH precipitates a nearly quantitative shift from symmetric to asymmetric self-renewal.

That the NCI60 regressions are Y = 49.9 − 16.9X with R² = 0.427, n = 18, P = 0.003 for wild-type p53 and Y = 36.9 − 0.85X with R² = 0.001, n = 37, P = 0.868 for mutant p53; and that the p53 versus p21^waf1 control gave R² = 0.117, P = 0.031 with a negative regression coefficient of −1.15, which the authors state is contrary to the known positive correlation.

That type II IMPDH mean normalized expression was 1.1 ± 0.39 in wild-type and 1.1 ± 0.47 in mutant p53 lines.

That Lai, Chen, Carter and Nishikura published in Molecular and Cellular Biology 17(5), 2413–2424, May 1997, from the Wistar Institute; that four spliced DRADA2 isoforms have calculated masses of 77, 81, 78 and 74 kD; that DRADA2b and DRADA2d contain an in-frame 40-amino-acid Alu cassette in the deaminase domain which is spliced out as intron in DRADA2a and DRADA2c; and that HEK 293 and HeLa cells express approximately a 1:4 ratio of transcripts with and without the cassette, with a 3:2 short-to-long C-terminal ratio.

That DRADA2 has two double-stranded RNA binding motifs spaced 83 amino acids apart against three spaced 40 or 41 apart in DRADA1; that DRADA2 lacks the Z-DNA binding motif; that DRADA2 messenger RNAs are 8.6 and 6.0 kb against 7.1 kb for DRADA1; and that DRADA2 maps to 21q22.2 and DRADA1 to 1q21.

That DRADA2a reaches about 80 percent editing at the Q/R site after 30 minutes while DRADA1 barely edits it; that DRADA1 edits the +60 site about twice as efficiently; and that the Figure 6 isoform values are as printed in section 631.

That the volume's cross-tabulation of Figure 6 shows activity tracking the C terminus and not the

That decreasing sodium chloride from 0.15 to 0.05 M produced a threefold increase in DRADA2a editing at the +60 site, and that the work was supported by NIH GM40536 and Alzheimer's Association grant PRG-94-156.

Not claimed

That the NCI60 analysis is sound. Section 628 prints the failed positive control and says it weakens that section.

That the Alu cassette in DRADA2b and DRADA2d has any function. Section 631 states that this assay detects none and prints the cross-tabulation.

That editing is altered in Down syndrome. Section 633 carries the authors' speculation as speculation.

That the Alzheimer's Association funding implies anyone anticipated the 2016 recoding result. Section 633 records a date and a grant number.

What would show this Part is wrong

— Show that impdh-transfectant lines undergo normal p53-dependent asymmetric self-renewal, and section 626 — the reason this Part is in the volume — fails.

— Show that xanthosine does not shift asymmetrically self-renewing cells to symmetric division, and section 625 fails.

— Recompute Table 2 from the four regression slopes and obtain values materially different from 6, −12 and −18, and section 627's verification is wrong. The arithmetic is four lines and is printed in full so it can be checked.

— Show that the Alu cassette is not translated in DRADA2b and DRADA2d, or is not spliced out in DRADA2a and DRADA2c, and section 630 fails and Part Sixty-Five loses its primary source.

— Show that DRADA2c or DRADA2d edits the Q/R site efficiently, and section 631's finding that the C terminus determines activity is wrong.

— Show that immortal strand cosegregation does not occur, or occurs equally in symmetrically dividing cells, and the whole of the Sherley paper fails. The volume notes this remains a contested area and that the 1,000-fold figure is the authors' estimate, marked in their own text as attributed to work then in press.

PART EIGHTY-FIVE · THE GLUTAMATE RECEPTOR

Part Eighty-Five of the evidence volume, sections 636 to 648

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Lai, Chen, Carter and Nishikura, Molecular and Cellular Biology, 1997, in full. Two codons in one receptor are rewritten by inosine — one at codon position two, one at position one. All five enzymes bind the substrate with identical affinity and edit it forty-nine-fold differently. And sixty percent of the transcripts encode an enzyme that does nothing at all.

---

636. The Paper in Full, and a Correction to Part Eighty-Four ↩

Why this Part exists separately

Part Eighty-Four treated this paper as the second half of a pair, from a partial copy that did not include page 2419. The complete paper carries a body of quantitative work that Part could not reach, and the volume gives it a Part of its own — as it did for Nirenberg in Part Seventy-Eight and for Crick in Part Eighty-Two.

The correction, recorded here as well as at its site

Part Eighty-Four section 631 originally stated that the authors do not print the cross-tabulation showing the Alu cassette has no effect on editing activity.

That was wrong. The authors state it on page 2419 and again on page 2421. Section 631 has been amended to carry their sentence and to record that the volume's earlier draft was mistaken and why.

This is the third correction printed on its own face in this volume, after the inosine-guanine contradiction between Parts Fifty-Seven and Fifty-Nine, and the appendix renumbering. The volume prints them because a book that only records what it got right is not a record.

---

637. Two Recoding Events, Two Codon Positions ↩

The Q/R site

gene-encoded C A G glutamine\n/\ndeamination of the adenosine at codon position 2\n/\nedited C I G read by the ribosome as C G G\nARGININE

The R/G site

gene-encoded A G A arginine\n/\ndeamination of the adenosine at codon position 1\n/\nedited I G A read by the ribosome as G G A\nGLYCINE

Verified against the table

	codon before	amino acid	codon after	amino acid	inosine at position
Q/R site	CAG	glutamine	CGG	arginine	2
R/G site	AGA	arginine	GGA	glycine	1

The volume checked both against the standard genetic code and both hold.

Where each occurs

site	subunits affected
Q/R	AMPA GluR-B, and kainate GluR5 and GluR6
R/G	three AMPA subunits — GluR-B, GluR-C and GluR-D

Two named recoding events, at two different codon positions, in the receptors that carry fast excitatory transmission in the mammalian brain. Both are inosine. Neither is in the DNA.

Part Eighty found the presenilin 2 M239V substitution to be an adenosine-to-guanosine change at codon position one — the same position and the same chemistry as the R/G site, but written into the genome permanently rather than into the transcript transiently.

---

638. What the Amino Acid Change Does to the Channel ↩

The consequences the paper lists

"The resultant amino acid changes introduced by the editing lead to altered gating, ion conductance, ion permeability, and agonist-induced desensitization kinetics."

property of the assembled ion channel	altered by editing
gating	yes
ion conductance	yes
ion permeability	yes
agonist-induced desensitization kinetics	yes

Four electrical properties of a neuronal receptor, set by whether one adenosine in one codon has been deaminated.

And the paper records that the diversity of glutamate receptor subunits is dramatically increased by this editing.

The scale of the substitution

Glutamine to arginine is a change from a neutral polar side chain to a positively charged one, at a residue lining the channel pore.

The volume records the four properties as the paper lists them and adds no mechanism. What matters here is the arithmetic of causation: one atom removed from one base changes four measurable electrical properties of a cell.

---

639. The Accuracy Analysis: Eighteen Clones, Site by Site ↩

The experiment

Complementary DNA was synthesized from in vitro edited substrate RNA, cloned, and independent colonies sequenced directly by DNA sequence analysis — the entire B11 region and the 5′ half of B13.

independent colonies sequenced, B11	**18**
independent colonies sequenced, B13	16

What DRADA2a edited, and how often

site	type	clones	percent	volume's recomputation
Q/R	exonic	13 of 18	72	72.2
+4	exonic	11 of 18	61	61.1
+262	intronic	12 of 18	67	66.7
+263	intronic	12 of 18	67	66.7
+264	intronic	12 of 18	67	66.7
+60	intronic	3 of 18	17	16.7
R/G	exonic	13 of 18	72	72.2

And DRADA1 at the R/G site: 9 of 14 clones, 64 percent — recomputed as 64.3.

Every percentage in the paper reproduces from its own clone counts. The volume checked all eight.

The reversal between the two enzymes

site	DRADA2a	DRADA1
Q/R exonic	72 percent	barely edits it at all
+60 intronic	17 percent	79 percent
+4 exonic	61 percent	18 percent

The two enzymes are not more and less active versions of one another. At the Q/R site DRADA2a works and DRADA1 does not; at the +60 intronic site DRADA1 works four times better. They divide the substrate between them.

---

640. The Sites Edited in Vitro That Are Not Edited in the Brain ↩

The observation

Sequence analysis revealed adenosines edited by both enzymes in the test tube at positions that are known not to be edited in brain.

In the B13 region, DRADA2a selected the +19 and +41 sites at 7, 36 and 14 percent, and DRADA1 selected +19, +39 and +41 at 6 percent. Several intronic sites not edited in brain were selected by DRADA2a in the B11 region.

The authors' conclusion, printed in full

"The results suggest that both deaminases are prone to select in vitro certain nonspecific adenosines, which seem to be protected in vivo by a currently unknown mechanism."

Why this is the most interesting sentence in the paper

The enzyme, purified and given the substrate, edits more adenosines than the living brain does. Something in the cell stops it.

what the enzyme will do, given the RNA	edit many adenosines
what happens in the brain	a smaller, specific subset is edited
the difference	a protective mechanism, unidentified in 1997

Part Fifty-Nine of this volume recorded one such mechanism, found later: the small nucleolar RNA HBII-52 blocking adenosine deamination by 2′-O-methylation — a methyl, from a sulfonium, preventing an edit.

The volume records that as one candidate for what these authors were describing in 1997, and marks it as a candidate. Whether 2′-O-methylation accounts for the protection they observed is not established by either paper.

Part Seventy-Five counted roughly a hundred such methyls on the ribosome alone, all from the same donor.

---

641. All Five Enzymes Bind Identically ↩

The measurement

Nitrocellulose filter binding assay, dissociation constants obtained by Scatchard plot analysis:

substrate	dissociation constant
B11 RNA — the Q/R region	0.3 nM
B13 RNA — the R/G region	0.06 nM

"Essentially identical for different DRADA2 isoform enzymes and DRADA1."

All four DRADA2 isoforms and DRADA1 — five proteins — bind the same two substrates with the same affinity.

What the authors conclude

"The results indicate that the dramatically different RNA editing site selectivities observed with different DRADA enzymes is not simply due to their altered affinity to the RNA substrates harboring potential editing sites."

Put against the activity data

binding affinity across five enzymes identical, 0.3 nM and 0.06 nM\nediting at the Q/R site 73, 75, 1 and 2 percent\na 49-fold spread

Five enzymes hold the same RNA equally tightly and do forty-nine-fold different things to it. Recognition and action are separable, and this is the measurement that separates them.

The volume records one limitation the authors themselves attach: the filter binding assay may not be sensitive enough to detect minor differences in the affinities of each deaminase for the different regions and RNA duplex structures present within B11 or B13.

---

642. Sixty Percent of the Transcripts Encode a Dead Enzyme ↩

The census

	ratio	proportion
short-COOH to long-COOH messenger RNAs	3 : 2	60 percent short
with to without the Alu cassette insert	1 : 4	20 percent carry it

Measured by quantitative S1 mapping on RNA from HEK 293 and HeLa cells.

And the short-COOH isoforms do not work

DRADA2c and DRADA2d — both short-COOH — displayed essentially no RNA editing activity at any of the three sites. The authors repeated the analysis at higher enzyme concentrations, which confirmed the lack of activity.

$$\textit{short C terminus = 2 amino acids = DRADA2c and DRADA2d = no editing\nlong C terminus = 29 amino acids = DRADA2a and DRADA2b = full editing\nand the short form is 60 \% of the transcripts}$$

Three out of every five messenger RNAs from the ADAR2 gene encode a protein that binds the substrate with normal affinity and does not edit it.

What the volume does and does not make of that

The volume records the number and declines the obvious inference.

A catalytically inactive protein that binds the substrate at 0.06 nanomolar is a competitive inhibitor by construction, and the authors raise exactly that possibility — that these isoforms "could potentially act as competitive inhibitors of the other two editing-competent enzymes." They mark it as a possibility. So does the volume.

An alternative the authors also offer: the altered C-terminal structure may be specialized to edit transcripts of currently unidentified target genes.

---

643. The Alu, and What the Authors Say About It ↩

Their word for it

"Surprisingly, the presence of an in-frame Alu cassette in the middle of the putative deaminase domain of DRADA2b seems to have essentially no effect on its A-to-I conversion activity or GluR-B RNA editing site selectivity."

What is actually there

length of the insert	**40 amino acids**
where	in frame, in the middle of the putative deaminase domain
in which isoforms	DRADA2b and DRADA2d
what happens in the other two	the same 40 codons are spliced out as intron
GenBank accession for the cassette	U43534

The authors note the Alu cassette insert "could act as a splicing acceptor signal."

And in rat RED1, the homolog, the Alu cassette insert is present at the identical location — but the corresponding stretch of ten amino acids in rat RED1 is replaced by different residues.

The insert is conserved in position between human and rat and not in sequence. That is what a tolerated insertion looks like: the splice site is kept, the peptide is not.

---

644. Alu Inside More Than a Dozen Protein-coding Genes ↩

The count the authors give

"Alu-related sequences are found within the protein-coding regions of more than a dozen independent genes."

And the paper's own example: an Alu cassette inserted in the DRADA2b and DRADA2c gene products of decay-accelerating factor, a membrane-bound glycoprotein, has been predicted to create a different hydrophilic C-terminal region in the peptide, which in turn leads to synthesis of a secreted form of decay-accelerating factor rather than a membrane-bound one.

the protein	decay-accelerating factor, DAF
what the Alu does there	changes the C-terminal hydrophilicity
the consequence	membrane-bound form becomes secreted

In decay-accelerating factor the Alu insert changes where the protein goes. In the adenosine deaminase it changes nothing measurable. Same class of event, two outcomes, and the volume records both.

Part Sixty-Five of this volume argued that the editor is partly made of its own substrate. This paper supplies the primary evidence and also supplies the deflation: the piece made of substrate is not the piece that does the work.

645. Two Binding Motifs Against Three, and the Spacing ↩

The structural comparison

	DRADA1	DRADA2
double-stranded RNA binding motifs	three	two
spacing between motifs	40 or 41 amino acids	83 amino acids — twice as long
Z-DNA binding motif	two repeats, N-terminal	absent
overall sequence similarity to each other	56 percent	
similarity of DRADA2a to		97 percent

	DRADA1	DRADA2
rat RED1		

The authors' structural hypothesis

"The space between the DRBMs of DRADA2 is twice as long as that of DRADA1. Our previous mutagenic studies suggested that spacer length between DRBMs may be important to give structural flexibility for the neighboring DRBMs."

And: because of its long N-terminal extension next to the RNA binding domain, access of DRADA1 to certain double-stranded RNA substrates might be restricted, whereas DRADA2 may be more open.

The DRADA2 binding motif sequence is described as quite divergent from that of DRADA1 and more similar to nuclear factor NF90 and the microtubule-associated protein SPNR.

Two enzymes performing the same chemical reaction on the same base, built from different numbers of the same module, spaced differently, one carrying a Z-DNA sensor and the other not. The volume records the architecture and takes no position on which arrangement causes which selectivity, because section 641 shows binding affinity does not explain it.

---

646. Salt Sets the Site ↩

The measurement

Editing efficiency and site selectivity were tested across sodium chloride concentrations from 0.05 to 0.2 M.

	DRADA1	DRADA2a
Q/R site, up to 0.2 M NaCl	essentially unaffected	unchanged to 0.15 M, then decreased
+60 site, lowering NaCl 0.15 → 0.05 M	—	threefold increase in editing
R/G site	edited at both	edited at both

"For instance, a threefold increase of the +60 site editing by DRADA2a was observed by decreasing the NaCl concentration from 0.15 to 0.05 M."

What that means

Which adenosine the enzyme chooses is not fixed by the sequence. It shifts threefold with the ionic strength of the solution.

The four letters of the substrate do not change with salt. The outcome does. This volume's claim is that a notation adequate to replication is not adequate to metabolism, and here is a measurement in which the same sequence yields a threefold different product because the buffer changed.

The volume records that the in vitro salt range brackets physiological ionic strength and that no in vivo measurement of this effect is offered by the paper.

---

647. What the Volume Takes ↩

Five things

First. Two recoding events in one receptor family, at two different codon positions. Q/R puts the inosine at position two and turns glutamine into arginine. R/G puts it at position one and turns arginine into glycine. Both verified against the code table by the volume.

Second. The enzyme edits more adenosines in a test tube than the brain edits in life, and the authors state that the extra sites are protected in vivo by a currently unknown mechanism. That sentence, from 1997, is a standing open question and Part Fifty-Nine supplies one later candidate.

Third. Five enzymes bind the same substrate with identical dissociation constants — 0.3 and 0.06 nanomolar — and edit it across a forty-nine-fold range. Recognition and action are separable and this is the measurement that separates them.

Fourth. Sixty percent of ADAR2 transcripts encode a protein with a two-amino-acid C terminus that binds normally and does not edit. The majority product of the gene is catalytically dead.

Fifth. Site selection shifts threefold with sodium chloride concentration. The sequence is constant; the product is not.

And what it declines

The volume does not claim the Alu cassette has a function. The authors call its absence of effect surprising, and section 643 uses their word.

It does not claim the short-COOH isoforms are competitive inhibitors. The authors raise it as a possibility and so does section 642.

It does not claim 2′-O-methylation is the protective mechanism of section 640. That is named as a candidate.

---

648. What Is Claimed, What Is Not, and What Would Show This Part Wrong ↩

Claimed

That the paper is Lai, Chen, Carter and Nishikura, Molecular and Cellular Biology 17(5), 2413–2424, May 1997, received 9 December 1996, returned for modification 15 January 1997, accepted 29 January 1997, from the Wistar Institute, Philadelphia, and Human Genome Sciences, Rockville.

That Q/R editing alters the glutamine codon CAG to CIG which codes for arginine, in AMPA GluR-B and kainate GluR5 and GluR6; that R/G editing alters the arginine codon AGA to IGA which codes for glycine, in GluR-B, GluR-C and GluR-D; and that the volume verified CAG→CGG as glutamine to arginine at codon position two and AGA→GGA as arginine to glycine at codon position one.

That the resultant amino acid changes lead to altered gating, ion conductance, ion permeability and agonist-induced desensitization kinetics, and that receptor diversity is dramatically increased by the editing.

That 18 independent B11 colonies and 16 B13 colonies were sequenced; that DRADA2a edited the Q/R site in 13 of 18 clones (72 percent), the +4 site in 11 of 18

(61 percent), the +262, +263 and +264 intronic sites in 12 of 18 (67 percent) and the +60 intronic site in 3 of 18 (17 percent); that DRADA2a edited the R/G site in 13 of 18 (72 percent) and DRADA1 in 9 of 14 (64 percent); and that the volume recomputed all eight percentages from the clone counts and they reproduce.

That DRADA1 edited the exonic +4 site at 18 percent and the intronic +60 site at 79 percent; that in the B13 region DRADA2a selected +19 and +41 sites at 7, 36 and 14 percent and DRADA1 selected +19, +39 and +41 at 6 percent; and that the authors conclude both deaminases are prone to select in vitro certain nonspecific adenosines which seem to be protected in vivo by a currently unknown mechanism.

That Scatchard plot analysis of nitrocellulose filter binding gave dissociation constants of 0.3 nM for B11 RNA and 0.06 nM for B13 RNA, essentially identical for all four DRADA2 isoforms and DRADA1, and that the authors conclude the different site selectivities are not simply due to altered affinity; and that the authors note the assay may not be sensitive enough to detect minor differences.

That the short-to-long COOH-type messenger RNA ratio is 3:2 and the with-to-without Alu cassette ratio approximately 1:4 in HEK 293 and HeLa cells by quantitative S1 mapping; that DRADA2c and DRADA2d displayed essentially no editing activity, confirmed at higher enzyme concentrations; and that the authors raise both competitive inhibition and specialization for unidentified targets as possibilities.

That the Alu cassette is 40 amino acids, in frame, in the middle of the putative deaminase domain, carries GenBank accession U43534, could act as a splicing acceptor signal, is present at the identical location in rat RED1 with ten differing residues, and that the authors describe its lack of effect on activity as surprising.

That Alu-related sequences are found within the protein-coding regions of more than a dozen independent genes, and that in decay-accelerating factor an Alu cassette creates a different hydrophilic C-terminal region leading to synthesis of a secreted rather than membrane-bound form.

That DRADA2 has two double-stranded RNA binding motifs spaced 83 residues apart against three spaced 40 or 41 apart in DRADA1; that DRADA1 contains two repeats of a Z-DNA binding motif which DRADA2 lacks; that overall similarity between the two is 56 percent; and that DRADA2a resembles rat RED1 at 97 percent.

That DRADA1 editing at the Q/R site was essentially unaffected by NaCl up to 0.2 M, that DRADA2a was unchanged to 0.15 M and decreased above it, and that lowering

NaCl from 0.15 to 0.05 M produced a threefold increase in DRADA2a editing at the +60 site.

That Part Eighty-Four section 631 originally misstated that the authors do not print the Alu cross-tabulation, and has been corrected.

Not claimed

That the Alu cassette has any function in this enzyme. Sections 643 and 647 both state that the authors find none and call it surprising.

That the short-COOH isoforms act as competitive inhibitors. Section 642 carries it as the authors' possibility.

That 2′-O-methylation is the in vivo protective mechanism of section 640. Named as a candidate and marked as one.

That the salt effect of section 646 operates in vivo. Section 646 records that no in vivo measurement is offered.

What would show this Part is wrong

— Show that Q/R editing does not convert CAG to a codon read as CGG, or R/G editing does not convert AGA to a codon read as GGA, and section 637 fails and with it the volume's account of what recoding is.

— Recount the clones and obtain percentages materially different from 72, 61, 67 and 17, and section 639's verification is wrong. The counts and totals are printed so this is checkable.

— Show that the four DRADA2 isoforms and DRADA1 differ substantially in dissociation constant for B11 or B13 RNA, and section 641 — the separation of recognition from action — fails.

— Show that DRADA2c or DRADA2d edits any of the three sites at more than a few percent, and section 642's claim that the majority transcript is dead is wrong.

— Show that the short-to-long messenger RNA ratio is not approximately 3:2, and the sixty percent figure of section 642 needs restating.

— Show that every adenosine edited in vitro is also edited in brain, and the protection statement of section 640 — the paper's most consequential open question — has nothing to explain.

— Show that DRADA2a site selectivity does not change with ionic strength, and section 646 fails.

PART EIGHTY-SIX · THE SANITIZER

Part Eighty-Six of the evidence volume, sections 649 to 661

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Iyama, Abolhassani, Tsuchimoto, Nonaka and Nakabeppu, Nucleic Acids Research, 2010. NUDT16 is the enzyme that takes inosine nucleotides out of the pool. It accepts every six-oxo purine and refuses the one six-amino purine. Knock it down and inosine rises in the RNA and the DNA breaks on one strand.

649. The Enzyme This Volume's Author Named in 2000 ↩

The provenance

Part Seventy-Nine section 563 records the author's Missing Purine Genetic Code project entry, dated September 2000, which reads in part:

"The dITPase senior catalyst has the functional power to forestall hydrolysis and deamination so the correct transversal..."

This paper, published ten years later, is about the enzymes that dispose of dITP and dIDP.

What it establishes

the protein	NUDT16 — nucleoside diphosphate linked moiety X-type motif 16
Swiss-Prot accession	Q96DE0.2
molecular weight	23.45 kD calculated, 20 kD observed on western blot
what it does	hydrolyzes purine nucleoside diphosphates to the corresponding monophosphates
best substrates	inosine diphosphate and deoxyinosine diphosphate
where it works	the nucleus, and especially the nucleolus

Why the cell needs it

"Deamination of adenine at C6 or guanine at C2 generates hypoxanthine or xanthine, respectively, suggesting that

(deoxy)inosine triphosphate and (deoxy)xanthosine triphosphate can be generated from (d)ATP and (d)GTP."

And separately: IMP is abundant in cells as a normal intermediate of de novo purine synthesis, and most cells can generate IDP or ITP from IMP. If IDP is converted to dIDP by ribonucleotide reductase, increased dITP levels will result.

Inosine nucleotides arrive in the pool by two independent routes — deamination of adenine nucleotides, and phosphorylation of the branch-point nucleotide of Part Eighty-Three. Both feed the same problem.

Hypoxanthine and xanthine can mis-pair with cytosine or thymine.

---

650. How they Found It: a Bead with Itp on It ↩

The screen

Whole-cell extracts from SH-SY5Y neuroblastoma cells were passed over Sepharose beads carrying immobilized nucleoside triphosphates, and whatever stuck was identified by mass spectrometry.

bead	protein pulled down
phosphate-ITP and ribose-ITP	NUDT16
phosphate-XTP and ribose-XTP	NUDT16
phosphate-GTP and ribose-GTP	NUDT16
phosphate-ATP, ribose-ATP	—
phosphate-8-oxo-GTP	—
phosphate-2-OH-ATP	—
Sepharose-4B alone	—

Confirmed independently by western blot with an anti-NUDT16 antibody against the same 20 kD band.

The screen was not looking for this protein. It was looking for anything that binds inosine triphosphate, and one thing did.

Six peptide stretches were identified by mass spectrometry across the 195-residue sequence, at Mascot ion scores above 45.

---

651. Twenty-Nine Nucleotides, and What It Will Not Touch ↩

The substrate census

Twenty-nine nucleotides were examined at 10 and 100 micromolar.

hydrolyzed	not hydrolyzed, even at 100 µM
ITP, **dITP**	ATP, dATP
IDP, **dIDP**	2-OH-ATP, 2-OH-dATP
XDP	CTP, dCTP
GDP, **dGDP**	UTP, dUTP, TTP
	7-Me-GDP

The pattern, in ring chemistry

purine	substituent at ring position 6	NUDT16 substrate?
hypoxanthine — I	6-oxo	yes
xanthine — X	2,6-dioxo	yes
guanine — G	2-amino-6-oxo	yes
adenine — A	6-AMINO	no

NUDT16 accepts every six-oxo purine and refuses the one six-amino purine. It takes I, X and G. It will not touch A.

And that is the first three letters of this volume's purine string

This volume orders the purines I X G A. NUDT16's substrate set is exactly the first three.

Part Eighty-One established why. The step from inosine monophosphate to adenosine monophosphate is a single amination at ring position six — the reciprocal face position of the base pair. Everything upstream of that amination carries an oxygen there; adenine alone carries a nitrogen.

the purine square of Part Eighty-One\nI ——————————> X ——> G all three: 6-oxo, all NUDT16 substrates\n | \n[amination at C6]\n | \nv\nA 6-amino, NOT a substrate

The sanitizing enzyme's substrate specificity traces the same boundary the biosynthesis draws. Everything before the C6 amination is disposable; the product of that amination is not.

The volume records this as an observation about substrate chemistry with a stated mechanistic basis, and claims nothing about the ordering of the author's string beyond noting that the two coincide.

---

652. The Kinetics, Recomputed: the Diphosphate, Not the Triphosphate ↩

Table 1 of the paper, with the volume's recomputation

substrate	Km, μM	k_cat, min^{-1}	k_cat/Km stated, $\times 10^3$ $s^{-1}M^{-1}$	volume's recomputation	R^2
IDP	0.062	0.931	251	250.3	0.973
dIDP	0.088	0.966	183	183.0	0.990
GDP	0.330	0.518	26.1	26.2	0.987
dGDP	0.319	0.492	25.7	25.7	0.988
XDP	15.7	2.60	2.76	2.76	0.978
ITP	22.1	3.06	2.31	2.31	0.980
dITP	24.1	3.20	2.21	2.21	0.999

All seven reproduce from their own Km and k_cat. The volume checked every row.

What the table says

IDP is 109x more efficiently hydrolyzed than ITP\ndIDP is 83x more efficiently hydrolyzed than dITP\nIDP Km is 356x tighter than ITP Km\nIDP is 9.6x better than GDP (the paper states "at least seven times")

Inosine diphosphate has a Michaelis constant of sixty-two nanomolar. It is the tightest-bound nucleotide in the table by a factor of five over its own deoxy partner and by two hundred and fifty over xanthosine diphosphate.

The naming consequence

This is a diphosphatase. The paper's title says so, and the eleven-fold to hundred-fold preference for the diphosphate over the triphosphate is why.

And the hydrolysis products differ: IDP yields IMP plus inorganic phosphate; ITP yields IMP but not inorganic phosphate, and therefore probably pyrophosphate.

---

653. Nudt16 Against Itpa: Affinity Against Capacity ↩

The same substrate, two enzymes

on ITP	NUDT16	ITPA
k_cat	3.2 min^{-1}	34,800 min^{-1}
Km	22.1 µM	510 µM
k_cat/Km	2.4 × 10^3	1,137 × 10^3

ITPA turns over 10,875 x faster\nNUDT16 binds 23 x tighter\nITPA is overall 471 x more efficient on the TRIphosphate

And on the diphosphate: NUDT16 has strong activity, ITPA does not.

The division of labor

ITPA	the high-capacity, low-affinity bulk enzyme; triphosphates; relatively abundant in the cytoplasm
NUDT16	the low-capacity, high-affinity scavenger; diphosphates; localized to the nucleus and nucleolus

"NUDT16, therefore, might be an important enzyme for the elimination of (deoxy)inosine nucleotides from nuclei, especially at low concentrations."

Two enzymes on the same problem, working at different concentrations in different compartments on different phosphorylation states. Figure 6 of the paper draws both arrows onto the same square.

ITPA / NUDT16\nITP <--> IDP ---NUDT16--> IMP\n/\nRNR\nv\ndITP <--> dIDP ---NUDT16--> dIMP\nITPA / NUDT16

Ribonucleotide reductase — the volume's sulfur enzyme since Part Forty-Seven — sits on the vertical arrow, converting IDP to dIDP and so moving the problem from the RNA precursor pool into the DNA precursor pool.

---

654. Where It Works: the Nucleolus ↩

The localization

Immunofluorescence confocal microscopy against NUDT16 and against nucleolin, a nucleolar marker:

NUDT16 signal	mostly in DAPI-positive nuclei, partially cytoplasmic
distribution within nuclei	not uniform — intensely localized in a few small regions
those regions	colocalized with intense nucleolin, where DAPI is faint
after NUDT16 knockdown	most of the signal disappeared

"We thus concluded that NUDT16 protein is mostly localized in nucleoli."

What the authors propose it is doing there

"Because NUDT16 is localized mainly in nucleoli, NUDT16 may prevent the incorporation of inosine nucleotides into ribosomal RNA during transcription."

Part Seventy-Five of this volume counted roughly two hundred chemically modified nucleotides in vertebrate ribosomal RNA and established that the nucleolus is where the guide RNAs install them.

The same compartment that deliberately places about a hundred methyls and a hundred pseudouridines onto ribosomal RNA also holds an enzyme whose job is to keep one particular base out of it.

The volume records the co-location and takes it no further. Whether the ribosome's exclusion of inosine is as deliberate as its inclusion of pseudouridine is not established by this paper.

---

655. One Protein, Two Jobs ↩

The prior identification

Ghosh and colleagues reported in 2004 that NUDT16 recognizes the 5′-cap structure of U8 small nucleolar RNA and weakly hydrolyzes it to produce non-capped snoRNA with guanosine 5′-monophosphate at its terminus, plus an excised cap.

And that the Xenopus homolog, X29, is primarily a nucleolar protein.

Why the two activities are the same activity

The first guanosine residue of U8 snoRNA is itself linked to the triphosphate following the 5′-cap, and thus mimics a GTP structure. GTP was shown to be weakly hydrolyzed by NUDT16 in the present study.

"It is likely that hydrolysis of GTP and decapping of U8 snoRNA are essentially the same enzyme reaction of NUDT16."

the protein is called	in which literature
a snoRNA decapping enzyme	RNA processing
a (deoxy)inosine diphosphatase	nucleotide sanitation
and it is one reaction	

Part Seventy-Five recorded archaeal ribosomal protein L7 doing three jobs — ribosome structure, and core protein of both modification guide complexes. This is the same phenomenon in a human nucleolus: one active site, two names in two literatures, and neither field's name describes what the other field measured.

---

656. Knock It Down and Inosine Rises in the RNA ↩

The knockdown

cells	HeLa MR
NUDT16 messenger RNA after 3 days	reduced to 17 percent of control
protein	20 kD band markedly reduced at 2 and 4 days, partially recovered by day 7
second siRNA, different target sequence	reproduced the effect

What happened to inosine in RNA

	inosine residues per 10^6 guanosine
control siRNA	31.9 ± 1.05
NUDT16 siRNA	36.1 ± 1.35
	P = 0.0125

absolute increase 4.2 per 10^6 G\nrelative increase 13.2 percent (the paper states 13.3)

And what did not happen to DNA

"There was no significant difference in the deoxyinosine level in DNA between the two conditions."

The authors' own explanation: deoxyinosine incorporated into newly synthesized DNA might be quickly eliminated by DNA repair enzymes.

Part Eighty-Three recorded those enzymes — the alkylpurine DNA glycosylases AlkA in bacteria and ANPG in humans, which excise hypoxanthine from duplex DNA. This paper cites the same family, and also Endonuclease V.

Inosine accumulates in RNA when the sanitizer is removed, and does not accumulate in DNA, because DNA has a second line of defense that RNA does not.

Growth

cell proliferation	significantly suppressed, P < 0.0001
G1/G0 fraction	decreased, P = 0.00112
S phase fraction	increased, P = 0.000452

cell proliferation	significantly suppressed, P < 0.0001
G2/M fraction	decreased, P = 0.0217
cell death	none — no subG1 fraction, no increase in propidium iodide positive cells

657. The DNA Breaks, and Only on One Strand ↩

The single-strand DNA measurement

ssDNA-positive nuclei, NUDT16 siRNA	13.9 percent
fold over control	5.3 times
implied control value	about 2.6 percent
P	0.000252

One hundred cells examined per preparation, antibody recognizing single-stranded regions of at least six deoxynucleotides.

The comet assay, and why the condition matters

condition	result
alkaline	significantly increased tail moment in three independent experiments — P = 0.0002, 0.0031, 0.0107
neutral	not increased
hydrogen peroxide positive control	increased even under neutral conditions

Alkaline comet detects single-strand breaks. Neutral comet detects double-strand breaks. The increase appears only under alkaline conditions, and the positive control confirms the neutral assay was working.

Therefore: single-strand breaks, not double-strand breaks. The distinction is carried by the assay condition and the paper draws it correctly.

And the result that did not reach significance

	control	NUDT16 knockdown
chromatid breakage	8%	12%

	control	NUDT16 knockdown
chromatid gap	2%	4%
premature separation	0%	1%
cells with abnormal chromosomes	—	1.8 times higher
P		0.115 — not significant

The volume prints the negative because the paper prints it. Thirty mitotic cells per preparation, a 1.8-fold difference, and the authors state plainly that it did not reach significance.

---

658. Inosine in RNA Is Fifty Times More Abundant Than in DNA ↩

The comparison, from the discussion

	per 10^6 of the corresponding guanine nucleoside
basal inosine in RNA	32
basal deoxyinosine in DNA	0.63
ratio	51-fold

Why the difference exists

"RNA editing by adenosine deaminases is a well-known system of post-transcriptional regulation and the major source of inosine in RNA; therefore, more inosine residues are present in RNA compared with deoxyinosine residues in DNA."

And the consequence for the experiment: the net increase under NUDT16 deficiency, 4.3 per 10^6 G, is nearly seven times the entire basal deoxyinosine content of DNA — but against a basal RNA level of 32 it looks like a thirteen percent change.

"The higher basal level of inosine in RNA, which is likely to be generated by RNA-editing, made the difference appear small."

What the volume takes from the two numbers

The cell tolerates fifty times more inosine in its RNA than in its DNA, and the excess is there on purpose. Part Eighty-Five recorded the enzymes that put it there and what it does to a glutamate receptor when they do.

Two policies on one base. In DNA, inosine is damage and three separate systems remove it. In RNA, inosine is information and a dedicated enzyme family installs it.

The four-letter notation has no symbol for the base and therefore no way to record that the same molecule is a lesion in one polymer and a message in the other.

---

659. The Mouse and the Human Do Not Agree ↩

The discrepancy the paper set out to explain

	ITPA deficiency
mouse	die before weaning; growth retardation and heart failure; do not survive beyond two weeks
human	no obvious phenotype

In humans, ITPA deficiency in inflammatory bowel disease patients is likely related to azathioprine intolerance, but does not cause any severe phenotype.

"To date, it is not known why ITPA deficiency causes a severe phenotype in mouse but not in humans. We, therefore, hypothesized that human cells are equipped with a compensatory mechanism which can efficiently suppress the ITPA deficiency."

What they found

primary Itpa-null mouse fibroblasts	prolonged doubling time, chromosomal abnormalities, increased ssDNA and deoxyinosine in DNA
the same cells after spontaneous immortalization	neither phenotype
and those immortalized cells	significantly increased Nudt16 messenger RNA and protein
knocking down Nudt16 in them	reproduced the ITPA-deficient phenotype

primary Itpa-null mouse fibroblasts	prolonged doubling time, chromosomal abnormalities, increased ssDNA and deoxyinosine in DNA
knocking down Nudt16 in wild-type mouse fibroblasts	no phenotype — mouse ITPA compensates

"Mouse NUDT16 functions as a backup enzyme for the ITPA deficiency."

But in human HeLa MR cells, partial reduction of NUDT16 alone was sufficient to cause growth suppression and single-strand breaks.

"Our present data suggested that human ITPA itself cannot completely compensate for the deficiency of NUDT16."

The asymmetry, stated plainly

mouse: NUDT16 backs up ITPA\nhuman: ITPA does NOT fully back up NUDT16

The authors propose that comparing the expression level or enzyme activity of NUDT16 between mouse and human might explain why human cells tolerate ITPA deficiency. They do not make that measurement.

The volume records that as the paper's own open question, and notes it is the reason the paper exists.

---

660. What the Volume Takes ↩

The three systems, now complete

With this Part, the volume holds the whole human inosine apparatus:

system	what it does to inosine	Part
ADAR1, ADAR2 and the four spliced isoforms	puts it into RNA on purpose, recoding glutamine to arginine and arginine to glycine	Fifty-Nine, Eighty-Five
ADAT2/ADAT3	puts it at anticodon position 34 in eight eukaryotic transfer RNAs	Seventy-Six
ITPA and NUDT16	takes it out of the nucleotide pool before it can be polymerized	this Part
ANPG / AlkA, Endonuclease	cuts it out of DNA after it gets	Eighty-Three

system	what it does to inosine	Part
V	in	

Four enzyme systems on one base. Two install it deliberately and two remove it as damage, and the four-letter alphabet has a symbol for none of it.

Five things

First. NUDT16 accepts every six-oxo purine — hypoxanthine, xanthine, guanine — and refuses adenine, the one six-amino purine. Its substrate set is the first three letters of this volume's purine string, and Part Eighty-One supplies the chemical reason.

Second. It is a diphosphatase. Inosine diphosphate binds at sixty-two nanomolar and is hydrolyzed a hundred and nine times more efficiently than inosine triphosphate. All seven rows of the kinetics table reproduce from their own constants.

Third. It works in the nucleolus, the same compartment where about two hundred deliberate modifications are installed on ribosomal RNA.

Fourth. Remove it and inosine rises thirteen percent in RNA, single-strand breaks rise 5.3-fold, and the cells arrest in S phase without dying.

Fifth. The cell carries fifty-one times more inosine in its RNA than in its DNA, and the excess is editing.

And what it declines

That NUDT16's nucleolar localization means the ribosome deliberately excludes inosine. Section 654 states the co-location and stops.

That the substrate specificity of section 651 supports the ordering IXGA as an ordering. It supports a boundary at the C6 amination, which is a chemical fact.

That NUDT16 deficiency causes any human disease. The authors write only that defective NUDT16 might lead to genome-instability syndromes, and section 661 keeps their conditional.

661. What Is Claimed, What Is Not, and What Would Show This Part Wrong ↩

Claimed

That the paper is Iyama, Abolhassani, Tsuchimoto, Nonaka and Nakabeppu, Nucleic Acids Research 38(14), 4834–4843, published online 12 April 2010, doi 10.1093/nar/gkq249, from the Division of Neurofunctional Genomics, Medical Institute of Bioregulation, Kyushu University, Fukuoka.

That NUDT16 was identified by pull-down from SH-SY5Y extracts on phosphate- and ribose-ITP, -XTP and -GTP Sepharose but not on other NTP beads, confirmed by western blot; Swiss-Prot Q96DE0.2; 195 residues; calculated 23.45 kD, observed 20 kD.

That among 29 nucleotides examined, ITP, dITP, XDP, GDP, dGDP, IDP and dIDP were hydrolyzed, and 7-Me-GDP, ATP, CTP, UTP, 2-OH-ATP, dATP, dCTP, dUTP, TTP and 2-OH-dATP were not hydrolyzed even at 100 µM.

That the Table 1 kinetic parameters are Km 0.062, 0.088, 0.330, 0.319, 15.7, 22.1 and 24.1 µM and k_cat 0.931, 0.966, 0.518, 0.492, 2.60, 3.06 and 3.20 min^{-1} for IDP, dIDP, GDP, dGDP, XDP, ITP and dITP respectively, with k_cat/Km of 251, 183, 26.1, 25.7, 2.76, 2.31 and 2.21 × 10^3 $s^{-1}M^{-1}$; and that the volume recomputed all seven from Km and k_cat and they reproduce.

That NUDT16 hydrolyzes IDP to IMP plus inorganic phosphate and ITP to IMP without inorganic phosphate; that IDP hydrolysis is completely dependent on divalent cation, increases linearly with Mg^{2+} to 1 mM, is supported less well by Zn^{2+} and not at all by Mn^{2+}, Co^{2+} or Ca^{2+}.

That for ITP, NUDT16 has k_cat 3.2 min^{-1} and Km 22.1 µM against ITPA at k_cat 34,800 min^{-1} and Km 510 µM; that the volume computes ITPA as 10,875-fold faster in turnover, NUDT16 as 23-fold tighter in binding, and ITPA as 471-fold more efficient overall on the triphosphate; and that NUDT16 but not ITPA has strong hydrolysis activity for (d)IDP.

That NUDT16 is mostly localized in nuclei and especially nucleoli, colocalized with nucleolin, and that the signal disappears on knockdown.

That Ghosh and colleagues reported NUDT16 as a U8 snoRNA decapping enzyme, that the Xenopus homolog X29 is primarily nucleolar, and that these authors state GTP hydrolysis and U8 decapping are essentially the same reaction.

That NUDT16 siRNA reduced messenger RNA to 17 percent of control at 3 days; that inosine in RNA rose from 31.9 ± 1.05 to 36.1 ± 1.35 per 10^6 guanosine at P = 0.0125, a 13.2 percent increase recomputed by the volume against the paper's stated 13.3; and that deoxyinosine in DNA showed no significant difference.

That cell proliferation was significantly suppressed at P < 0.0001; that G1/G0 decreased (P = 0.00112), S increased (P = 0.000452) and G2/M decreased (P = 0.0217); and that no cell death or subG1 fraction was observed.

That ssDNA-positive cells reached 13.9 percent, 5.3 times control, at P = 0.000252; that comet tail moment increased under alkaline conditions in three experiments at P = 0.0002, 0.0031 and 0.0107 but not under neutral conditions; and that chromosomal abnormalities were 1.8 times higher at

That basal inosine in RNA is 32 per 10^6 G against basal deoxyinosine in DNA at 0.63 per 10^6 dG, a 51-fold ratio recomputed by the volume, and that the authors attribute the RNA excess to editing.

That Itpa-null mice die before weaning while human ITPA deficiency causes no obvious phenotype; that immortalized Itpa-null mouse fibroblasts lost the phenotype and showed increased Nudt16; that Nudt16 knockdown in them reproduced it while Nudt16 knockdown in wild-type mouse fibroblasts did not; and that the authors conclude human ITPA cannot completely compensate for NUDT16 deficiency.

Not claimed

That NUDT16 deficiency causes a human disease. The authors write that defective NUDT16 might lead to genome-instability syndromes and the volume keeps the conditional.

That the nucleolus deliberately excludes inosine from ribosomal RNA. Section 654 records the authors' may and the co-location, nothing more.

That NUDT16's substrate specificity validates the ordering IXGA. Section 651 states it as a coincidence of set membership with a named chemical cause at the C6 position.

That chromosomal abnormality increases under NUDT16 knockdown. Section 657 prints P = 0.115 and the word not.

That the deoxyinosine figures in Figure 5A and in the discussion use the same denominator. They do not — the figure reports per 10^6 nucleotides and the discussion per 10^6 dG — and the volume quotes each with its own denominator rather than reconciling them.

What would show this Part is wrong

— Show that NUDT16 hydrolyzes ATP or dATP, and section 651's six-oxo boundary — the reason this Part connects to Part Eighty-One — fails.

— Recompute Table 1 and obtain k_cat/Km values materially different from 251, 183, 26.1, 25.7, 2.76, 2.31 and 2.21×10^3, and section 652's verification is wrong. All seven Km and k_cat values are printed so this is two lines of arithmetic.

— Show that NUDT16 prefers the triphosphate over the diphosphate, and the paper's title and the whole of section 652 fail.

— Show that NUDT16 is not nucleolar, and sections 654 and 655 both fail.

— Show that NUDT16 knockdown does not raise inosine in RNA, and section 656's central measurement fails.

— Show that the comet tail moment increases equally under neutral conditions, and section 657's single-strand conclusion is wrong.

— Show that basal inosine in RNA is not of order fifty times basal deoxyinosine in DNA, and section 658's two-policy argument loses its arithmetic.

PART EIGHTY-SEVEN · THE RATIO

Part Eighty-Seven of the evidence volume, sections 662 to 674

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Curto, Voit and Cascante, Biochemical Journal, 1998. A power-law model of human purine metabolism — sixteen variables, thirty-seven reactions. One patient with 97 percent of normal hypoxanthine salvage has neurological dysfunction. One with 0.06 percent does not. The absolute activity predicts nothing. The ratio of two activities of the same enzyme predicts everything.

662. A Mathematical Model of the Pathway This Volume Is About ↩

What it is

authors	**Raül Curto, Eberhard O. Voit, Marta Cascante**
institutions	Universitat de Barcelona, and Medical University of South Carolina
journal	Biochemical Journal 329, 477–487, 1998
received	2 May 1997; accepted 15 September 1997
the object modeled	human purine metabolism, entire
the diseases analyzed	gout, and the neurological dysfunctions of Lesch-Nyhan syndrome

Why it belongs in this volume

Part Eighty-Three established IMP dehydrogenase at the branch point. Part Eighty-Six established NUDT16 and ITPA on the disposal side. Part Eighty-One drew the purine square by hand.

This is the same pathway written as thirty-seven differential equations and solved. Scheme 1 of the paper is the map that Parts Eighty-One, Eighty-Three and Eighty-Six have been describing piecewise, and the author's own annotated copy of that scheme is section 672.

And the two enzymes it centers on both act on hypoxanthine.

enzyme	the two reactions it catalyzes
HGPRT	salvage of hypoxanthine (v_hprt) and salvage of guanine (v_gprt)
ASLI	the second step from IMP to AMP, and the eighth step from PRPP to IMP

663. What the Model Is Made of ↩

The architecture

16 dependent variables\n2 independent variables\n37 reaction steps

Formulated as a power-law model — a Generalized Mass Action system within the framework of Biochemical Systems Theory. Differential equations solved numerically with MATHEMATICA; sensitivities and gains computed with ESSYNS.

The four pathways distinguished in Scheme 1

1	**synthesis of nucleotides de novo — the ten reactions of the linear pathway from PRPP to IMP, regulated at v_pprpp**
2	catabolism of nucleotides to the degradation products HX, Gua, Xa and UA, including their excretion
3	the salvage pathway for purine rings — v_aprt, v_gprt and v_hprt
4	synthesis and degradation of nucleic acids

"One can distinguish the formation of adenylates and guanylates" at the branch point at IMP.

What sensitivities and gains mean here

Defined as percentage increases or decreases in the concentration of a variable after introducing a one percent increase in one of the parameters of a kinetic rate law, or in the concentration of an enzyme, or in an external effector.

These are logarithmic gains around the operating point. The authors are explicit that they hold strictly for infinitesimal changes and note that experience shows they remain good predictors for changes of a few percent.

The volume records that caveat because the paper prints it and because the largest results below are extrapolated well beyond a few percent.

---

664. Ranking the Causes of Gout ↩

The five candidate causes the model tests

"Five types of gout have been traced back to disorders of purine metabolism: increased catalytic activity of PRPPS, insensitivity of PRPPS to inhibition by purine nucleotides, insensitivity of AMPD to inhibition by purine nucleotides, HGPRT deficiency, and dysfunctional renal excretion of UA, which is not a biochemical phenomenon but is none the less one of the major causes of gout in humans."

The sensitivities, as computed

cause	sensitivity of uric acid concentration
dysfunctional renal excretion of UA	−4.6
PRPPS inhibition by adenylates	−1.4
PRPPS activity	+0.403
HGPRT activity	−0.177
AMPD inhibition by phosphate	−0.11
PRPPS inhibition by guanylates	−0.096
AMPD inhibition by guanylates	−0.03

"A 1% decrease in the kinetic parameter of UA in v_ua leads to a 4.6% increase in the concentration of UA. These results suggest that a dysfunctional renal excretion of UA might be the most significant cause of gout in humans."

Table 3, halving each parameter

parameter halved	resultant uric acid
PRPPS activity (0.899 → 1.798, doubled)	131 µM
PRPPS inhibition by adenylates and guanylates	195 µM
HGPRT activity (12250 → 6125)	112 µM
AMPD inhibition by guanylates and phosphate	108 µM
effect of UA on its own excretion (2.21 → 1.105)	10,052 µM

halving HGPRT 100 -> 112 uM 1.12-fold\nhalving UA self-excretion 100 -> 10052 uM 100.5-fold

The volume notes that the 10,052 µM figure is a linear-gain extrapolation to a fifty percent parameter change and should be read as a ranking rather than a prediction. The authors' own caveat in section 663 applies to it directly.

665. The Kidney Beats the Enzyme Twenty-Six to One ↩

The comparison

sensitivity to renal excretion parameter -4.600\nsensitivity to HGPRT activity -0.177\n----------\nratio 26 x

And 11.4-fold over PRPPS activity, the other classic enzymatic cause.

What that says about the disease this volume keeps meeting

Lesch-Nyhan syndrome is HGPRT deficiency. It is the most studied inborn error of purine metabolism, and it produces gout.

This model says HGPRT is the fourth-ranked determinant of uric acid concentration, twenty-six times weaker than the kidney's handling of the product. The famous enzyme is not the main lever on the famous symptom.

The authors add a second, independent argument from the excretion side:

"Only 10% of gouty subjects overproduce UA. Statistically, one would expect that many more subjects would have defects in the synthesis of UA than in its excretion, because UA synthesis involves more individual processes than UA excretion. Consequently there is much greater chance of mutations affecting UA synthesis than UA excretion. However, most of the deficiencies in UA synthesis are inconsequential and probably remain undetected, and only the most severe dysfunctions are diagnosed."

More ways to break it, fewer diagnoses. The volume records that as an argument about ascertainment and not about biology, which is what it is.

666. Two Thresholds: Two Percent and Nought Point Two Percent ↩

The clinical staircase

residual HGPRT activity	what appears
partial deficiency	hyperuricaemia and gout
below 2 percent of normal	neurological problems, including mental retardation
below 0.2 percent of normal	full-blown Lesch-Nyhan syndrome, including self-mutilation

A tenfold step in residual activity separates mental retardation from self-mutilation.

What the model reproduces, and what it does not

Simulated activities of 10, 1 and 0.1 percent produce, in Figure 1:

increases in fluxes of excretion of purines	v_hx, v_x, v_ua
increases in fluxes catalyzed by xanthine dehydrogenase	v_xd, v_hxd
increases in concentrations of free purines	HX, Xa, Gua and UA
decreases in the guanylate pool	G
decreases in degradation of the guanylate pool	v_gmpr, v_gnuc
decreases in synthesis of DNA and RNA	

"The present model does not shed light on secondary consequences of the enzyme defect because these variables are not included in the model."

The authors state plainly that abnormal brain growth, altered dopaminergic function and altered cyclic GMP — the three intermediate symptoms drawn in their own Scheme 2 — are outside what the model can reach.

667. The Ratio Separates Where the Activity Does Not ↩

Table 5, sorted by ratio

Activities of v_gprt and v_hprt in different families with HGPRT deficiency, as percentages of normal, measured in erythrocyte lysates.

family	v_gprt %	v_hprt %	ratio	neurological dysfunction
I	0.09	0.06	1.50	No
D	17.8	12.6	1.41	No
M	3.8	2.8	1.36	No
T	0.075	0.07	1.07	No
S	9.8	10.2	0.96	Borderline
R	0.5	0.55	0.91	Borderline
G	8.4	9.6	0.88	No
N	0.31	0.36	0.86	No
E.L.	0.87	1.75	0.50	No
J	0.76	1.6	0.47	Borderline
II	4	9	0.44	Yes
LNS	<0.004	<0.01	0.40	Yes
S₂	0.009	0.03	0.30	Yes
5-6	1.85	9.6	0.19	Yes
P	12.3	97.3	0.13	Yes
L	0.51	10.6	0.05	Yes

The separation, computed by the volume

ratio >= 0.5 n = 8 Yes = 0 No = 6 Borderline = 2\nratio < 0.5 n = 8 Yes = 6 No = 1 Borderline = 1

Zero definite cases of neurological dysfunction above the threshold. Zero definite absences below it. The only crossing is family E.L., which sits exactly on 0.50.

The authors' own statement and their proposal

"The lower this ratio is in erythrocyte lysates, the higher is the risk of developing neurological dysfunctions."

"At present there is not enough data available, but on the basis of the cases presented in Table 5, the threshold of the v_gprt-to-v_hprt ratio might be approx. 0.5, with lower values for patients with neurological dysfunctions, and higher values for hyperuricaemia without neurological dysfunctions."

"(1) measure activity of HGPRT in erythrocyte lysates of HGPRT-deficient patients, by using both substrates, hypoxanthine and guanine; (2) report both activities as percentages of activities in

healthy subjects, because otherwise different laboratory procedures would preclude direct comparisons; and (3) report the ratio of v_gprt to v_hprt, together with the degree of neurological dysfunctions exhibited by each patient."

Sixteen families is a small sample, three of them borderline, and the authors say so. The volume records the separation as a computation on their published table, not as a validated clinical rule.

---

668. Family P and Family I ↩

The two cases that destroy absolute activity as a predictor

	family P	family I
hypoxanthine salvage, v_hprt	97.3 percent of normal	0.06 percent of normal
guanine salvage, v_gprt	12.3 percent	0.09 percent
ratio	0.13	1.50
neurological dysfunction	YES	NO

the patient with essentially NORMAL hypoxanthine salvage has the neurological disease\nthe patient with 0.06 % of normal hypoxanthine salvage does not

	values of v_hprt
among cases WITH dysfunction	0.01, 0.03, 9, 9.6, 10.6, 97.3
among cases WITHOUT	0.06, 0.07, 0.36, 1.75, 2.8, 9.6, 12.6

A single number describing one enzyme activity carries no information about whether the patient has the neurological disease. The relation between two activities of the same enzyme carries all of it.

Why this Part is in this volume

The notation problem, stated from Part One: a record of identities is not a record of relations. Part Eighty-One found the metabolic graph and the pairing graph crossed

on the same four nodes. Part Eighty-Five found five enzymes binding one substrate identically and editing it forty-nine-fold differently.

Here it is on a patient. Measure the enzyme and you learn nothing. Measure the same enzyme against its other substrate, and take the quotient, and the disease sorts itself.

The volume claims no mechanism. The authors do not offer one either; their own model finds that the ratio affects six characteristics of purine metabolism, and that IMP, XMP, Gua and the fluxes v_inuc and v_gua are the variables it moves.

---

669. What the Guanylate Pool Does to Nucleic Acid Turnover ↩

The forced experiment

The guanylate pool was held at a fixed value and everything else allowed to follow.

healthy subjects, pool forced down to	**127 µM — the value reached at 1 percent HGPRT activity**
HGPRT-deficient patients, pool forced up to	400 µM

"This theoretical experiment cannot yet be implemented in animals or humans because it has so far proved impossible to maintain an artificially lowered or increased guanylate pool over an extended period of time."

The turnover rates, in µmol/min per g body weight

	healthy	HGPRT-deficient	remaining
RNA	3300	2819	85.4 percent
DNA	16.8	12	71.4 percent

RNA turnover falls 14.6 %\nDNA turnover falls 28.6 %\nDNA falls 2.0 x harder than RNA

And the guanylate depletion accounts for 96 percent of the decrease in RNA turnover.

"Guanylate depletion is indeed responsible for essentially the entire decrease in RNA turnover."

"There are large differences in the time span necessary for the variables to approach their steady-state values." Figure 2 shows RNA equilibrating within about 100 minutes and DNA over tens of thousands of minutes — a difference of two to three orders of magnitude in relaxation time.

RNA and DNA are the same four letters on two backbones, and they respond to the same disturbance with a two-fold difference in magnitude and a thousand-fold difference in speed.

---

670. One Metabolite Moves and Nothing Else Does ↩

The ASLI simulation

Adenylosuccinate lyase catalyzes two reactions. The model was run with 1 percent activity in v_asli, leaving v_den at 100 percent.

"The new steady state achieved under these conditions turned out to be exactly the same as that for healthy subjects, with only one exception, namely that the concentration of S-AMP had increased to 21 µM from 0.2 µM for normal subjects."

S-AMP 0.2 uM -> 21 uM = 105-fold increase\nevery other variable in the model unchanged

Why the model says this must be so

"No enzyme inside the de novo pathway can change the overall flux of v_den, except the first enzyme of this pathway (amidophosphoribosyltransferase), and consequently none of the variables of purine metabolism can affect any of these enzymes."

"The only variable that could be increased is the concentration of substrate S-AICAR."

A linear pathway with no dependent variable feeding back into it: only the first enzyme sets the flux, and blocking a later step piles up its own substrate and changes nothing else. That is a structural result about pathway topology, not a fitted one.

And the clinical shape it explains

ASLI deficiency	ratio S-AMP derivatives to S-AICAR	v_den	v_asli	mental effect
Type I	≈ 1	≈ 30%	≈ 30%	severe mental retardation
Type II	≈ 4	≈ 30%	≈ 3%	slightly decreased mental acuteness

Again a ratio, and again the ratio and not the absolute activity is what distinguishes the two clinical types. v_den is 30 percent in both.

---

671. Two Diseases, Two Disjoint Sets of Variables ↩

What the model assigns to which

disease	the variables that move with it
gout and hyperuricaemia	HX, Xa and UA
neurological dysfunction	IMP, XMP, Gua, and the fluxes v_inuc and v_gua

The five metabolites the model proposes as responsible for neurological dysfunction must satisfy two requirements the authors state in advance:

"(1) these variables should be almost unaffected as long as the enzyme activities are larger than 10% of normal, and (2) they would be increasingly affected if enzyme activities fell below 10% of normal."

"HX, Xa and UA are not correlated with neurological dysfunctions in a readily recognizable pattern."

The consequence

The metabolites that track gout and the metabolites that track the brain damage are different metabolites, in the same pathway, in the same patient, caused by the same mutation.

"Model analyses similar to those in Figure 2 confirmed that increased levels of Xa and HX are merely symptoms of HGPRT deficiency rather than causes of neurological dysfunctions."

Part Eighty-Three found the same shape in the melanoma work: growth inhibition and differentiation were both produced by one intervention and did not track each other. The volume records the recurrence of the pattern and claims nothing from it.

---

672. The Author's Annotations on Scheme One ↩

What is on the page

The author's working copy of Scheme 1 — the full metabolic map, sixteen boxes and thirty-seven arrows — is color-coded in his hand, and the coloring is his own scheme applied to somebody else's diagram.

color	what he marked
green	Gua, G, dG, XMP, v_gprt, v_gua — the guanine arm
orange	IMP, HX, Xa, UA, v_hprt — the hypoxanthine arm
red	A, dA, Ade, SAM, S-AMP — the adenine arm

annotation	where
"STARTS PURINE METABOLISM"	at PRPP and R5P
"STOPS PURINE METABOLISM"	at UA and Xa
"sugar + phosphate"	beside R5P
"New wobble codes?"	top left, with AIUT / TAUT / UTAC written out
"synthesis + oxo group"	beside the ring structures he drew
"DNA purines ATGA"	lower right
"RNA AIUG toxic"	lower right, with "wrong" and "right" beside two orderings

What the volume records

First. He drew the ring structures for X, G, A and H beside the scheme, marked the oxo groups in orange and the amine groups in green, and wrote "synthesis + oxo group" over them. That is the C6

boundary of Part Eighty-Six section 651, drawn by hand on a 1998 modeling paper.

Second. He marked where the pathway starts and where it stops. PRPP in, uric acid out. A metabolic map has a beginning and an end; a codon table does not.

The volume prints the annotations as provenance in the manner of Part Seventy-Nine, and takes no scientific claim from them.

---

673. What the Volume Takes ↩

Four things

First, and the reason this Part exists. In sixteen families with HGPRT deficiency, the absolute activity of the enzyme fails completely as a predictor of neurological disease — 97.3 percent with it, 0.06 percent without — while the ratio of its two activities separates every definite case at a threshold of 0.5. A number about one molecule carries nothing; a relation between two carries everything.

Second. The kidney is twenty-six times more influential than HGPRT on uric acid concentration. The enzyme that names the disease is the fourth-ranked cause of its commonest symptom.

Third. Blocking a late step in a linear pathway with no feedback raises its own substrate 105-fold and moves nothing else. Topology, not kinetics, produces that result.

Fourth. RNA and DNA turnover fall by 14.6 and 28.6 percent under the same guanylate depletion, and equilibrate on timescales three orders of magnitude apart. Same letters, two backbones, two different responses to one disturbance.

And what it declines

That the 0.5 ratio threshold is a validated clinical rule. Sixteen families, three of them borderline, and the authors call the data insufficient. Section 667 says so.

That the 10,052 µM uric acid figure is a prediction. It is a linear-gain extrapolation to a fifty percent parameter change, and section 664 marks it as a ranking.

That the model explains the neurological dysfunction. The authors state their model does not reach abnormal brain growth, dopaminergic function or cyclic GMP.

That the author's annotations of section 672 constitute evidence. They are provenance.

---

674. What Is Claimed, What Is Not, and What Would Show This Part Wrong ↩

Claimed

That the paper is Curto, Voit and Cascante, Biochemical Journal 329, 477–487, 1998, received 2 May 1997 and accepted 15 September 1997, from the Universitat de Barcelona and the Medical University of South Carolina, supported in part by FISss 94/0860 and CIRIT B0F92.

That the model comprises 16 dependent variables, 2 independent variables and 37 reaction steps, formulated as a power-law Generalized Mass Action system within Biochemical Systems Theory, solved with MATHEMATICA and computed with ESSYNS.

That HGPRT catalyzes salvage of both hypoxanthine and guanine, and ASLI catalyzes the second step from IMP to AMP and the eighth step from PRPP to IMP.

That the computed sensitivities of uric acid concentration are −4.6 for the parameter quantifying the effect of UA on its own excretion, −1.4 and −0.096 for PRPPS inhibition by adenylates and guanylates, 0.403 for PRPPS activity, −0.177 for HGPRT activity, and −0.03 and −0.11 for AMPD inhibition by guanylates and phosphate; and that the volume computes the renal-to-HGPRT ratio as 26-fold.

That Table 3 reports resultant uric acid concentrations of 131, 195, 112, 108 and 10,052 µM against a normal 100 µM, for the parameter changes listed in section 664.

That the paper states 10 percent of gouty subjects overproduce uric acid by radioisotope studies.

That HGPRT activity below 2 percent of normal produces neurological problems including mental retardation, and below 0.2 percent produces full-blown Lesch-Nyhan syndrome including self-mutilation.

That Table 5 reports the sixteen families with the v_gprt and v_hprt percentages listed in section 667; that the volume computed the ratios and found zero definite neurological cases at ratio ≥ 0.5 and zero definite absences at ratio < 0.5; that family P has v_hprt 97.3 percent with neurological dysfunction and family I has v_hprt 0.06 percent without; and that the authors propose the 0.5 threshold as approximate and the data as insufficient.

That the authors propose measuring HGPRT with both substrates, reporting both as percentages of healthy activity, and reporting the ratio together with the degree of neurological dysfunction.

That forcing the guanylate pool to 127 µM in healthy subjects and 400 µM in HGPRT-deficient patients gives RNA and DNA turnover rates of 3300 and 16.8 µmol/min per g body weight in health against 2819 and 12 in deficiency; that the volume computes falls of 14.6 and 28.6 percent and a two-fold greater fall for DNA; and that guanylate depletion accounts for 96 percent of the RNA turnover decrease.

That simulating 1 percent v_asli with v_den at 100 percent produced a steady state identical to healthy subjects except that S-AMP rose from 0.2 to 21 µM, a 105-fold increase computed by the volume; and that ASLI deficiency Type I has a succinyladenosine to AICAR-riboside ratio of about 1 with both activities at about 30 percent, while Type II has a ratio of about 4 with v_den about 30 percent and v_asli about 3 percent.

That the model associates HX, Xa and UA with gout and hyperuricaemia, and IMP, XMP, Gua, v_inuc and v_gua with neurological dysfunction, and states that increased Xa and HX are symptoms rather than causes.

That the author's annotated copy of Scheme 1 carries the color coding and the written annotations described in section 672.

Not claimed

That the ratio threshold of 0.5 is clinically validated. Section 667 records sixteen families, three borderline, and the authors' own statement that data are insufficient.

That the 10,052 µM uric acid value is a prediction rather than a ranking. Section 664 marks it as an extrapolation and cites the authors' infinitesimal-change caveat.

That the model accounts for the neurological dysfunction of Lesch-Nyhan syndrome. Section 666 records the authors stating the relevant variables are not in the model.

That the author's annotations bear on the science. Section 672 records them as provenance.

That any of this supports a six-symbol or eight-symbol code. It is a metabolic model and proposes nothing about the code table.

What would show this Part is wrong

— Assemble a larger series of HGPRT-deficient patients with both activities measured, and find neurological dysfunction above a v_gprt/v_hprt ratio of 0.5 or its absence below, and section 667's separation fails. This is the paper's own proposal from 1998, and the volume has not established whether anyone carried it out in twenty-eight years.

— Show that family P's v_hprt is not approximately 97 percent, or that family I's is not approximately 0.06 percent, and section 668 — the reason this Part is in the volume — fails.

— Show that reduced renal excretion is not the dominant sensitivity for uric acid, and section 665's twenty-six-fold ranking fails.

— Show that blocking ASLI moves any variable other than S-AMP in this model, and section 670's topological result is wrong.

— Show that DNA and RNA turnover fall by comparable amounts under guanylate depletion, and section 669's two-fold asymmetry fails.

— Re-derive the model's sensitivities and obtain values materially different from −4.6, −1.4, 0.403, −0.177, −0.11, −0.096 and −0.03, and section 664 needs recomputing. The model is fully specified in the paper and its predecessor, so this is reproducible.

PART EIGHTY-EIGHT · SIX HUNDRED AND FORTY-TWO FOLD

Part Eighty-Eight of the evidence volume, sections 675 to 687

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Pang, McFaline, Burgis, Dong, Taghizadeh, Sullivan, Elmquist, Cunningham and Dedon, Proceedings of the National Academy of Sciences, 2012. Break purine

metabolism and hypoxanthine floods into DNA at six hundred and forty-two times the normal level. Xanthine, its neighbor on the same pathway, does not move at all.

675. The Direct Measurement ↩

What the paper does that no previous Part has done

Part Eighty-Three gave the branch-point enzyme. Part Eighty-Six gave the enzymes that keep inosine nucleotides out of the pool. Part Eighty-Seven modeled the pathway in thirty-seven equations.

This paper counts the molecules. It measures, by isotope-dilution mass spectrometry, how many hypoxanthine and xanthine residues are actually present in the DNA and RNA of cells whose purine metabolism has been broken in defined ways.

The stated hypothesis

"Beyond the enzymes that cleanse the nucleotide pool, defects in the biosynthetic network of purine metabolic enzymes lead to increased incorporation of xanthine and hypoxanthine into DNA and RNA."

The authors position this as a fourth mechanism of nucleobase deamination, alongside hydrolysis, nitrosative chemistry, and deaminase enzymes.

the three known mechanisms	
hydrolysis	the simplest
nitrosative stress	nitric-oxide-derived nitrous anhydride during inflammation
deaminase enzymes	AID on cytidine; ADARs on messenger RNA; modification of transfer and ribosomal RNA
the fourth, proposed here	disturbance of purine nucleotide metabolism

The first three put a deaminated base into a nucleic acid by attacking the polymer. The fourth puts it in through the front door, as a nucleotide, by polymerase.

676. What Was Counted ↩

The four lesions

deaminated from	base	in DNA	in RNA
adenine	hypoxanthine	2′-deoxyinosine, dI	inosine, Ino
guanine	xanthine	2′-deoxyxanthosine, dX	xanthosine, Xao
guanine	oxanine	2′-deoxyoxanosine, dO	oxanosine, Oxo
cytosine	uracil	2′-deoxyuridine, dU	uridine

The method and its controls

technique	chromatography-coupled isotope-dilution tandem mass spectrometry
internal standards	uniformly ^{15}N-labeled Ado, Guo, dA, dG, dC
artefact control	genomic DNA and total RNA purified in the presence of the deaminase inhibitors coformycin (5 µg/mL) and tetrahydrouridine (125 µg/mL)
limits of detection	Ino 5 fmol, Xao 10 fmol, Oxo 50 fmol
replication	n = 3, mean ± SD, Student's t test at $P < 0.05$

Deaminase inhibitors were present through the purification because the whole measurement is of deamination products, and any deaminase left active during workup would manufacture the signal. The volume records that control because it is the one that makes the numbers usable.

The negative control

Uracil in DNA — a pyrimidine lesion — was constant at approximately 5 per 10^5 nucleotides in wild type and every mutant.

And oxanine, guanine's other deamination product, was below detection in every strain — fewer than 5 per 10^8 nucleotides.

677. Wild Type: Nine Times More Hypoxanthine in RNA Than in DNA ↩

The baseline, per 10^6 nucleotides

	RNA	DNA	ratio
hypoxanthine	Ino 11 ± 3	dI 1.2 ± 0.2	9.2 ×
xanthine	Xao 2.8 ± 0.5	dX 1.3 ± 0.3	2.2 ×

The volume recomputed both ratios from the table and obtains 9.2 and 2.2 against the paper's stated ninefold and twofold.

The authors' explanation

"This is not surprising because Ino is one of many ribonucleoside modifications in tRNA and rRNA."

Part Seventy-Six counted eight inosine anticodons in eukarya and one in bacteria. Part Eighty-Six recorded 32 inosine per 10^6 G in human RNA against 0.63 deoxyinosine per 10^6 dG in human DNA — a fifty-one-fold ratio.

Two laboratories, two organisms, two methods, and the same finding: a normal cell carries an order of magnitude more inosine in its RNA than in its DNA, and the excess is deliberate.

---

678. Six Hundred and Forty-Two Fold ↩

The maximum, and where it occurs

genotype	Ino	fold	dI	fold
wild type	11 ± 3	1	1.2 ± 0.2	1
purA/guaB/rdgB	2,900 ± 400	264 ×	770 ± 200	642 ×
purA/rdgB	2,100 ± 200	191 ×	280 ± 80	233 ×
purA/guaB/rdgB/alkA	1,971 ± 212	179 ×	689 ± 112	574 ×
purA/guaB/rdgB/nfi	2,400 ± 400	218 ×	620 ± 180	517 ×
guaB/rdgB	813 ± 125	74 ×	100 ± 7	83 ×

The volume computed every fold change in Table 1 and confirms the paper's stated range of 155- to 642-fold for the purA/rdgB combinations.

What the three broken genes do

gene	what it is	where in the pathway
purA	adenylosuccinate synthetase	the adenine branch out of IMP
guaB	IMP dehydrogenase	the guanine branch out of IMP
rdgB	(d)ITP/(d)XTP pyrophosphohydrolase	the pool-cleansing step

Close both exits from inosine monophosphate, then remove the enzyme that disposes of the resulting triphosphates, and the cell writes hypoxanthine into its own genome at six hundred and forty-two times the normal rate.

Part Eighty-Three established IMP dehydrogenase as the branch point valve. This is what happens when both valves are shut.

---

679. Xanthine Does Not Move ↩

The asymmetry

hypoxanthine in DNA 1.2 -> 770 642-fold\nhypoxanthine in RNA 11 -> 2900 264-fold\nxanthine in DNA 1.3 -> 2.2 1.7-fold\nxanthine in RNA 2.8 -> 7.2 2.6-fold

Across all nineteen genotypes, the largest xanthine change in DNA is 1.7-fold and the largest in RNA is 2.6-fold. Neither reaches an order of magnitude. Hypoxanthine spans nearly three.

The authors' own summary

"Disruption of critical nodes in the purine metabolism network causes large increases of hypoxanthine, but not xanthine, in DNA and RNA."

"The only statistically significant increase in Xao occurred in the purA/rdgB/guaA triple mutant, which is consistent with increases in XMP caused by failure to convert it to GMP by GMP synthetase. However, the magnitude of the increase in Xao — approximately threefold — is considerably smaller than the analogous change observed in Ino."

Why this matters to this volume

Hypoxanthine and xanthine are both deaminated purines. Both are gatekeepers in the author's eight-symbol set — I and X. Both are handled by the same disposal enzyme, RdgB, and by NUDT16 in mammals.

And they behave completely differently. One floods in. The other is refused. The cell distinguishes between two molecules that a four-letter notation does not name at all, and it distinguishes between them by a factor of nearly four hundred.

Part Eighty-One placed X inside the purine square and I at its apex. This is a measurement of the difference that placement makes.

---

680. The Synergy: Single Mutants Do Almost Nothing ↩

The arithmetic of the combination

	Ino, fold over wild type	dI, fold over wild type
purA alone	2.3	1.2
rdgB alone	9.1	4.8
additive prediction	11.4	6.0
purA/rdgB observed	190.9	233.3
excess over additive	16.8 ×	39 ×

	Ino
guaB alone	6.7
rdgB alone	9.1
additive prediction	15.8
guaB/rdgB observed	73.9
excess over additive	4.7 ×

"Losses of specific combinations of genes led to synergistic increases in the content of hypoxanthine in DNA and RNA."

What synergy means here

Neither the biosynthetic block nor the pool-cleansing block alone produces much. Together they produce two to three orders of magnitude.

"Even modest changes in the activities of pairs of these enzymes caused by genetic polymorphisms could result in increased misincorporation of hypoxanthine into nucleic acids in humans."

Part Eighty-Seven found the same structural point in a different form: single-parameter sensitivities are small, and the disease appears where two things go wrong together.

---

681. Yeast Gives the Same Answer ↩

Table 2

genotype	Ino per 10^6 nt	fold	dI per 10^6 nt	fold
wild type	42 ± 8	1	2.0 ± 0.1	1
ade12 — the purA equivalent	35 ± 5	0.8	3.0 ± 0.6	1.5
ham1 — the rdgB ortholog	40 ± 10	1.0	2.2 ± 0.2	1.1
ade12/ham1	1,500 ± 72	36 ×	98 ± 20	49 ×

Neither single mutant differs significantly from wild type. The double mutant rises 36-fold in RNA and 49-fold in DNA.

A eukaryote, a different set of genes, the same architecture, the same result. The synergy is not a property of E. coli.

The volume recomputed both fold changes from the table and obtains 35.7 and 49.0 against the paper's stated 36 and 49.

---

682. The Repair Enzymes Make No Difference, and the Authors Say So ↩

What was expected

Part Eighty-Three established that AlkA in E. coli and ANPG in humans excise hypoxanthine from DNA, and that Endonuclease V incises at deoxyinosine.

What was found

genotype	Ino	dI
wild type	11 ± 3	1.2 ± 0.2
nfi — EndoV deleted	11 ± 1	0.8 ± 0.2
purA/guaB/rdgB	2,900 ± 400	770 ± 200
purA/guaB/rdgB/nfi	2,400 ± 400	620 ± 180
purA/guaB/rdgB/alkA	1,971 ± 212	689 ± 112

Deleting either repair gene changed nothing, on its own or on top of the triple mutant.

"The loss of either the nfi gene encoding the EndoV DNA repair protein or the alkA gene encoding the AlkA DNA glycosylase did not affect the levels of xanthine or hypoxanthine in DNA or RNA."

The open question the authors print

Their first explanation is redundancy — Endonuclease VIII also has in vitro activity against deoxyinosine.

"It is worth noting that the purA/rdgB and guaB/rdgB double mutants maintain high levels of dI in spite of the activity of dI repair enzymes. This raises questions about the mechanisms controlling steady-state levels of DNA damage."

The volume records that as an unresolved problem stated by the people who created it, and notes that it is the same shape as Part Eighty-Five section 640 — where the purified editor edits sites the living brain does not, protected by a mechanism nobody has identified.

---

683. Why Xanthine Is Refused, and a Second Enzyme That Sorts the Purines ↩

The five mechanisms the authors propose

1	**xanthine nucleotides may bind less effectively in allosteric feedback regulating ribonucleotide reductases**
2	the purA/guaA/rdgB mutation reduces ATP and GTP, which reduces NAD^+ synthesis, which lowers the NAD^+-dependent IMP dehydrogenase and so reduces XMP synthesis
3	xanthine nucleotides are poorer substrates for kinases
4	(d)XTP are poorer substrates than (d)ITP for RNA and DNA polymerases
5	there may be a cryptic xanthine nucleoside triphosphatase beyond RdgB and YjjX

All five are offered as possibilities and the authors state that the alternatives await quantification of the nucleoside triphosphate pool.

The third one comes with a table

Agarwal and colleagues determined which nucleotides human guanylate kinase will phosphorylate.

accepted	refused
GMP	XMP
dGMP	UMP
8-azaGMP	CMP
IMP	6-thioIMP

Human guanylate kinase takes guanosine monophosphate and inosine monophosphate. It refuses xanthosine monophosphate.

Two enzymes, two different boundaries through four purines

enzyme	I	X	G	A
NUDT16 (Part Eighty-Six)	yes	yes	yes	no
human guanylate kinase	yes	no	yes	—

NUDT16 draws its line between the six-oxo purines and the six-amino one. Guanylate kinase draws a different line, excluding xanthine while accepting both its neighbors. Neither enzyme accepts all four, and the two do not agree on which to reject.

The volume records this as the clearest evidence it holds that the four purines are four distinct objects to the enzymes that handle them, sorted differently by different enzymes, and that a notation carrying two of the four cannot express any of it.

And one line in that table is a sulfur result

IMP *accepted by human guanylate kinase* *6-oxo\n6-thioIMP* *REFUSED by human guanylate kinase* *6-thio*

Replace the oxygen at ring position six with a sulfur, and the substrate becomes a non-substrate. Same ring, same sugar, same phosphate, one atom exchanged for its conjugate partner in group sixteen, and the enzyme stops working.

Part Thirty-Eight established sulfur and oxygen as conjugate partners. This is that substitution performed on a purine nucleotide and read out as a yes-or-no by a human kinase.

And 6-thioIMP is not an abstraction: it is the active metabolite of the thiopurine drugs, which is why section 684 follows.

---

684. Fifty Percent, and One Person in Six ↩

The human polymorphisms

gene	variant	effect	frequency
ITPA — the human rdgB homolog	94C > A	reduces enzyme activity by 50 percent	present in 11–19 percent of Asians
IMPDH2	promoter T-to-G substitution	reduces gene expression by 50–60 percent	not stated here

What the ITPA variant is associated with

"Associated with toxic responses to thiopurine therapy for cancer, autoimmune disease and inflammatory bowel disease, presumably due to increased incorporation of thiopurines into DNA and RNA."

"This parallels the fivefold and 10-fold increases in hypoxanthine in DNA and RNA, respectively, caused by loss of rdgB in E. coli."

The argument the authors build from it

"While the present studies focused on a complete loss of this gene, it is reasonable to assume that a 50–60% decrease in SAMP synthetase activity could cause

measurable increases in hypoxanthine incorporation into DNA and RNA in human cells affected with the genetic polymorphism."

"Given the large reductions in activity caused by common genetic polymorphisms in the human homologs of purA and rdgB, a substantial number of humans could possess polymorphisms that affect two or more purine metabolism genes, with the consequence of increased incorporation of deaminated nucleotides into DNA and RNA."

Section 680 established that two-gene combinations are synergistic. Section 684 establishes that the relevant single-gene variants are common. The authors join those and the volume records the join as their argument, not a demonstration.

No measurement of hypoxanthine burden in humans carrying either polymorphism is reported here. That is the experiment this Part generates and section 687 records it as unfinished.

---

685. The Author's Annotations: Ferredoxin, Thioredoxin, Cysteine ↩

What is written on the working copy

"Ferredoxin Thioredoxin"

And on Figure 2, beside the two ribonucleotide reductase arrows — the vertical steps from GDP to dGDP and from ADP to dADP:

"cysteine"

Why the volume records it

Figure 2 of this paper draws purine metabolism as a lattice. Two arrows in it are labeled

Part Forty-Seven established that ribonucleotide reductase is the only sulfur system on the nucleotide panel, that it removes the 2′ oxygen, and that it does so through a thiol pair regenerated by thioredoxin.

Every deoxynucleotide in that figure — dGDP, dADP, and by extension dGTP, dATP, dXTP and dITP, and therefore every lesion counted in the dI and dX columns of Table 1 — passed through a pair of cysteines.

The author marked the two arrows where the volume's element does its work on somebody else's diagram, and wrote the names of the two electron carriers beside the heading.

The other annotations, recorded as written

annotation	where
"purine aromatic ring electron nucleotide 1st"	right margin, page 2319, with two ring structures drawn
"N_2O_4 → uric acid"	on Figure 1, beside the nitrous anhydride arrows
"NH_3 + H_2O"	beside the adenosine-to-inosine deamination arrow
"2, 10 G 1st steps"	above Salvage pathways or de novo synthesis
"HPRT" and "IMPDH 1 or 2"	written onto Figure 2
"bases X A H", "sides 5′", "nucleotide tri-phosphate"	along the DNA strand at the foot of Figure 2
"by definition mutation causes changes / wild type / only growth medium agar"	right margin, beside the hypothesis paragraph
"early contamination"	beside the isotopically labeled internal standards paragraph
RNA—SS/SH … DNA … SS RNA/SH	drawn as a box, top right

Two of these are methodological objections to the paper, and the volume prints them as such: the note about growth medium, and the note about the internal standards. Neither is developed into an argument here and neither is adopted by the volume.

---

686. What the Volume Takes ↩

Five things

First. Six hundred and forty-two fold. When both exits from inosine monophosphate are blocked and the pool-cleansing enzyme is removed, deoxyinosine in DNA rises from 1.2 to 770 per million nucleotides. That is the largest number in this volume for the incorporation of a base the alphabet does not name.

Second, and the finding this Part is named for as much as the first. Xanthine does not move. Across nineteen genotypes the largest xanthine change is 1.7-fold in DNA. Two deaminated purines, the same disposal enzyme, the same pathway, and a four-hundred-fold difference in how the cell treats them.

Third. The effect is synergistic and not additive — 16.8 times greater than the sum of the single mutants — and it reproduces in yeast with a different gene set. Single defects are nearly silent; pairs are catastrophic.

Fourth. Deleting the repair enzymes changed nothing, and the authors say so and call it an open question about how steady-state DNA damage is controlled.

Fifth. Human guanylate kinase accepts IMP and refuses 6-thioIMP. One oxygen exchanged for one sulfur at ring position six turns a substrate into a non-substrate.

And what it declines

That any human carrying the ITPA or IMPDH2 polymorphism has been shown to carry elevated hypoxanthine. Section 684 states that this is the authors' inference and that no such measurement is reported.

That the reason xanthine is refused is known. Section 683 lists five candidate mechanisms and records that the authors call them alternatives awaiting quantification.

That the author's methodological annotations of section 685 are endorsed. They are printed as his marginalia.

---

687. What Is Claimed, What Is Not, and What Would Show This Part Wrong ↩

Claimed

That the paper is Pang, McFaline, Burgis, Dong, Taghizadeh, Sullivan, Elmquist, Cunningham and Dedon, PNAS 109(7), 2319–2324, 14 February 2012, from MIT and

the University at Albany, edited by Gerald N. Wogan, received 13 November 2011 and approved 19 December 2011, supported by NIH grants CA116318, CA026731, ES002109 and RR0154464.

That the authors propose disturbance of purine nucleotide metabolism as a fourth mechanism of nucleobase deamination alongside hydrolysis, nitrosative chemistry and deaminase enzymes.

That quantification used isotope-dilution LC-MS/MS with uniformly ^{15}N-labeled internal standards, with coformycin at 5 µg/mL and tetrahydrouridine at 125 µg/mL present during purification to prevent deamination artefacts, and limits of detection of 5, 10 and 50 fmol for Ino, Xao and Oxo.

That in wild-type E. coli the levels per 10^6 nucleotides are Ino 11 ± 3, Xao 2.8 ± 0.5, dI 1.2 ± 0.2 and dX 1.3 ± 0.3, giving RNA-to-DNA ratios of 9.2 for hypoxanthine and 2.2 for xanthine as recomputed by the volume against the paper's ninefold and twofold; that dU was constant at approximately 5 per 10^5 nucleotides in all strains; and that oxanine was below detection at fewer than 5 per 10^8 nucleotides.

That the purA/guaB/rdgB triple mutant reached Ino 2,900 ± 400 and dI 770 ± 200 per 10^6 nucleotides, which the volume computes as 264-fold and 642-fold over wild type; and that the paper states increases ranging from 155- to 642-fold for the purA/rdgB combinations.

That across all nineteen genotypes in Table 1 the largest xanthine changes computed by the volume are 1.7-fold for dX and 2.6-fold for Xao; and that the authors state disruption causes large increases of hypoxanthine but not xanthine.

That the volume computes purA alone at 2.3-fold Ino and rdgB alone at 9.1-fold, against purA/rdgB at 190.9-fold — 16.8 times the additive prediction.

That in S. cerevisiae wild type gives Ino 42 ± 8 and dI 2.0 ± 0.1 per 10^6 nucleotides, ade12 and ham1 singly give no significant change, and ade12/ham1 gives 1,500 ± 72 and 98 ± 20 — 35.7 and 49.0 fold as recomputed by the volume against the paper's 36 and 49.

That loss of nfi or alkA, alone or in the triple-mutant background, did not affect xanthine or hypoxanthine levels, and that the authors state this raises questions about the mechanisms controlling steady-state levels of DNA damage.

That rdgB loss alone gave 10-fold and fivefold increases in Ino and dI, that yjjX loss alone and in combination with rdgB had no effect, and that the authors conclude

RdgB is the major xanthine and hypoxanthine nucleoside triphosphatase in E. coli and that in vivo substrate specificities need reconsidering.

That the authors propose five mechanisms for the absence of xanthine accumulation as listed in section 683; and that Agarwal and colleagues showed GMP, dGMP, 8-azaGMP and IMP are substrates for human guanylate kinase while XMP, UMP, CMP and 6-thioIMP are not.

That the ITPA 94C>A allele is present in 11–19 percent of Asians and reduces enzyme activity by 50 percent, and is associated with toxic responses to thiopurine therapy; and that an IMPDH2 promoter T-to-G substitution reduces gene expression by 50–60 percent.

That the author's working copy carries the annotations listed in section 685, including "Ferredoxin Thioredoxin" beside the Results heading and "cysteine" beside the ribonucleotide reductase arrows of Figure 2.

Not claimed

That elevated hypoxanthine has been measured in humans carrying the ITPA or IMPDH2 variants. Section 684 records this as the authors' inference and as an unperformed experiment.

That the cause of xanthine's exclusion is established. Section 683 prints five candidates and the authors' statement that they await quantification.

That the 6-thioIMP result of section 683 was presented by these authors as a sulfur result. It is a line in a substrate table they cite. The reading is the volume's and the chemistry is standard.

That the author's marginal objections about growth medium and internal standards are endorsed by the volume. Section 685 prints them as marginalia.

What would show this Part is wrong

— Repeat the measurement in purA/guaB/rdgB E. coli and obtain deoxyinosine near wild-type levels, and section 678 — the number this Part is named for — fails.

— Show xanthine rising by more than an order of magnitude in any purine-metabolism mutant, and the asymmetry of section 679 fails, and with it the Part's second finding.

— Show that purA and rdgB losses are additive rather than synergistic, and section 680 fails.

— Show that ade12 or ham1 single mutants raise inosine in yeast, and section 681's synergy claim is wrong.

— Show that deleting nfi or alkA does raise deoxyinosine, and section 682's open question dissolves — which would be a resolution rather than a refutation, and the volume would print it as such.

— Show that human guanylate kinase accepts XMP, or accepts 6-thioIMP, and the two-boundary argument of section 683 and its sulfur reading both fail.

— Measure hypoxanthine burden in humans homozygous for ITPA 94C>A and find it normal, and the clinical extrapolation of section 684 fails. Eleven to nineteen percent of one population carries the allele, so the cohort exists.

PART EIGHTY-NINE · THE MISSING BASE

Part Eighty-Nine of the evidence volume, sections 688 to 700

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Kopietz, Raorane, Guo and colleagues, with Helm and Motorin, Journal of Molecular Biology, 2025. The enzyme that installs queuosine at the wobble position removes the guanine first. When the replacement base fails to arrive, the reaction stalls and the transfer RNA is left with no base at position 34 at all. The gene still says G.

---

688. The Enzyme That Deletes the Base It Came to Replace ↩

What was found

tRNA-guanine transglycosylase — TGT — installs queuosine at anticodon position 34 by a base exchange reaction: it cuts the guanine off the sugar and puts a 7-deazaguanine derivative on instead.

The authors show that TGT, in bacteria and in eukaryotes, "accidentally leaves RNA abasic sites (rAP) in the anticodon loop of substrate tRNAs."

The mechanism, in their words

"The formation of an rAP site is a part of the TGT catalytic mechanism, involving the cleavage of the N-glycosidic bond, and the formation of a covalent enzyme-tRNA adduct."

step 1 TGT cleaves the N-glycosidic bond at G34\nthe guanine leaves\nstep 2 the ribose is held as an acetal, esterified to an active-site aspartate\nstep 3 preQ1 or queuine arrives and is attached\n--- OR ---\nthe incoming base does not arrive, the intermediate hydrolyzes,\nand the tRNA is released with NO BASE at position 34

The reaction is committed to removing the guanine before it is committed to replacing it.

Why this Part exists

Part Seventy-Five counted about two hundred modifications on the ribosome that the four-letter alphabet cannot write. Part Eighty-Five found an editor putting inosine into codons the notation records as adenine.

This is the same problem turned inside out. Here the notation records a base that is not present at all — not modified, not edited, not substituted. Absent. And the enzyme responsible is the one whose job was to improve that position.

The authors' own framing: "a unique molecular mechanism of RNA modification that, via a presumably erroneous reaction, diminishes RNA function rather than enhancing it."

---

689. What Tgt Does, and the Four TRNAs It Does It to ↩

The queuosine pathway

GTP —GCHI→ … —QueD→ … —QueE/C/F→ preQ1\n|\nTGT: base exchange at G34\n|\n▼\ntRNA-preQ1 —QueA→ epoxyQ —QueG→ tRNA-Q34

Part Seventy-Six recorded the domain census: bacteria modify G34 to preQ1, eukarya to queuosine, and archaea do not modify position 34 at all, modifying G15 to archaeosine instead.

The four substrates

Queuosine goes into the four transfer RNAs whose anticodon begins GUN:

tRNA	anticodon	codons read
Asn	GUU	AAU, AAC
Asp	GUC	GAU, GAC
His	GUG	CAU, CAC
Tyr	GUA	UAU, UAC

And one of those four is already in this volume

Part Eighty established that the presenilin 2 N141I mutation moves codon 141 out of the asparagine box — read by anticodon GUU carrying queuosine, 1859 gene copies, ninety-five percent of the pool — and into the isoleucine box read by inosine.

tRNA-Asn(GUU) is one of the four TGT substrates. The transfer RNA that reads the wild-type codon at PSEN2 position 141 is one of the four that this paper shows can be left without a base at its reading position.

The volume records the intersection and claims nothing causal from it.

---

690. How the Damage Was Found ↩

By accident, and the authors say so

"During our characterization of the specificity of AlkAnilineSeq we fortuitously came across the observation that aniline-driven cleavage profiles for both bacterial and eukaryotic tRNAs show variable and sub-stoichiometric, but still well distinguishable signals at the wobble position 34 in the anticodon loop."

The method

AlkAnilineSeq: alkaline fragmentation produces fragile nucleobases, aniline then cleaves the phosphodiester bond, and the resulting 5′-phosphate is used for direct adapter ligation. Counting read 5′-ends locates the fragile positions.

the method reliably detects	
m^7G, m^3C, dihydrouridine, ho^5C	the established targets
RNA abasic sites	efficiently, even at sub-stoichiometric amounts

The control that identified the chemistry

"Examining the experimental conditions required for the signal to occur at position 34, we found it to be aniline-dependent, but not alkaline-dependent."

The alkaline step of the protocol is what converts a modified base into a fragile one. If the signal does not need that step, the lesion was already fragile — which is what an abasic site is. One control, and the chemistry is narrowed.

And what it could not be

The authors rule out the obvious alternatives explicitly. It cannot be m^7G, which is found at the wobble position only in some rare mitochondrial tRNAs. It cannot be instability of queuosine itself, because the other GUN tRNAs from the same organisms show no signal. It cannot be epoxyQ, galQ, manQ or preQ1, because in E. coli only one form of modified Q34 has been characterized.

---

691. The Genetics: Tgt Required, PreQ1 Supply Decisive ↩

Four E. coli strains

strain	what is missing	result at G/Q34
wild type	—	signal present, strong in tRNA-Tyr(GUA)
tgt knockout	the enzyme itself	background only, in every tRNA and every replicate
queD knockout	preQ1 biosynthesis — TGT still present	substantial and statistically significant INCREASE in Asn, Asp and His
queA knockout	conversion of inserted preQ1 to mature Q	no substantial increase

What the four together establish

Remove the enzyme and the damage disappears. Remove the enzyme's incoming substrate and leave the enzyme running, and the damage increases.

That is the mechanism stated as a genetic experiment: the lesion is the enzyme operating without the base it needs to complete the reaction.

And the queA result places the failure earlier than maturation — the chemical structures at the terminal steps of the pathway are not responsible.

The eukaryotic side

In eukaryotes TGT activity requires a complex of two proteins, QTRT1 and QTRT2.

mouse cell line	result
wild type embryonic stem cells	signal present in tRNA-Asp(GUC)
qtrt1 knockout	no signal
qtrt2 knockout	no signal
knockout tRNA + recombinant mouse TGT in vitro	very strong signal

---

692. The Organisms with No Queuosine Have No Damage ↩

The natural knockouts

"Interestingly, natural knockout controls, namely organisms totally lacking queuosine and the Q-biosynthetic pathway, also lack such G34 AAS signals, and no signal was found in any tRNA(GUN) species from the budding yeast Saccharomyces cerevisiae and the plant Arabidopsis thaliana."

organism	queuosine pathway	abasic sites at G34
E. coli, B. subtilis	present	yes
human, mouse	present	yes
S. cerevisiae	absent	none
Arabidopsis thaliana	absent	none

Two organisms that never evolved the enzyme never suffer the lesion. That is a control the authors did not have to construct, and it is stronger than the engineered knockouts because nothing was deleted.

What the volume takes from it

Part Seventy-Six recorded archaea as the third case: no tadA homolog, no inosine at position 34, and no queuosine at position 34 either — archaeosine at position 15 instead.

Three domains, three different policies at the wobble position, and now a fourth column: the organisms that decline to modify it also decline the damage that comes with modifying it.

A modification system is not free. It carries a failure mode, and the failure mode is the loss of the base it was installed to improve.

---

693. The Stalled Intermediate, Caught in Vitro ↩

The reconstruction

Recombinant GFP-tagged E. coli TGT, run on a protein gel and scanned two ways.

condition	shifted band on GFP scan
enzyme alone	faint
enzyme + tRNA substrate	increased
enzyme + tRNA + 9-deazaguanine	yet more

The GelRed scan confirmed the shifted band contains RNA. Reproduced with murine TGT and with in vitro transcribed tRNA-Asp(GUC).

9-deazaguanine is an inhibitor that occupies the base pocket without being transferable. Adding it traps the covalent enzyme-tRNA adduct, which is exactly the intermediate the mechanism predicts. The stalled state for human TGT is deposited as PDB 7NQ4.

And the confirmations

absolute quantification of rAP by LC-MS/MS	clear increase over control
signal when natural substrate present in excess	lost
tRNA from tgt knockout + recombinant enzyme	signal recreated, all four GUN tRNAs
tRNA from qtrt1/qtrt2 knockout + recombinant mouse enzyme	signal recreated

"Ruling out the involvement of other cellular factors in TGT-mediated RNA damage."

The lesion was made in a tube, from purified protein and purified RNA, with the abasic site counted by mass spectrometry rather than inferred from a sequencing signal.

---

694. Stress, and Oxidative Stress Most of All ↩

Three treatments

condition	rAP at G34 in tRNA-Tyr(GUA)
rich LB medium, untreated	very low
starvation in PBS	raised
mild antibiotic — sub-MIC streptomycin	clearly enhanced
oxidative stress — 0.3 mM paraquat	most prominent

Biological triplicate. The other GUN tRNAs showed only very moderate increase, if any, under the same conditions.

What the authors decline to claim

"Accumulation of rAP sites in tRNAs (GUN) under ROS and antibiotic stress may be linked to global disturbances of translation and thus cellular homeostasis. However, the exact molecular mechanisms connecting TGT-dependent rAP sites in tRNAs and cellular stress remain to be elucidated."

The volume keeps their sentence intact. An association under three stresses, and no mechanism offered.

---

695. Brain, Lung and Spleen ↩

The mouse tissue survey

Transfer RNA extracted from dissected tissues — cortex, cerebellum, hippocampus, spleen, heart, lungs, kidneys, liver, muscle and intestine.

	rAP level
brain, lungs, spleen	highest
kidney, liver	consistently low, in all tRNAs

tRNA	rAP signal in mouse
Asp(GUC)	very strong
Asn(GUU)	moderate
His(GUG)	moderate
Tyr(GUA)	almost negligible

And despite the very different levels, the three tRNAs specific for Asn, Asp and His show very similar global profiles across tissues. Different amounts, same tissue ranking.

The reversal between organisms

In E. coli the strongest signal is tRNA-Tyr(GUA) and in mouse it is almost absent. In mouse the strongest is tRNA-Asp(GUC).

The same enzyme family, the same four substrate tRNAs, and the one that suffers most is different in bacteria and in mammals. The volume records the inversion and offers no explanation, because the authors offer none either.

Their own caution

"The reasons for such variations remain badly understood, since they may be related both to oxidative and other stress levels observed in these tissues as well as to the availability of queuine required for the TGT-catalyzed reaction."

Part Eighty recorded that humans cannot synthesize queuosine and salvage it from diet and gut bacteria. Queuine availability is a nutritional variable, and the authors name it as a candidate for a tissue difference in molecular damage.

696. The Damaged TRNA Is Excluded from the Ribosome ↩

The separation

fraction	contents
F0	free RNA — the cytosolic transfer RNA pool
F3	polysome-associated RNA — transfer RNA in active translation

The result

	rAP signal in tRNA-Tyr(GUA)
free fraction, F0	strong
polysome fraction, F3	lower

Obtained both under normal cultivation and under paraquat oxidative stress.

"tRNA molecules bearing rAP have diminished translational activity… rAP-containing E. coli tRNA-Tyr(GUA) should be considered as a damaged — because at least partially nonfunctional — molecular entity as a direct consequence of the catalytic action of an RNA modification enzyme."

Why it must be so

The abasic site is at position 34. That is the wobble position — the base that pairs with the third position of the codon.

A transfer RNA with no base at position 34 cannot read the third letter of its codon, because there is nothing there to read it with. Part Sixty-Nine established what sits at that position. This is what happens when nothing does.

The authors note the mechanism of exclusion remains to be determined.

697. Four Chemical States, One Letter ↩

The count

Consider position 34 of a single transfer RNA — say tRNA-Asp, anticodon GUC — across the four states it can occupy in a living cell:

state	what is physically at position 34	what the gene sequence says
1	guanine, unmodified	G
2	preQ1, a 7-deazaguanine	G
3	queuosine, with its cyclopentene diol	G
4	nothing — an abasic ribose	G

Four chemically distinct states of one position. One of them is not a base at all. The four-letter notation writes the same character in every case.

What each state does

state	can it read a codon?
guanine	yes — pairs with C, and with U by wobble
preQ1	yes
queuosine	yes
abasic	no — excluded from polysomes

This volume has argued since Part One that a notation records what it was built to record. Part Seventy-Five made that argument about modifications the alphabet cannot express.

This is stronger. The alphabet cannot express the difference between a base being present and a base being absent, at the one position in the transfer RNA where the reading actually happens.

And the sequencing methods that would report the transfer RNA's sequence read it as G in all four cases. It took a chemical protocol using aniline, developed for something else, to see the difference.

698. The Sulfur Modifications in the Same Paragraph ↩

What the introduction lists as RNA modification damage

The authors set their finding in a category they and others have been building, and every prior example they cite involves a sulfur:

modification	what happens to it	consequence
s^2C — 2-thiocytidine, near the anticodon in four tRNAs	methylated to ms^2C under alkylation stress	negatively affects translation efficiency
mnm^5s^2U	UV irradiation converts it to nm^5U	the sulfur is lost
ms^2i^6A	oxidation, including by MiaB	$msms^2i^6A$ and ms^2eA, classified as damage

And the repair: E. coli either uses the AlkB RNA demethylase to remove the methyl from ms^2C, or strips the thiomethylation entirely and re-introduces s^2C to restore normal translational activity.

What the volume takes

Three of the three previously documented cases of RNA modification damage are attacks on a sulfur atom at or beside the anticodon. And in one of them the cell's repair is to put the sulfur back.

Part Sixty-Nine established that a sulfur at the wobble position restricts reading while inosine expands it. Part Seventy-Six found s^2U at position 34 for glutamate, glutamine and lysine in two domains, and Figure 8 of that paper annotating the ring position "S <> O".

Here the same thiolated positions appear as the field's canonical examples of what gets damaged. The sulfur is where the modification is, and therefore the sulfur is where the damage is.

The volume records this as a pattern in the literature the authors assembled, not as a finding of this paper.

699. What the Volume Takes ↩

Five things

First. The enzyme that installs queuosine at the wobble position removes the guanine before it installs anything, and when the replacement fails to arrive the transfer RNA is left with no base at position 34. An RNA modification enzyme that damages its own substrate as part of its normal catalytic cycle.

Second. Four chemical states at one position — guanine, preQ1, queuosine, and nothing — and the notation writes G for all four. The alphabet cannot distinguish a base from its own absence at the reading position.

Third. The genetics are complete. Delete the enzyme and the damage vanishes. Delete the enzyme's incoming substrate and the damage increases. And two organisms that never evolved the pathway — yeast and Arabidopsis — carry none of it.

Fourth. The damaged transfer RNA is depleted from polysomes. It is made, it is not used, and it accumulates in the free pool.

Fifth. In mouse the damage is highest in brain, lung and spleen and lowest in kidney and liver, and the authors name dietary queuine availability as one candidate cause.

And what it declines

That the abasic sites are physiologically regulated. The authors call the reaction "presumably erroneous" and "accidental," and section 694 records that they state the mechanism connecting stress to rAP remains to be elucidated.

That the tRNA-Asn(GUU) intersection with Part Eighty means anything. Section 689 records the overlap and claims nothing causal.

That the sulfur pattern of section 698 is a finding of this paper. It is a pattern in the literature the authors cite in their introduction, and section 698 says so.

700. What Is Claimed, What Is Not, and What Would Show This Part Wrong ↩

Claimed

That the paper is Kopietz, Raorane, Guo, Flegler, Bourguignon, Thuillier, Kilz, Weber, Marchand, Reuter, Tuorto, Helm and Motorin, Journal of Molecular Biology 437 (2025) 169000, part of the special issue on tRNA modifications, edited by Ute Kothe, from Mainz, Nancy, Heidelberg, Mannheim and Marburg.

That TGT forms RNA abasic sites in the anticodon loop of substrate tRNAs as part of its catalytic mechanism, involving cleavage of the N-glycosidic bond and formation of a covalent enzyme-tRNA adduct esterified to an active-site aspartate.

That the four queuosine-containing substrates are tRNA-Asn(GUU), tRNA-Asp(GUC), tRNA-His(GUG) and tRNA-Tyr(GUA); that the strongest in vivo signal is tRNA-Tyr(GUA) in bacteria and tRNA-Asp(GUC) in vertebrates; and that the signal was observed in E. coli, B. subtilis, H. sapiens and

That the signal is aniline-dependent but not alkaline-dependent; that the authors exclude m^7G, queuosine instability, epoxyQ, galQ, manQ and preQ1 as explanations.

That the tgt knockout gives background only; that the queD knockout gives a substantial and statistically significant increase in Asn, Asp and His; that the queA knockout gives no substantial increase; and that qtrt1 and qtrt2 knockout mouse cell lines give no signal while recombinant mouse TGT in vitro gives a very strong one.

That no signal was found in any tRNA(GUN) from S. cerevisiae or A. thaliana, organisms lacking queuosine and the Q-biosynthetic pathway entirely.

That a GFP-tagged E. coli TGT produced a shifted band on SDS-PAGE increasing with tRNA and further with 9-deazaguanine, confirmed to contain RNA by GelRed; that LC-MS/MS absolute quantification of rAP showed a clear increase; that the signal was lost when natural substrate was present in excess; and that the human TGT stalled intermediate is PDB 7NQ4.

That rAP at G34 in tRNA-Tyr(GUA) was very low in rich LB, raised under starvation in PBS and sub-MIC streptomycin, and most prominent under 0.3 mM paraquat oxidative stress, in biological triplicate.

That mouse tissue levels were highest in brain, lung and spleen and lowest in kidney and liver; that tRNA-Asp(GUC) showed a very strong signal and tRNA-Tyr(GUA)

almost negligible; and that Asn, Asp and His showed similar global tissue profiles despite different levels.

That sucrose-gradient fractionation showed a strong rAP signal in the free RNA fraction F0 and a lower signal in the polysome fraction F3, under normal and paraquat conditions, and that the authors conclude rAP-bearing tRNA has diminished translational activity and should be considered damaged.

That the only other documented link between a natural RNA modification and rAP formation concerns wybutosine yW37 in eukaryotic tRNA-Phe(GAA); that RNA pseudouridine synthases also cleave the N-glycosidic bond and form a covalent aspartate intermediate without documented rAP formation; that an rAP inserted at position 1503 of bacterial 16S rRNA left ribosomes active but increased −1 frameshifting; and that a single ricin cleavage in the sarcin-ricin loop totally inactivates translation.

That the authors' introduction cites s^2C methylation to ms^2C under alkylation stress with AlkB demethylation or s^2C re-introduction as repair; UV conversion of mnm^5s^2U to nm^5U; and oxidation of ms^2i^6A to $msms^2i^6A$ and ms^2eA, previously classified by the same group as RNA modification damage.

Not claimed

That abasic site formation is regulated or functional. Sections 688 and 694 use the authors' words — "accidental," "presumably erroneous," and mechanism "to be elucidated."

That the tRNA-Asn(GUU) overlap with Part Eighty's presenilin analysis is causal. Section 689 records an intersection.

That queuine availability explains the tissue distribution. Section 695 records it as one of two candidates the authors name.

That the sulfur pattern of section 698 is this paper's result. It is their literature introduction and the section says so.

That rAP-bearing tRNAs are absent from polysomes. They are depleted, not absent, and section 696 uses the word.

What would show this Part is wrong

— Show abasic sites at G34 in a tgt knockout, or in S. cerevisiae or A. thaliana, and the attribution to TGT — the whole of sections 691 and 692 — fails.

— Show that the queD knockout does not raise the signal, and the mechanism of section 688 loses its genetic support.

— Show that recombinant TGT plus tRNA plus 9-deazaguanine does not generate rAP by LC-MS/MS, and section 693's in vitro reconstruction fails.

— Show equal rAP signal in the free and polysome fractions, and section 696's functional claim is wrong, and the lesion becomes a curiosity rather than damage.

— Show that the signal is alkaline-dependent after all, and the identification of the lesion as an abasic site is unsafe.

— Show a sequencing method that reports position 34 differently for guanine, preQ1, queuosine and an abasic site without chemical derivatization, and section 697's central claim — that the notation writes one letter for four states — is wrong. The volume expects no such method, which is why the claim is printed.

PART NINETY · THE AXIS AT THIRTY-SEVEN

Part Ninety of the evidence volume, sections 701 to 713

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Masuda, McGuigan, Maharjan, Yamaki and Hou, Journal of Molecular Biology, 2025. The base one place 3′ of the anticodon is not in the anticodon and is nowhere near the amino acid. Two modifications there decide both whether the transfer RNA gets charged and whether it reads its codon correctly — and one of them is a methyl from a sulfonium.

---

701. The Axis, and What It Connects ↩

The claim

"Charging and decoding of tRNA are two steps in an elongation cycle of protein synthesis that embody the essence of the genetic code."

"The nucleotide base at position 37 on the 3′-side of the anticodon can connect charging with decoding in one elongation cycle, providing an

axis to coordinate these two steps in the making of a new peptide bond."

The two modifications the review identifies

m¹G37	**N1-methylguanosine**	**installed by TrmD using S-adenosylmethionine**
t⁶A37	N6-threonyl-carbamoyladenosine	built from threonine, bicarbonate and ATP

And the review states plainly why the question went unanswered for so long: "past studies…largely used unmodified tRNA transcripts for analysis of charging."

The field could not see the effect because the material it worked with had the modification removed. Part Seventy-Five made the same observation about the ribosome, Part Eighty-Two about Crick's Table 1. Here it is stated by the review as the reason for a decades-long gap.

Why this Part follows the last one

Part Eighty-Nine dealt with position 34 — the wobble base — and what happens when the enzyme meant to modify it removes it instead. This Part deals with the base immediately beside it.

Part Sixty-Four of this volume already carries m¹I37: the deaminase acts first, the methyltransferase second. This is the general case of which that was one instance.

---

702. The Energy Bill for One Peptide Bond ↩

What it costs

"Making a new peptide bond is the most energy-consuming process of the central dogma, where at least three high-energy bonds are consumed."

ATP hydrolyzed to charge the amino acid onto the tRNA\nGTP hydrolyzed to accommodate the charged tRNA in the A site (EF-Tu)\nGTP hydrolyzed to translocate (EF-G)\n----------\nthree high-energy bonds, minimum, per peptide bond

Why coordination matters

"In some tRNAs, without a coordinated coupling of these two energy sources, while peptide bond formation can still take place, it is slow and error-prone, making the ribosome stall in the A site or shift to an incorrect reading frame downstream."

The argument is thermodynamic before it is informational. The cell spends three high-energy bonds to place one amino acid, and position 37 is where it decides whether that expenditure will be wasted.

And where the coordination is needed

Not everywhere. "The coordination of charging and decoding does not need to occur with all isoacceptors of each amino acid. Rather, it only needs to occur on the isoacceptors that address unusual codon assignments in a codon box."

The two examples the review names:

codon box	the awkward member
AUN	the Ile codon AUA, in a box with the Met codon AUG
UGN	the Cys codons UG[C/U], in a box with stop UGA and Trp UGG

Both of those boxes appear elsewhere in this volume. Part Eighty-Two recorded Crick's prediction that UGA could code only for cysteine or tryptophan or nothing. Part Seventy-Six recorded the AUA problem from the three-domain census. The review names them independently as the two places where the machinery needs extra help.

---

703. Why Position 37 and Not Position 34 ↩

The structural argument

	position 34 — the wobble base	position 37
inside the anticodon triplet?	yes	no
read by the aminoacyl-tRNA synthetase?	yes — the anticodon is often a critical charging determinant	not obviously
stabilized by the ribosome A site for codon pairing?	yes	adjacent only
typical identity	any base, heavily modified	typically a purine

The review's own reasoning: position 34's dual role is unsurprising because the anticodon is read by both machines. Position 37 is "not within the anticodon triplet and is also distant from the tRNA 3′-end for charging."

"While the proximity of nucleotide 37 to the anticodon provides the basis for a role in decoding, how this nucleotide is involved in charging is less obvious."

And what makes it interesting

"Nucleotide 37, along with the nucleotide 34, is frequently post-transcriptionally modified, possessing one of the largest collections of chemical structures."

And the distinction the review draws, which this volume has been drawing since Part One:

"While the unmodified nucleotide is hard-wired by each tRNA gene, the extent of each modification can change in response to environmental cues."

Two adjacent positions. The letters are in the genome. The chemistry is not.

---

704. Lysidine: One Modification, Two Specificities, Both Flipped ↩

The prelude, at position 34

Lysidine — L, or k²C — is a lysine-containing cytidine derivative at the wobble position of bacterial tRNA-Ile(CAU).

	without L34	with L34
charged with	methionine	isoleucine
decodes	AUG	AUA

One chemical modification, and both the amino acid and the codon change. Not the sequence — the sequence is CAU either way.

"L34 is the single determinant that governs the specificity of both charging and decoding for Ile(CAU)."

Why the review opens with it

"It was the discovery of this modification that opened the door to appreciate the ability of a single nucleotide modification to control both charging and decoding in a tRNA. This was ground-breaking as it shows that an epigenetic modification of a tRNA nucleotide, not hard-wired in the genome sequence but responsive to environmental cues, can regulate the quality of tRNA translation at specific codons."

A transfer RNA whose gene reads CAU is charged with methionine and reads AUG, or is charged with isoleucine and reads AUA, depending on a modification the gene does not specify. The four letters are identical in both cases and the outcome is a different amino acid at a different codon.

The volume records this as the strongest single demonstration it holds that the notation does not determine the reading.

---

705. And in Eukaryotes, Inosine Makes the Whole TRNA Unnecessary ↩

Three chemical inventions, and one deamination

lineage	tRNA used to read AUA	the chemistry at position 34
most bacteria	Ile(CAU)	lysidine, k²C
archaea	Ile(CAU)	agmatidine, agm²C
plant organelles, some bacteria	Ile(CAU)	2-amino-valeramididine, ava²C — a further modification of lysidine
eukaryotes and archaea	Ile(AAU)	inosine — A34 deaminated to I34

The sentence

"In eukaryotes and archaea, the AUA codon is read by Ile(AAU), where the wobble A34 is modified to I34 (I: inosine), which can base-pair with A/C/U, thus eliminating the need for the Ile(CAU) tRNA."

What that is

Three separate chemical solutions were invented to let a CAU anticodon read AUA without reading AUG — a lysine adduct, an agmatine adduct, and a valeramidine adduct, each requiring its own biosynthetic enzyme.

And the alternative is to remove one amine from one adenosine. The deamination product reads three bases instead of one, and an entire transfer RNA species becomes unnecessary.

Part Fifty-Seven established the three-partner rule. Part Eighty-Two found Crick stating it in 1966. Part Seventy-Six counted eight inosine anticodons in eukarya against one in bacteria.

This is the accounting behind that count. Where bacteria need three inventions, eukarya need one deamination, and the transfer RNA that would otherwise have been required is simply absent from the genome.

The volume notes that eukaryotes also carry a separate Ile(UAU) with a modified U34, recorded in Part Seventy-Six at 300 gene copies against 953 for the inosine anticodon. The two coexist. What is absent in eukaryotes is Ile(CAU) and the lysidine machinery.

---

706. Cysteine 37: the Identity Matters and the Modification Does Not ↩

The evolutionary switch

	nucleotide 37 in tRNA-Cys(GCA)
bacteria and yeast	A37
multicellular eukaryotes and archaea	G37

Charging

Substituting nucleotide 37 costs catalytic efficiency:

enzyme	discrimination against substitution at 37
E. coli CysRS	10^3-fold

enzyme	discrimination against substitution at 37
human CysRS	10^5 to 10^6-fold
for comparison — the discriminator base U73	10^6-fold

In the human enzyme, a base outside the anticodon and outside the acceptor stem discriminates almost as strongly as U73, which the review calls "the major determinant of tRNA charging with Cys."

And the strength of that recognition increased by two to three orders of magnitude between E. coli and human.

Decoding, in a reconstituted E. coli ribosome

	A37	G37	ratio
selectivity against a first-position near-cognate codon	5.7-fold	44-fold	7.7 ×
proof-reading against the same	1.2-fold	5.7-fold	4.8 ×

The control that makes this Part honest

"Notably, this analysis was done with an unmodified tRNA transcript, indicating that the position 37 modification is not required for the discrimination. A comparison between the unmodified A37 in the transcript of E. coli tRNA and the modified ms^2i^6A37 in the native tRNA showed little difference in codon selectivity."

For cysteine, the identity of base 37 does the work and its modification does not. That is the opposite of the m^1G37 and t^6A37 cases below, and the review prints it in the same paper.

The volume records the exception at full weight. A review that only assembled the cases supporting its own axis would not have included this one.

---

707. M^1G37 and the Two Frameshifts ↩

What it is and where

enzyme in bacteria	TrmD
methyl donor	S-adenosylmethionine — the sulfonium
conservation	all three domains, in a subset of tRNAs
which tRNAs	Pro(UGG, CGG, GGG), Leu(CAG, GAG, UAG), Arg(CCG)
status	a determinant for cell viability

Part Forty-Five established S-adenosylmethionine as the volume's sulfonium. Part Seventy-Five counted about a hundred of its methyls on the ribosome. This is the same donor placing one methyl on one nitrogen, and the cell dies without it.

What losing it does

Two distinct +1 frameshifts, measured:

	during translocation A → P	during stalling in the P site beside an empty A site
rate	0.1 – 0.2 s^{-1}	10^{-3} – 10^{-4} s^{-1}
scale	1 – 5 percent	30 – 40 percent

the slow shift is roughly 270x SLOWER\nand roughly 12x LARGER in scale

The fast shift is at a speed comparable to the rate of protein synthesis itself, so it can challenge quality during active growth. The slow shift catches the tRNA when the ribosome has nowhere to go.

And it is not sufficient on its own

tRNA	what suppresses +1 frameshifting
Pro(UGG)	m^1G37 alone is sufficient
Pro(GGG)	m^1G37 is insufficient — requires elongation factor EF-P

And both m^1G37 and EF-P exert their strongest suppression when the frameshift-prone motif sits next to the initiation codon AUG.

"Indicating that maintaining the reading-frame immediately after initiation of protein synthesis is an essential aspect of the translation machinery."

The A-site consequence

Genome-wide ribosome profiling: m¹G37 deficiency induces global ribosome stalling in E. coli, specifically at Pro codons CCN, Arg codon CGG and Leu codon CUA in the A site — every one of them translated by a normally m¹G37-methylated tRNA.

Cryo-EM shows why the methylation does not act in the A site itself: the conserved ribosomal RNA nucleotides there stabilize the codon-anticodon helix in the normal frame regardless. The methylation acts during translocation and in the P site.

---

708. Position 37 Governs What Position 34 Can Read ↩

The suppressor experiment

Analysis of suppressors of an E. coli trmD knockout strain:

"m¹G37 enables the cmo⁵U34-modified Pro(UGG) to decode all Pro codons CCN, while loss of m¹G37 causes insufficient reading of Pro codons CC[C/U] by the tRNA."

And the rescue: over-expressing the minor isoacceptor rescued translation of genes enriched in the rare CC[C/U] codons.

What that establishes

position 37 is methylated or not\n|\nv\nposition 34 cmo5U, the wobble base, can or cannot read CC[C/U]

A modification at position 37 determines what the modified base at position 34 is able to read. Two adjacent chemical marks, neither in the genome, and one governs the other.

Part Sixty-Nine established what sits at position 34 and what it does. Part Eighty-Nine established what happens when nothing sits there. This establishes that whatever does sit there is under the control of its neighbor.

And the whole cycle

"The discovery of m¹G37 being important for charging and decoding in the A site, together with its importance in maintaining the ribosome reading frame during tRNA translocation and during residency in the P site, suggests a sustained

involvement of the methylation throughout the entire elongation cycle of protein synthesis."

---

709. T⁶A37, and the TRNA That Does the Most Work ↩

The modification

full name	N6-threonyl-carbamoyladenosine
conservation	all three domains; essential in most bacterial species
built from	threonine + bicarbonate + ATP → threonyl-carbamoyl-adenylate (TC-AMP) → transfer to A37
found on	tRNAs reading ANN codons — Ile, Met, Thr, Asn, Lys, Ser, Arg

Three different machineries build the same molecule:

	enzymes
bacteria	TsaBCDE complex
eukaryote and archaeal cytosol	YRDC + the KEOPS complex
human mitochondria	YRDC + OSGEPL1

The same chemical structure, conserved across all three domains, assembled by three non-equivalent enzyme systems — including two different systems in the same human cell, one in the cytosol and one in the mitochondrion.

Where it is required for charging, and where it is not

tRNA	is t⁶A37 required for charging?
E. coli Ile(GAU) by E. coli IleRS	yes
yeast Ile(GAU) by yeast IleRS	no
human cytosolic Ile(AAU) and Ile(GAU)	yes
human cytosolic Ile(UAU) and other ANN readers	no
human mt-Thr(UGU) and mt-Lys(UUU)	yes
human mt-Ile(GAU)	no

The review calls the cytosol-to-mitochondrion switch "unexpected and should be further explored."

And the transfer RNA the axis is built around

The review's conclusion: t⁶A37 controls both charging and decoding in exactly two human transfer RNAs — cytosolic Ile(AAU) and mt-Thr(UGU).

"Ile(AAU) is the most abundant isoacceptor of the Ile family, which is used to decode all Ile codons via the A-to-I modification at the wobble position. This high demand for reading multiple Ile codons may subject the tRNA to coordinated regulation of charging and decoding via the axis of t⁶A37."

Position 34 of that transfer RNA carries inosine. Position 37 carries t⁶A. The two adjacent modifications together regulate the busiest isoacceptor in the isoleucine family, and the reason given for the extra regulation is that inosine at 34 makes it read three codons instead of one.

position 34 inosine - reads AUU, AUC, AUA\nposition 37 t6A - controls charging and prevents +1 frameshifting

The volume records this as the closest thing it has found to a stated reason why the inosine transfer RNA needs additional machinery: because inosine gave it more work to do.

What t⁶A37 does structurally

NMR and molecular dynamics of the human Lys(UUU) anticodon stem-loop: t⁶A37 stabilizes base stacking of U35 and U36, prevents mis-pairing of U33 with A37, and positions the wobble U34 in the direction for reading the codon.

Losing it produces increased non-AUG initiation, elevated +1 and −1 frameshifting, and stop-codon readthrough.

---

710. Diet, Stress, and the Enzymes That Install Them ↩

Three environmental responses the review reports

enzyme	modification	responds to	direction
TrmD	m^1G37	cell-wall disruption and quorum sensing stress	elevated
TilS	lysidine at 34	sporulation stress	strongly elevated
OSGEP	t^6A37	high-fat diet	decreased

A dietary variable changes the level of an enzyme that installs a transfer RNA modification which controls both charging and decoding of the most abundant isoleucine isoacceptor.

Part Eighty recorded that humans cannot synthesize queuosine and obtain it from diet and gut bacteria. Part Eighty-Nine recorded the authors naming queuine availability as a candidate cause of tissue-to-tissue variation in transfer RNA damage.

Three separate papers, three separate modifications, and the same finding: what the organism eats reaches the anticodon loop.

And the alternative mechanism it displaces

"MetRS enzymes across evolutionary domains are the only examples known to respond to stress by mis-acylation of non-Met tRNAs. In contrast, modulating charging by modification enzymes may have a broader scope, as each modification occurs in multiple tRNAs belonging to different amino-acid families."

Two routes by which a cell can change what its transfer RNAs carry under stress: mis-acylate them, or modify them. The review argues the second has the wider reach, because one modification enzyme touches many families at once.

---

711. The Minimal Set ↩

The prediction

"m^1G37 and t^6A37… are predicted to represent the bare minimum of tRNA modifications that support cellular life."

The basis: comparisons of transfer RNA modifications across genomes, showing that intracellular symbionts of insects, whose genomes have been reduced to near the minimum, still retain these two.

And the honest sentence

"However, direct validation of the prediction has not been done."

The review's own explanation for why these two and not others: "the essentiality of these two modifications for cell viability is linked to their ability to control the energy flow from charging to decoding."

And the accounting:

"The absence of this modification reduces charging and causes ribosome stalling at codons translated by tRNAs that normally have the modification, which in turn induces a stress response that shuts down global protein synthesis. In this case, the energy that is used to charge all other tRNAs and the energy that is used to decode all other codons up to the point of ribosome stalling would all have been wasted."

"Notably, while each modification is associated with multiple tRNAs, each only needs to control charging and decoding in one tRNA at one codon to affect global protein synthesis."

What the volume takes from this

If the prediction is right, then the irreducible minimum of transfer RNA chemistry is two modifications, and neither is expressible in the four-letter alphabet. The gene sequence of a minimal cell would show G at one position and A at the other, and a cell built from that sequence without the two modifications would not live.

The volume marks this as a prediction from comparative genomics that the review itself states has not been directly tested.

And the medical note

m^1G37	ranked a high-priority antibacterial target
why it is targetable	TrmD in bacteria and Trm5 in humans are non-orthologous in structure and mechanism
t^6A37	harder — key components share structural similarities across

m¹G37	ranked a high-priority antibacterial target
	domains

712. What the Volume Takes ↩

Five things

First, and the reason this Part exists. In bacterial tRNA-Ile(CAU), the lysidine modification at position 34 decides both which amino acid is loaded and which codon is read. Without it the transfer RNA is charged with methionine and reads AUG. With it, isoleucine and AUA. The gene reads CAU in both cases.

Second. Where bacteria evolved three separate chemical inventions — lysidine, agmatidine and 2-amino-valeramididine — to let a CAU anticodon read AUA, eukaryotes remove one amine from one adenosine and the whole transfer RNA species becomes unnecessary.

Third. Position 37, which is neither in the anticodon nor near the amino acid, discriminates against substitution by 10^5 to 10^6-fold in the human cysteine synthetase — comparable to the discriminator base itself.

Fourth. m¹G37, a single methyl from a sulfonium, is a determinant of cell viability, suppresses two kinetically distinct frameshifts, and governs what the modified wobble base at position 34 is able to read.

Fifth. The transfer RNA that carries inosine at position 34 is the one that gets the t⁶A37 axis, and the reason the review gives is that inosine made it read three codons instead of one.

And what it declines

That m¹G37 and t⁶A37 are the minimal set. Section 711 records that the review calls this a prediction and states directly that it has not been validated.

That the position 37 modification matters in every case. Section 706 prints the cysteine exception, where identity matters and modification does not.

That the mechanism by which either modification affects charging is understood. The review states it is "not well understood" and calls for structures of the synthetase with the modified substrate.

That the dietary and stress responses of section 710 have been shown to change translation in vivo. They are expression-level observations the review assembles.

---

713. What Is Claimed, What Is Not, and What Would Show This Part Wrong ↩

Claimed

That the paper is Masuda, McGuigan, Maharjan, Yamaki and Hou, Journal of Molecular Biology 437 (2025) 169095, received 27 December 2024, accepted 14 March 2025, from Thomas Jefferson University, edited by Jane E. Jackman, supported by NIGMS grant R35 GM134931.

That at least three high-energy bonds are consumed per peptide bond — ATP for charging, GTP for accommodation via EF-Tu, GTP for translocation via EF-G — and that the review calls peptide bond formation the most energy-consuming process of the central dogma.

That coordination of charging and decoding is needed only for isoacceptors addressing unusual codon assignments, and that the review names the Ile codon AUA in the AUN box and the Cys codons UG[C/U] in the UGN box.

That lysidine (L, k²C) at position 34 of bacterial tRNA-Ile(CAU) confers both correct charging with isoleucine and correct decoding of AUA, and that without it the transfer RNA is mischarged with methionine and decodes AUG; that archaea use agmatidine (agm²C) and plant organelles and some bacteria use 2-amino-valeramididine (ava²C); and that in eukaryotes and archaea AUA is read by Ile(AAU) with A34 modified to inosine, base-pairing with A, C and U, eliminating the need for Ile(CAU).

That nucleotide 37 in tRNA-Cys(GCA) is conserved as A37 in bacteria and yeast and G37 in multicellular eukaryotes and archaea; that E. coli CysRS discriminates against substitution at 10^3- fold and the human enzyme at 10^5–10^6-fold, comparable to U73 at 10^6-fold; that decoding selectivity against a first-position near-cognate codon is 5.7-fold for A37 and 44-fold for G37, and proof-reading 1.2-fold and 5.7-fold;

and that this analysis used unmodified transcripts and that native ms²i⁶A37 showed little difference in codon selectivity from unmodified A37.

That m¹G37 is synthesized by TrmD using S-adenosylmethionine, is conserved across all three domains in Pro(UGG, CGG, GGG), Leu(CAG, GAG, UAG) and Arg(CCG), and is a determinant for cell viability.

That loss of m¹G37 permits a fast +1 shift at k_obs 0.1–0.2 s^{-1} and 1–5 percent scale during translocation, and a slow shift at k_obs 10^{-3}–10^{-4} s^{-1} and 30–40 percent scale during P-site stalling; that m¹G37 alone suffices for Pro(UGG) but Pro(GGG) additionally requires EF-P; that suppression is strongest when the motif is next to the initiation codon AUG; and that m¹G37 deficiency causes global ribosome stalling at Pro CCN, Arg CGG and Leu CUA in the A site.

That m¹G37 enables cmo⁵U34-modified Pro(UGG) to decode all CCN codons and that its loss causes insufficient reading of CC[C/U].

That t⁶A37 is conserved in all three domains, essential in most bacteria, built from threonine and bicarbonate with ATP via TC-AMP, found on ANN-reading tRNAs, and synthesized by TsaBCDE in bacteria, YRDC with KEOPS in eukaryotic and archaeal cytosol, and YRDC with OSGEPL1 in human mitochondria.

That t⁶A37 is required for charging of E. coli Ile(GAU) but not yeast Ile(GAU); of human cytosolic Ile(AAU) and Ile(GAU) but not Ile(UAU); and of human mt-Thr(UGU) and mt-Lys(UUU) but not mt-Ile(GAU); and that the review concludes it controls charging and decoding in two human tRNAs — cytosolic Ile(AAU) and mt-Thr(UGU).

That t⁶A37 stabilizes stacking of U35 and U36, prevents U33-A37 mis-pairing, positions U34 for reading, and that its deficiency increases non-AUG initiation, +1 and −1 frameshifting, and stop-codon readthrough.

That TrmD expression is elevated by cell-wall disruption and quorum sensing stress, TilS strongly elevated by sporulation stress, and OSGEP decreased in response to high-fat diet; and that MetRS enzymes are the only known synthetases responding to stress by mis-acylation.

That m¹G37 and t⁶A37 are predicted to be the bare minimum of tRNA modifications supporting cellular life on the basis of insect intracellular symbiont genomes, that the review states direct validation has not been done, and that m¹G37 is ranked a high-priority antibacterial target with TrmD and Trm5 non-orthologous in structure and mechanism.

Not claimed

That the minimal-set prediction is established. Section 711 quotes the review's own statement that it has not been validated.

That position 37 modification governs charging universally. Section 706 prints the cysteine counter-example at full weight.

That the mechanism of the charging effect is known. The review states it is not.

That inosine at position 34 causes the requirement for t^6A37. Section 709 records the review's "may" and prints it as their proposed rationale.

That the dietary and stress effects alter translation in vivo. Section 710 records them as expression-level observations.

What would show this Part is wrong

— Show that lysidine-free tRNA-Ile(CAU) is charged with isoleucine, or decodes AUA, and section 704 — the strongest demonstration in the volume that a modification and not a sequence sets the reading — fails.

— Show that eukaryotes retain a functional Ile(CAU) with lysidine, and section 705's account of what inosine replaced is wrong.

— Show that human CysRS discriminates against substitution at position 37 by only around 10^3-fold, and section 706's comparison with the discriminator base fails.

— Show that m^1G37-deficient cells do not frameshift, or that TrmD is dispensable for viability, and section 707 fails.

— Show that loss of m^1G37 does not impair CC[C/U] reading by cmo^5U34-Pro(UGG), and section 708's claim that position 37 governs position 34 fails.

— Build a viable minimal cell lacking both m^1G37 and t^6A37, and the prediction of section 711 is falsified. The review states this test has not been performed, and the volume records it as the open experiment this Part generates.

PART NINETY-ONE · THIRTY SECONDS

Part Ninety-One of the evidence volume, sections 714 to 726

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Zhao, Snow, Stathis, Febbraio and Carey, Journal of Applied Physiology, 2000. Seven men, thirty seconds of maximal sprint cycling, and a needle into the thigh. Inosine monophosphate rises sixty-four-fold. This is the deamination channel of this volume, measured in a living human being, in half a minute.

714. The Measurement ↩

What was done

subjects	**seven healthy, active, non-specifically trained men**
age, weight	23.9 ± 2.3 yr, 74.4 ± 3.6 kg
peak oxygen consumption	55.0 ± 2.9 ml·kg⁻¹·min⁻¹
the exercise	30 seconds of all-out sprint cycling on an air-braked ergometer
the sample	percutaneous needle biopsy of the vastus lateralis, modified for suction
sampling points	rest, immediately after, 5 minutes, 10 minutes of passive recovery
handling	frozen immediately in liquid nitrogen
ethics	approved by the Human Research Ethics Committee, Victoria University of Technology

Four separate incisions in the same leg. Subjects fasted overnight and abstained from intense exercise, tobacco, alcohol and caffeine for twenty-four hours.

Why this Part exists

Part Eighty-Three established inosine monophosphate as the branch point of purine metabolism and measured what happens when the enzyme that consumes it is blocked in cultured cells. Part Eighty-Six measured the enzymes that keep inosine nucleotides out of the pool. Part Eighty-Seven modeled the pathway in thirty-seven equations. Part Eighty-Eight counted the lesions in bacterial and yeast DNA.

This Part is the same chemistry in a human thigh, under load, with a stopwatch. Nothing is knocked out, nothing is inhibited, nothing is transfected. Seven men pedal as hard as they can for half a minute.

And a note on the authorship, printed because the volume's own filing required it: this is S. Zhao of Victoria University of Technology in Australia, an exercise physiologist. It is not Huimin Zhao of the University of Illinois, nor Yu-Fen Zhao of

Tsinghua. Three scientists, one surname, and only this one is the source of what follows.

---

715. What Happens in Thirty Seconds ↩

Table 1 of the paper, in millimoles per kilogram dry mass

metabolite	rest	after 30 s	5 min	10 min
ATP	25.9 ± 1.0	16.7 ± 1.3	19.7 ± 1.5	23.4 ± 1.3
ADP	2.20 ± 0.20	2.00 ± 0.15	2.08 ± 0.16	2.01 ± 0.15
AMP	0.070 ± 0.004	0.060 ± 0.007	0.060 ± 0.004	0.060 ± 0.006
IMP	0.10 ± 0.02	6.40 ± 1.28	4.92 ± 1.08	1.73 ± 0.66
Ammonia	0.98 ± 0.10	6.24 ± 1.08	4.36 ± 0.76	2.62 ± 0.49
Inosine	0.02 ± 0.004	0.18 ± 0.10	0.43 ± 0.07	0.39 ± 0.14
Hypoxanthine	< 0.01	< 0.01	0.06 ± 0.02	0.06 ± 0.01
Phosphocreatine	84.3 ± 2.5	28.0 ± 1.2	80.0 ± 0.7	89.5 ± 2.0
Lactate	4.5 ± 0.7	68.2 ± 5.7	42.7 ± 3.2	21.4 ± 1.1
TAN = ATP+ADP+AMP	28.2 ± 1.1	18.7 ± 1.3	21.9 ± 1.5	25.4 ± 1.3

The headline

IMP 0.10 -> 6.40 64-fold, in thirty seconds\nATP 25.9 -> 16.7 down 36 percent\nammonia 0.98 -> 6.24 6.4-fold\nphosphocreatine 84.3 -> 28.0 down to a third\nlactate 4.5 -> 68.2 15-fold

A sixty-four-fold rise in the branch-point nucleotide of purine metabolism, in a healthy adult human, in half a minute of voluntary effort.

And the ordering of the cascade

Inosine does not peak until five minutes. Hypoxanthine is undetectable at rest and undetectable immediately after the sprint, and appears only at five minutes.

ATP -> ADP -> AMP --deaminase--> IMP -> inosine -> hypoxanthine\n|
| | |\n0 s 30 s 5 min 5 min

Part Eighty-One's purine square, running in reverse under load, with timestamps.

716. The Deamination, and a Stoichiometry That Checks Twice ↩

The reaction

AMP deaminase removes the exocyclic amine from adenosine monophosphate:

AMP + H2O --> IMP + NH3

One ammonia released for every inosine monophosphate made. This is the same chemical operation as the adenosine-to-inosine editing of Parts Fifty-Nine and Eighty-Five, performed on a free nucleotide instead of on a base in a polymer.

The first measurement

The paper's regression of total adenine nucleotide depletion against IMP accumulation:

correlation	**r = −0.97, P < 0.01**
slope	−0.83
the authors' test	not significantly different from 1.0
their conclusion	a 1:1 stoichiometric relationship

The second measurement, which the volume computed

The ammonia data are in the same table and were not used for this comparison by the authors.

IMP rose 6.40 - 0.10 = 6.30 mmol/kg dm\nammonia rose 6.24 - 0.98 = 5.26 mmol/kg dm\nammonia / IMP = 0.83

The regression slope from the adenine nucleotide pool is −0.83. The ratio of ammonia released to inosine monophosphate made is 0.83. Two independent quantities, from two different assays in the same seven men, agreeing to six-tenths of one percent.

The volume computed the second and records that the agreement is its own observation, not a claim of the paper.

What the agreement means

Each molecule of ATP that goes down this route loses one amine, and the amine appears as ammonia in the muscle.

The deamination channel of this volume is not an inference from enzymology. It is a mass balance in a human leg, and both sides of it were measured.

---

717. The Purine That Goes Missing ↩

The anomaly the authors print against themselves

Add every purine species measured — the adenine nucleotide pool, inosine monophosphate, inosine and hypoxanthine:

	TAN + IMP + inosine + hypoxanthine
rest	28.3 ± 1.1
immediately after 30 s	25.3 ± 0.7
5 min	27.3 ± 1.1
10 min	27.6 ± 0.8

$$\textit{deficit immediately after exercise} = 3.0\ \textit{mmol/kg dm} \quad P < 0.05$$

"Indicating that some of the purine pool had disappeared."

It did not leave the muscle

Plasma inosine and hypoxanthine were measured. "Very little accumulation of these metabolites occurred in this fluid compartment during exercise. Consequently, it is very unlikely that the 3 mmol/kg dm decrease in the muscle purine pool content could have resulted from a large efflux of purines into the extracellular fluid during the 30-s sprint."

And it is not unique to this laboratory: Tullson and colleagues reported that 18 percent of the fall in ATP was not accounted for by accumulated purines after exhaustive exercise.

The authors' candidate, and their own verdict on it

They propose oligophosphoglyceroyl-ATP — OPG-ATP — an acid-insoluble polymer of alternating ATP and 3-phosphoglycerate units, which the acid extraction used in this study would not detect.

reported in resting rat skeletal muscle	**0.2 to 0.4 µmol/g wet weight**
effect of exercise on the oligomer	no data available
measurements in human skeletal muscle	none ever reported

"Clearly, OPG-ATP as a possible source contributing to the restoration of TAN during the first 5 min of recovery is speculative."

And they print the argument against themselves as well: the 1:1 slope during the sprint "suggests that no OPG-ATP was produced."

The volume's position

Three millimoles per kilogram of purine leaves the accounting and comes back. It is not in the plasma. The proposed carrier has never been measured in a human muscle. The volume records the deficit as measured, the explanation as unmeasured, and the authors' own word for it — speculative — as theirs.

---

718. The Number That Matches ↩

One arithmetic coincidence the authors do point out

	mmol/kg dm
purine missing from the pool at the end of exercise	3.0
total adenine nucleotide restored during the first 5 min of recovery	3.0

"The magnitude of the restoration of the TAN pool during the first 5 min of recovery was equivalent to the fall in the sum of TAN + IMP + inosine + hypoxanthine pool during exercise."

And why that matters

During the first five minutes of recovery the adenine nucleotide pool rose by three, and inosine monophosphate did not fall.

first 5 minutes of recovery	
correlation between TAN increase and IMP decrease	r = −0.18, P > 0.05 — none
change in IMP	not significant
change in TAN	small but significant increase

"The increase in TAN during the first 5 min of recovery, in the absence of any change in IMP, indicates that skeletal muscle IMP reamination was not the major source for the restoration of the TAN pool in this time period."

Something restored three millimoles of adenine nucleotide, and it was not inosine monophosphate. The same three millimoles that had gone missing.

The volume records the match and marks it as the authors' own observation and their reason for proposing a carrier they could not measure.

---

719. And Then, in the Second Five Minutes, It Behaves ↩

The reversal

	first 5 min	second 5 min
correlation, TAN increase vs IMP decrease	r = −0.18, not significant	r = −0.80, P < 0.05
slope	—	−1.12
stoichiometry	none	1:1
the authors' reading	some other source	"restoration of the TAN pool is achieved primarily by IMP reamination"

Two consecutive five-minute windows in the same muscle. In the first, the adenine pool refills and inosine monophosphate does not move. In the second, every molecule of adenine nucleotide recovered is one molecule of inosine monophosphate consumed.

After ten minutes

TAN	still 10 percent below resting values, P < 0.05
IMP	not significantly different from pre-exercise

Thirty seconds of effort, and ten minutes later the adenine nucleotide pool has not fully returned.

---

720. Why the Inosine Monophosphate Will Not Clear ↩

The enzyme that would clear it

Adenylosuccinate synthetase — the first step from IMP to AMP — is "regarded as the rate-limiting enzyme in the reamination process."

Part Eighty-One drew that step as the left branch of the purine square: a single amination at ring position six, using aspartate as the nitrogen donor. Part Eighty-Seven modeled it as purA. Part Eighty-Eight deleted it and found six hundred and forty-two-fold hypoxanthine in DNA.

Three things inhibit it, and all three are present after a sprint

inhibitor	the value after 30 s	the threshold
high IMP	~2.1 mmol/l intramuscular	a concentration at which "marked inhibition of the synthetase is known to occur in vitro"
low pH	muscle falls to 6.6 – 6.8, and stays there for at least 6 min	the enzyme optimum is 6.8 – 7.2
low phosphocreatine	28.0 against 84.3 at rest	reamination in rat muscle occurs only above ~75 percent of resting PCr

The product inhibits the enzyme that would consume it, at a concentration the muscle actually reaches, while the pH sits below the enzyme's optimum and the phosphocreatine is at a third of normal.

Three independent brakes, all applied by the same thirty seconds of work.

The honesty note

"It should be noted, however, that some researchers argue that IMP inhibition of adenylosuccinate synthetase does not occur."

The volume records the dissent because the paper does.

---

721. And Salvage Loses the Race ↩

The enzyme

"The human muscle enzyme catalyzing purine salvage — hypoxanthine/guanine 5-phosphoribosyl 1-pyrophosphate."

That is HGPRT. Part Eighty-Seven built an entire Part on it: the Lesch-Nyhan enzyme, whose ratio of guanine to hypoxanthine activity separates neurological disease where absolute activity fails.

Its speed in muscle

HGPRT in vitro maximal activity in human muscle	< 0.1 μmol·min⁻¹·g dm⁻¹
purine nucleoside phosphorylase — the degradation enzyme	9 to 24 times faster

And a second limitation: HGPRT's in vivo activity in skeletal muscle "is also likely to be attenuated by the limited availability of one of its substrates — 5-phosphoribosyl 1-pyrophosphate."

In a working muscle the enzyme that recovers hypoxanthine is an order of magnitude slower than the enzyme that destroys it, and short of its co-substrate as well. Salvage is not a race the muscle wins.

Dephosphorylation of IMP accounts for less than 20 percent of the observed decrease during recovery — 1.49 mmol/kg dm — which the authors note is "consistent with other research that shows that the dephosphorylation of IMP is a minor fate for muscle IMP content during recovery from intense exercise."

---

722. Ammonia, and Where the Nitrogen Goes ↩

The other product

Muscle ammonia rose 6.4-fold during the sprint and declined through the ten-minute recovery. Plasma ammonia rose above basal during recovery, along with plasma inosine and hypoxanthine.

muscle ammonia, rest	**0.98 mmol/kg dm**
muscle ammonia, after 30 s	6.24 mmol/kg dm

What the volume takes from it

Every one of those ammonia molecules was an exocyclic amine on an adenine ring thirty seconds earlier.

The nitrogen that distinguishes adenine from hypoxanthine — the one atom at ring position six that Part Eighty-One identified as the boundary between the six-amino purine and the six-oxo purines, and that Part Eighty-Six found NUDT16 using to decide what it will and will not hydrolyze — leaves the ring and appears in the tissue as ammonia, in quantities you can measure with a biopsy needle.

Part Sixty-Seven of this volume recorded glutamate, serotonin and toxic ammonia exposure in the author's own 2001 statement. This paper measures the ammonia.

The volume records the connection as a connection and offers no clinical inference of any kind.

---

723. What This Part Is and Is Not ↩

What it is

The only measurement in this volume of the purine deamination channel operating in a healthy human being under ordinary physiological conditions. No mutant, no inhibitor, no cell line, no model organism. Seven men on a bicycle.

The limits, stated plainly

sample size	**seven**
sex	all male
training status	untrained, non-specifically trained

sample size	seven
muscle sampled	one — vastus lateralis
exercise	one bout, one duration, one modality
recovery observed	ten minutes only
extraction method	acid extraction, which by the authors' own argument cannot see OPG-ATP
replication	four biopsies from one leg per subject

And the authors' own caution on their headline result: "This interpretation must be treated cautiously, because all subjects displayed a greater decrease in TAN compared with the increase in IMP content."

The re-analysis they performed against themselves

Combining their seven subjects with six from an earlier study using the identical protocol, equipment and analytical procedures:

	n	r	slope
this study alone	7	−0.97	−0.83, not different from 1.0
combined data	13	−0.89, $P < 0.05$	different from 1.0, $P < 0.05$

With more subjects, their own 1:1 stoichiometry fails. They print it, and they state that this "supports the possibility that OPG-ATP may have accumulated."

The volume records both analyses and does not choose between them.

---

724. What the Volume Takes ↩

Five things

First. Inosine monophosphate rises sixty-four-fold in a human thigh in thirty seconds of voluntary effort. That is the branch-point nucleotide of Part Eighty-Three, measured in a person, without intervention.

Second. The stoichiometry checks twice. The paper's regression slope of adenine-pool depletion against IMP accumulation is 0.83, and the

ratio of ammonia released to IMP made — which the volume computed from the same table — is also 0.83. AMP deaminase, one amine per nucleotide, measured on both sides.

Third. Three millimoles per kilogram of purine leaves the accounting during the sprint and the same three millimoles returns to the adenine pool during the first five minutes of recovery. It is not in the plasma. The proposed carrier has never been measured in human muscle and the authors call the proposal speculative.

Fourth. The enzyme that would clear the accumulated IMP is inhibited by the IMP itself, by the acidosis, and by the depleted phosphocreatine — three brakes applied by the same thirty seconds that made the substrate.

Fifth. HGPRT in muscle runs nine to twenty-four times slower than the degradation enzyme and is short of its co-substrate. Salvage cannot keep up, and the purine is lost as hypoxanthine.

And what it declines

That OPG-ATP exists in human muscle. Sections 717 and 723 record that it has never been measured there and quote the authors' own word, speculative.

That the 1:1 stoichiometry is established. Section 723 prints their own combined-cohort re-analysis in which it fails.

That any of this bears on the six-symbol or eight-symbol question. It is a physiology paper. It measures the chemistry the volume is about and proposes nothing about the code.

Any clinical or training inference whatever. Section 722 states this explicitly.

---

725. What Would Show This Part Is Wrong ↩

— Repeat the biopsy protocol and find IMP rising by less than an order of magnitude after 30 s of maximal effort, and section 715 — the reason this Part is in the volume — fails.

— Show that the ammonia rise does not approximate the IMP rise, and the double stoichiometry of section 716 collapses. Both numbers are in the paper's own Table 1, so this is one subtraction and one division.

— Measure plasma purine efflux during the sprint and find it accounts for 3 mmol/kg dm, and section 717's missing pool is not missing.

— Measure OPG-ATP in human skeletal muscle and find none, and the authors' explanation for section 718 fails while the deficit itself remains — which would sharpen the problem rather than resolve it.

— Show that adenylosuccinate synthetase is not inhibited at 2.1 mmol/l IMP, and one of the three brakes of section 720 is removed. The paper itself records that some researchers argue exactly this.

— Show muscle HGPRT activity comparable to purine nucleoside phosphorylase, and section 721's ordering fails.

— Extend the study beyond seven untrained men, and find the 1:1 stoichiometry holds, and section 723's re-analysis is superseded. The authors' own thirteen-subject combination already says it does not.

726. What Is Claimed and What Is Not ↩

Claimed

That the paper is Zhao, Snow, Stathis, Febbraio and Carey, Journal of Applied Physiology 88, 1513–1519, 2000, from the Exercise Metabolism Unit, Victoria University of Technology, Deakin University and the University of Melbourne; and that this S. Zhao is not Huimin Zhao of the University of Illinois nor Yu-Fen Zhao of Tsinghua University.

That seven untrained men aged 23.9 ± 2.3 years, weighing 74.4 ± 3.6 kg, with peak oxygen consumption 55.0 ± 2.9 ml·kg^{-1}·min^{-1}, performed 30 seconds of all-out sprint cycling on an air-braked ergometer, with vastus lateralis needle biopsies at rest, immediately after, and at 5 and 10 minutes of passive recovery.

That the Table 1 metabolite concentrations in mmol/kg dry mass are as printed in section 715, including ATP 25.9 → 16.7, IMP 0.10 → 6.40, ammonia 0.98 → 6.24, inosine 0.02 → 0.18 → 0.43, hypoxanthine below 0.01 at rest and post-exercise rising to 0.06 at 5 minutes, phosphocreatine 84.3 → 28.0, lactate 4.5 → 68.2, and TAN 28.2 → 18.7.

That the exercise-induced increase in IMP was linearly related to the decrease in TAN at r = −0.97, P < 0.01, with slope −0.83 which the authors state is not significantly different from 1.0; and that the volume computed the ammonia-to-IMP ratio from the same table as 0.83.

That TAN + IMP + inosine + hypoxanthine was 28.3 at rest and 25.3 immediately after exercise, a deficit of 3.0 mmol/kg dm at P < 0.05; that plasma inosine and hypoxanthine showed very little accumulation during exercise; and that Tullson and colleagues reported 18 percent of the ATP fall unaccounted for after exhaustive exercise.

That the authors propose OPG-ATP as the missing species, that it is acid-insoluble and therefore invisible to their extraction, that resting rat skeletal muscle content is 0.2 to 0.4 μmol/g wet weight, that no data exist on the effect of exercise on it, that no measurements have been reported in human skeletal muscle, and that the authors call the proposal speculative.

That during the first 5 minutes of recovery TAN rose without a significant change in IMP and the correlation was r = −0.18, P > 0.05; that during the second 5 minutes the correlation was r = −0.80, P < 0.05 with slope −1.12; and that after 10 minutes TAN remained 10 percent below resting while IMP had returned to pre-exercise levels.

That adenylosuccinate synthetase is described as rate-limiting for reamination and is inhibited by high IMP, low pH and reduced phosphocreatine; that post-sprint intramuscular IMP was approximately 2.1 mmol/l; that muscle pH falls to 6.6–6.8 against an enzyme optimum of 6.8–7.2; that rat muscle requires PCr above about 75 percent of resting for reamination; and that the authors record the existence of researchers who dispute the IMP inhibition.

That human muscle HGPRT has in vitro maximal activity below 0.1 μmol·min⁻¹·g dm⁻¹, 9 to 24 times lower than purine nucleoside phosphorylase, and is further limited by PRPP availability; and that IMP dephosphorylation accounts for less than 20 percent, or 1.49 mmol/kg dm, of the recovery decrease.

That combining these seven subjects with six from an earlier identical-protocol study gave r = −0.89, P < 0.05, n = 13, with a slope significantly different from 1.0 at P < 0.05.

Not claimed

That OPG-ATP exists in human skeletal muscle. Never measured there; the authors say so.

That the 1:1 stoichiometry during the sprint is established. The authors' own thirteen-subject re-analysis contradicts it and section 723 prints both.

That the ammonia-to-IMP agreement of section 716 is a finding of the paper. The computation is the volume's, from the paper's own table, and section 716 states this.

That any of this supports a change to the genetic code. Section 724 states the opposite.

Any clinical, dietary or training recommendation. The volume makes none and section 722 says so.

PART NINETY-TWO · FORTY AND SIXTY-FIVE

Part Ninety-Two of the evidence volume, sections 727 to 739

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Varani and McClain, EMBO Reports, 2000. Crick proposed the guanine-uracil pair in 1966 as a permitted wobble at the reading position. Thirty-four years later it turns out to be the commonest mismatch in ribosomal RNA, the conserved cleavage signal of two classes of self-splicing intron, and the reason selenocysteine transfer RNA is kept out of ordinary translation.

---

727. The First Paper in the First Issue ↩

The publication

journal	**EMBO Reports, volume 1, number 1, pages 18–23**
year	2000
authors	Gabriele Varani, MRC Laboratory of Molecular Biology, Cambridge; William H. McClain, Department of Bacteriology, University of Wisconsin, Madison
received	6 February 2000; revised 22 March; accepted 4 April

journal	EMBO Reports, volume 1, number 1, pages 18–23
DOI	10.1093/embo-reports/kvd001

Volume one, number one. The digital object identifier ends in kvd001.

What it is for in this volume

Part Eighty-Two recorded Crick's 1966 paper and its Figure 4: guanine with uracil, requiring the glycosidic bond to move about 2.5 ångströms from the standard position. Crick offered it as one of five candidate geometries at the third codon position.

This review is what became of that one pair over the following three decades, in every class of RNA in all three domains.

The authors' own opening: "Little did Francis Crick realize 30 years ago that his G·U wobble base pair used in decoding mRNA codons would have such an expansive biological significance."

---

728. Crick Noticed It, and Holley's Molecule Already Had It ↩

The order of events

year	
1965	Holley and colleagues determine the primary sequence of yeast tRNA-Ala — the first RNA molecule ever sequenced — and it folds into a secondary structure containing a single G·U wobble pair
1966	Crick, considering codon-anticodon interactions, notices that G and U can form two hydrogen bonds through the same face used in Watson-Crick pairing
1975	The prediction is confirmed when the G·U pair in yeast tRNA-Phe is observed at atomic resolution — Ladner and colleagues, Quigley and Rich
1988	The G·U pair is shown to be a major determinant of tRNA-Ala's amino acid acceptor identity — Hou and Schimmel; McClain and Foss

"The history of the G·U pair is, in fact, even older."

The molecule this volume keeps returning to

Yeast transfer RNA for alanine appears in this volume for the third time.

Part	what it carried
Seventy-Eight	Holley gave it to Nirenberg's laboratory; Leder and Nirenberg showed it reads GCU, GCC and GCA, and that the residue in the third anticodon position is hypoxanthine
Eighty-Two	Crick derived its anticodon as IGC and called it "almost certain to my mind"
this Part	its acceptor-helix G·U pair is a determinant of which amino acid it accepts

The first nucleic acid whose sequence was ever determined carries an inosine at one end of the molecule and a G·U wobble pair at the other, and both of them turned out to be functional determinants. Neither is expressible in the four letters the sequence was written in.

---

729. Where G·u Appears ↩

The census the review assembles

location	status
tRNA-Ala acceptor helix, third position	conserved in nearly all living organisms
helices of ribosomal RNA	the most common mismatch
other transfer RNAs	as many as four, typically one
mRNA of ribosomal protein S15	recognition signal for autoregulation of protein synthesis
mRNA of ribosomal protein L30	recognition signal for autoregulation
group I self-splicing introns	at the site of cleavage, nearly universally conserved
hepatitis delta virus ribozyme	identifies its own self-cleavage site through a G·U pair
group II self-splicing introns, domain 5	nearly universally conserved, surrounded by two nearly invariant base pairs

The inference the authors draw from the conservation

"This conservation implies that the G·U pair possesses unique features that cannot be duplicated by any other nucleotide pair."

And the consequence when it is replaced: "Replacement of this wobble pair with a Watson-Crick pair compromises reactivity and fidelity" in the group I intron.

And the ribosomal protein connection

Part Seventy-Five recorded ribosomal protein L30 binding kink-turns in 25S ribosomal RNA and in its own pre-messenger RNA, regulating how much of itself gets made.

Here is the same protein again, and the recognition element in its own transcript is a G·U pair. Two Parts, two structural motifs, one autoregulating protein.

---

730. The Geometry: Forty Degrees and Sixty-Five ↩

What the angles are

	glycosidic angle
every nucleoside in a Watson-Crick pair	≈ 54°
guanosine in the G·U wobble pair	≈ 40°
uridine in the G·U wobble pair	≈ 65°

Watson-Crick pair both nucleosides at 54 deg spread = 0 deg\nG·U wobble pair guanosine 40, uridine 65 spread = 25 deg

The volume computed the deviations: guanosine sits 14° below the canonical angle, uridine 11° above.

And this is Crick's 2.5 ångströms, measured a second way

Part Eighty-Two section 599 recorded Crick's requirement that the glycosidic bond move about 2.5 ångströms from the standard position for the G·U pair to form.

A displacement he inferred in 1966 from paper models, expressed as one distance. Here it is resolved into two angles, twenty-five degrees apart, from crystallography and solution structures.

The consequence

"The substitution of G·U by any Watson-Crick pair or by a U·G pair therefore results in a structural disturbance in any sequence context in which the wobble pair is located."

Watson-Crick pairs can be interchanged at a site in a double-stranded region without substantially affecting the helical parameters. G·U cannot.

731. G·u and U·g Are Not the Same Object ↩

The clause that matters

The review says substitution "by any Watson-Crick pair or by a U·G pair" perturbs the structure.

G·U and U·G are two different arrangements. Which strand carries the guanine and which carries the uracil changes the geometry, because the two bases sit at different glycosidic angles and project different groups into different grooves.

What that costs the notation

the sequence records … G … on one strand\n… U … on the other\nit does not record whether that is G·U or U·G\nand the two are structurally distinct

Part Forty-Eight established that four bases close under complement — a unique involution, one partner each. That closure assumes the pairing is symmetric.

A G·U pair is not symmetric under exchange. The volume records this as the clearest structural case it holds where a pair is orientation-dependent, and the notation records orientation only by convention of which strand is written first.

732. The Electrostatic Hole, and the Metal That Binds in It ↩

What is different in the major groove

pair	what projects into the major groove
G·C	an NH_2 group, which interrupts the electrostatic gradient
A·U	an NH_2 group, same
G·U	guanosine N7, guanosine O6 and uridine O4 — co-planar

"The presence of co-planar guanosine N7, guanosine O6 and uridine O4 defines a region of deep negative electrostatic potential."

Three electronegative atoms in a plane, with no amine to break the field. Figure 2 of the paper shows the surface electrostatic potential of tRNA-Ala acceptor-end minihelices, wild type against a mutant in which G·U has been replaced by G·C, and the difference is visible as a red patch.

And what fills it

"This steep electrostatic gradient is a major determinant of the ability of G·U pairs, but not that of double helical tracts composed entirely of Watson-Crick pairs, to bind divalent metal ions."

affinity when two G·U pairs sit side by side	even stronger
the significance	"most RNA enzymes are metalloenzymes" in the sense that metal-binding sites generated by unique RNA structures position metals for catalysis
the conclusion	the ability of G·U pairs to bind divalent metal ions is likely to be important for RNA catalysis

A pair the four-letter notation calls a mismatch is the site at which ribozymes hold the metal they catalyze with.

The volume's note on the oxygens

Two of the three atoms defining that negative pocket are oxygens — guanosine O6 and uridine O4. Part Eighty-One established purine C6 and pyrimidine C4 as the reciprocal face positions of a canonical pair, and section 591 of that Part showed that the biosynthetic aminations of the two branch points install amines at exactly those two positions.

In A·T and G·C, one of those two positions carries an amine. In G·U, both carry an oxygen, and the resulting hole in the field is what binds the metal.

The volume records the correspondence as structural bookkeeping and claims no mechanism from it.

733. Nearly as Stable as Watson-crick, and That Is Not Enough ↩

The thermodynamics

"A second important aspect of G·U pair function is its thermodynamic stability, which approaches that of Watson-Crick pairs and exceeds that of most other mispairs."

Which is why it can substitute: "This high thermodynamic stability allows G·U pairs to substitute for Watson-Crick base pairs in phylogenetically conserved double-helical tracts in rRNA, ribozymes and other RNAs."

And it does structural work in its own right: in transfer RNA the G·U pair is most frequently found at the junction of the single-stranded V loop and the T helix, where the polynucleotide chain makes a sharp turn.

And then the sentence that undoes the simple reading

"However, thermodynamic stability is not sufficient for G·U function. For example, the aminoacylation capacity of active and inactive mutants of tRNA-Ala with various substitutions of G·U does not correlate with their respective thermodynamic stability."

Active and inactive mutants, and the stability does not sort them.

The pair is nearly as stable as a canonical pair, which explains why it is tolerated. It is not the stability that makes it work, which is why nothing else substitutes for it.

The volume records this as the review printing the limit of its own simplest explanation.

---

734. Conformationally Soft, and Recognized by Induced Fit ↩

The third property

"G·U pairs are conformationally soft in the sense that they are found in different conformations in different chemical and structural environments."

observation	
pattern introduced into the double helix	overtwisting and undertwisting
what sets the twist	the identity of the base pairs immediately adjacent to the wobble pair
the phosphodiester backbone conformation	varies between G·U-containing sequences and even between crystallographic environments of a given sequence
response to sequence context and crystal packing	sharper than Watson-Crick pairs

And the consequence

"Because of this property, the conformation of the RNA double helix can be more easily altered at sites containing wobble pairs, allowing for recognition by induced fit."

With a measured instance: a significant helical kink is observed at a G·U pair in the aspartyl-tRNA synthetase-bound form of tRNA-Asp, relative to the free unbound molecule.

The enzyme bends the RNA at the wobble pair. The pair is the hinge.

Part Thirty-Four of this volume dealt with induced fit and conformational selection as the two models of recognition. This is induced fit with the pivot point named.

---

735. What the Synthetase Actually Touches ↩

The chemical groups identified

In vitro analysis of alanyl-tRNA synthetase activity on the acceptor minihelix identified the specific groups critical for the enzyme:

the exocyclic amino group of two guanosines, including that of the G·U	
several ribose 2′-OH groups	
where they all sit	the minor groove of the tRNA acceptor end

"A related but not identical ensemble of chemical groups was also demonstrated to be important for the ability of the catalytic core of group I introns to recognize the substrate for splicing or to stabilize the enzyme's transition state."

The 2′ position again

Part Forty-Seven established the 2′ oxygen as the whole chemical difference between RNA and DNA, removed by ribonucleotide reductase, the volume's sulfur enzyme. Part Seventy-Five found about a hundred methyls placed on that same oxygen in ribosomal RNA, all from a sulfonium.

Here the same hydroxyls are among the atoms a synthetase reads to decide which amino acid to attach. The 2′ oxygen is removed to make DNA, decorated to tune the ribosome, and read to charge a transfer RNA.

And what the read-out combines

"The G·U pair in tRNA-Ala is recognized through a combination of the direct read-out of its distinctive chemical identity and by the indirect recognition of the structural features of the double helix in which the G·U pair is embedded."

Two mechanisms at once — the atoms, and the shape the atoms produce in their neighbors.

And the substitutions that work: C·C and C·A nucleotide substitutions functionally replace the G·U in tRNA-Ala, even though they contain different chemical features. For the group I intron, A·C — "which may be a close structural analogue of G·U" — provides the best substitute, while other mispairs do not.

---

736. Selection from Ten to the Fourteenth Finds It Anyway ↩

The in vitro evolution result

"Finally, RNAs that have been selected in vitro from large (10^{14}) pools of randomized RNA sequences to perform various biological functions often contain G·U pairs."

Why the volume prints it

Every other line of evidence in this review is phylogenetic — the pair is conserved, therefore it matters. That argument is circular if the conservation has a historical rather than a functional cause.

Selection from a hundred trillion random sequences has no history. Nothing is conserved in a randomized pool. And functional RNAs pulled out of it still carry G·U pairs.

That is an independent test of the conservation argument, and it passes.

The volume records it as the strongest single line in the review, and notes that the authors give it one sentence at the end of a paragraph.

---

737. The Selenocysteine Exception ↩

The last example in the summary

"An example of the latter type of discrimination is the non-productive interaction between charged selenocysteine tRNA and elongation factor Tu, which results from a particular G·U pair in that specialized tRNA."

What that means

Elongation factor Tu delivers every charged transfer RNA to the ribosomal A site. Selenocysteine transfer RNA must not be delivered that way — it has its own dedicated factor and its own codon-recontextualizing machinery.

what keeps Sec-tRNA out of ordinary elongation	a particular G·U pair
the mechanism	a non-productive interaction with EF-Tu
what the notation records at that position	G on one strand, U on the other

The twenty-first amino acid is excluded from the general delivery system by a single wobble pair. Remove the pair and the exclusion fails.

Why this Part ends here

Part Seventy-Eight section 556 recorded Dolph Hatfield — a post-doctoral fellow in Nirenberg's code laboratory, listed in Table 2 of Nirenberg's own account — spending his career at the National Cancer Institute on selenocysteine, the amino acid the sixty-four-cell table does not contain.

Part Twenty-Five dealt with the twenty-first and twenty-second amino acids and the selenium question.

Here is the structural device that keeps the twenty-first amino acid out of the ordinary machinery, and it is the same pair Crick drew in 1966 to explain how the third codon position is read. One geometry, doing a reading job at the anticodon and a gatekeeping job in the acceptor stem of a different transfer RNA entirely.

---

738. What the Volume Takes ↩

Five things

First. The first RNA molecule ever sequenced — Holley's yeast tRNA-Ala — carries an inosine at the anticodon and a G·U pair in the acceptor helix, and both turned out to be functional determinants. Neither is expressible in the four letters the sequence was written in.

Second. The geometry. Every nucleoside in a Watson-Crick pair sits at about 54°. In the G·U wobble pair the guanosine sits at 40° and the uridine at 65° — a twenty-five degree spread where a canonical pair has none. That is Crick's 2.5 ångströms, resolved into two angles a quarter of a century later.

Third. G·U and U·G are structurally different objects. A sequence records which base is on which strand only by the convention of which strand is written first.

Fourth. Three co-planar electronegative atoms — guanosine N7, guanosine O6, uridine O4 — make a deep negative pocket in the major groove that Watson-Crick pairs interrupt with an amine, and that

pocket is where the divalent metal binds. Ribozymes hold their catalytic metals at what the notation calls a mismatch.

Fifth, and the line the volume rates highest. RNAs selected from pools of 10^{14} randomized sequences to perform biological functions still contain G·U pairs. Conservation arguments can be historical accidents. A randomized pool has no history.

And what it declines

That thermodynamic stability explains G·U function. Section 733 prints the authors' own statement that it does not, and their tRNA-Ala counter-example.

That the O6 and O4 correspondence with Part Eighty-One's amination positions is more than bookkeeping. Section 799 says so.

That anything here bears on the six-symbol or eight-symbol question. It is a structural review of one non-canonical pair and proposes nothing about the code table.

---

739. What Is Claimed, What Is Not, and What Would Show This Part Wrong ↩

Claimed

That the paper is Gabriele Varani and William H. McClain, "The G·U wobble base pair: A fundamental building block of RNA structure crucial to RNA function in diverse biological systems," EMBO Reports volume 1, number 1, pages 18–23, 2000, DOI 10.1093/embo-reports/kvd001, from the MRC Laboratory of Molecular Biology, Cambridge, and the University of Wisconsin, Madison; received 6 February 2000, revised 22 March, accepted 4 April.

That yeast tRNA-Ala was the first RNA molecule whose primary sequence was determined (Holley and colleagues, 1965) and could be folded into a secondary structure containing a single G·U wobble pair; that the G·U pair was later shown to be a major determinant of that molecule's amino acid acceptor identity (Hou and Schimmel 1988; McClain and Foss 1988); and that Crick's prediction was confirmed when the G·U pair in yeast tRNA-Phe was observed at atomic resolution in 1975.

That the wobble pair at the third position of the tRNA-Ala acceptor helix is conserved in nearly all living organisms; that G·U pairs are the most common mismatch in the helices of ribosomal RNA; that other transfer RNAs contain as many as four but typically one; that the mRNAs of ribosomal proteins S15 and L30 contain G·U pairs providing autoregulation signals; that group I self-splicing introns contain a nearly universally conserved G·U pair at the cleavage site whose replacement by a Watson-Crick pair compromises reactivity and fidelity; that the hepatitis delta virus ribozyme identifies its self-cleavage site through a G·U pair; and that group II introns contain a nearly universally conserved G·U pair within domain 5 surrounded by two nearly invariant pairs.

That the glycosidic angle is approximately 54° for all nucleosides in Watson-Crick pairs, and approximately 40° for G and 65° for U in the wobble pair; that the volume computes the deviations as 14° and 11° and the spread as 25°; and that substitution of G·U by any Watson-Crick pair or by a U·G pair results in structural disturbance in any sequence context.

That co-planar guanosine N7, guanosine O6 and uridine O4 define a region of deep negative electrostatic potential; that G·C and A·U both project an NH_2 group into the major groove which interrupts the electrostatic gradient; that this gradient is a major determinant of the ability of G·U pairs but not all-Watson-Crick tracts to bind divalent metal ions; that affinity increases when two G·U pairs are side by side; and that the authors state most RNA enzymes are metalloenzymes in the sense described and that this metal binding is likely important for RNA catalysis.

That G·U thermodynamic stability approaches that of Watson-Crick pairs and exceeds most other mispairs, allowing substitution in conserved helical tracts; that in transfer RNA the pair is most frequently found at the junction of the V loop and T helix where the chain makes a sharp turn; and that the authors state thermodynamic stability is not sufficient for G·U function, citing aminoacylation capacity of active and inactive tRNA-Ala mutants not correlating with stability.

That G·U pairs introduce overtwisting and undertwisting influenced by adjacent base pairs; that backbone conformation varies between sequences and between crystallographic environments of a given sequence; that they respond more sharply to sequence context and crystal packing than Watson-Crick pairs, allowing recognition by induced fit; and that a significant helical kink is observed at a G·U pair in aspartyl-tRNA synthetase-bound tRNA-Asp relative to the free molecule.

That the groups critical for alanyl-tRNA synthetase activity include the exocyclic amino group of two guanosines and several ribose 2′-OH groups, all in the minor groove of the acceptor end; that a related but not identical ensemble matters for group I intron substrate recognition; that C·C and C·A substitutions functionally replace G·U in tRNA-Ala; and that A·C provides the best substitute in the group I intron.

That RNAs selected in vitro from pools of 10^{14} randomized sequences to perform biological functions often contain G·U pairs.

That the non-productive interaction between charged selenocysteine tRNA and elongation factor Tu results from a particular G·U pair in that specialized transfer RNA.

Not claimed

That thermodynamic stability explains G·U function. The authors state it is not sufficient and section 733 prints their counter-example.

That the O6 / O4 correspondence with Part Eighty-One's amination positions carries a mechanism. Section 799 calls it bookkeeping.

That this review supports a change to the genetic code. It is a structural review of one pair.

That G·U pairs are always metal-binding sites. The review says the gradient is a determinant of the ability to bind and that this is likely important, and the volume keeps both hedges.

What would show this Part is wrong

— Show that the glycosidic angles in a G·U wobble pair are near 54° for both bases, and section 730 — and with it the structural distinction from Watson-Crick geometry — fails.

— Show that U·G substitutes for G·U without structural disturbance, and section 731's orientation asymmetry fails.

— Show that all-Watson-Crick helical tracts bind divalent metals as well as G·U-containing tracts, and section 732's electrostatic argument fails.

— Show that aminoacylation capacity of tRNA-Ala G·U mutants does correlate with thermodynamic stability, and section 733's limit is not a limit — which would simplify the picture rather than break it, and the volume would print that.

— Show that in vitro selected functional RNAs contain G·U pairs no more often than chance predicts, and section 736 — the line the volume rates highest — fails. This is checkable against any published SELEX dataset.

— Show that selenocysteine tRNA interacts productively with EF-Tu when its G·U pair is replaced, and section 737 fails.

PART NINETY-THREE · THE OTHER OXYGEN

Part Ninety-Three of the evidence volume, sections 740 to 752

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The uracil in a Watson-Crick pair bonds through O4. The uracil in a wobble pair bonds through O2. It is not a different angle. It is a different oxygen, at the other end of the ring. That one relocation explains the metal-binding pocket of Part Ninety-Two, and it is invisible in a four-letter notation. This Part then asks what order costs, and answers it in kilocalories.

---

740. The Question That Started This Part ↩

What was asked

Part Ninety-Two recorded the geometry of the guanine-uracil wobble pair and the electrostatic pocket in its major groove. It did not ask why the pocket was there.

The question put to this volume was this: in an adenine-uracil pair the oxygen bonds to the uracil from one direction, and in a guanine-uracil pair from another. If the same position is being read both ways, what does that do to what happens at that position?

The question was posed about angles. The answer turns out to be about atoms, and it is a larger difference than the question supposed.

What this Part does

section	
741 to 745	the two pairs atom by atom, and what follows from the difference

section	
746 to 750	what the order of two pairs costs, in measured energy
751 to 752	whether any of this reaches the folded protein

741. The Two Pairs, Atom by Atom ↩

The canonical pair

In a Watson-Crick adenine-uracil pair there are two hydrogen bonds.

donor	acceptor
adenine N6-H	uracil O4
uracil N3-H	adenine N1

The uracil presents O4 and N3. Its O2 is not involved.

The wobble pair

Garg and Heinemann, refining an eighteen-base-pair RNA duplex at 1.38 ångström resolution, state the wobble bonds exactly:

"Both G·U pairs are organized in well-defined wobble geometry with two hydrogen bonds between O6(G)...N3(U)-H and N1(G)-H...O2(U)."

donor	acceptor
uracil N3-H	guanine O6
guanine N1-H	uracil O2

The uracil presents O2 and N3. Its O4 is not involved.

742. The Other End of the Ring ↩

What actually changed

uracil ring, the two carbonyl oxygens\nO4 O2\n/ /\nC4 C2\n\ /\nN3 - - - - - - - - - - - - -\nthe shared edge\nWatson-Crick A : U uses N3 and O4\nwobble G · U uses N3 and O2

N3 is common to both. The second contact moves from one carbonyl to the other.

O2 and O4 sit on opposite sides of the uracil ring, separated by the whole width of the molecule. The pairing does not tilt from one to the other. It lets go of one oxygen and takes hold of the other.

Why the framing matters

Part Ninety-Two described this as a displacement — Crick's 2.5 ångströms, resolved into two glycosidic angles twenty-five degrees apart. That description is correct and it is incomplete.

The angles are the consequence. The cause is that a different atom is doing the bonding, and the bases must rotate to bring it into register.

---

743. And That Is Why the Pocket Is There ↩

What Part Ninety-Two recorded

Section 732 recorded that guanine N7, guanine O6 and uracil O4 sit co-planar in the major groove of a G·U pair and make a region of deep negative electrostatic potential — the pocket that binds catalytic divalent metal.

It was recorded as an observation. It is a consequence.

The chain

in A : U uracil O4 is engaged in the pair no free carbonyl, no pocket\nin G . U uracil O4 is released O4 joins G-N7 and G-O6\nthree electronegative atoms, co-planar\none region of negative potential\none bound metal

The pocket exists because the pairing moved off O4 and onto O2. The wobble does not merely distort the helix. It liberates an oxygen, and the liberated oxygen is the site.

Garg and Heinemann add that the vacated groove is not empty even without a metal: a third hydrogen bond in each wobble pair is mediated by a water molecule in the major groove.

The volume's own statement

This inference is the volume's. Neither source states it. Varani and McClain name the three atoms of the pocket; Garg and Heinemann name the two bonds of the pair. Placing them together gives the reason, and the volume records that it did the placing.

CORRECTED IN PART NINETY-FOUR. Two things in this section are wrong. It treats the major groove as the whole account, and the minor groove carries the other half of the displacement — see section 754. And it names uracil O4 among the atoms of the pocket in a way that implies O4 ligates the metal; the solution structure shows guanine N7 and O6 make the hydrogen bonds while the uracil carbonyls contribute to the negative surface only — see section 762.

---

744. The Angles, Measured a Third Time ↩

Three independent determinations

source	year	what was measured
Crick	1966	glycosidic bond must move about 2.5 Å from standard — inferred from models
Varani and McClain	2000	guanosine ≈ 40°, uridine ≈ 65°, against a canonical ≈ 54°
Garg and Heinemann	2018	average λ shift of −12.5° for the purine and +15° for the pyrimidine

The comparison the volume computes

Varani & McClain purine -14.0 pyrimidine +11.0 spread 25.0 deg\nGarg & Heinemann purine -12.5 pyrimidine +15.0 spread 27.5 deg\ndifference 1.5 4.0 2.5 deg

Two crystallographic determinations, eighteen years apart, on different molecules, agree on the purine displacement to one and a half degrees and on the total spread to two and a half.

The caveat that must be printed

The Garg and Heinemann figures are averaged over six wobble pairs, of which two are G·U and four are C·A⁺. They are therefore not a strict replicate of the Varani and McClain values, which are for G·U. The agreement is real and it is not exact like for like.

And the same paper reports a second, different quantity: the C1′–C1′ distance falls to an average of 10.3 Å from the 10.6 Å of a Watson-Crick pair. That 0.3 Å is not Crick's 2.5 Å. They measure different things and the volume does not add them.

---

745. The Rule Generalizes: Purine Down, Pyrimidine Up ↩

What the 2018 structure shows beyond G·U

The six wobble pairs in that duplex "display clear wobble geometry, which is characterized by opposite drifts of λ angles for purines and pyrimidines."

	direction of drift
the purine of a wobble pair	below the canonical angle
the pyrimidine of a wobble pair	above the canonical angle

The forty and the sixty-five of Part Ninety-Two are not a fact about guanine and uracil. They are an instance of a rule about purines and pyrimidines in any wobble pair.

And a second wobble chemistry

The four remaining pairs in that helix are cytosine with protonated adenine — C·A⁺ — which the literature reports as isosteric with G·U and able to substitute for it.

pair	the two bonds
G · U	O6(G)…N3(U)-H and N1(G)-H…O2(U)
C · A⁺	N3(C)…N6(A)-H and O2(C)…N1(A⁺)-H

The same architecture, on different bases: a shared ring nitrogen, and a carbonyl at the two position. And the second pair only exists when the adenine is protonated — it requires a hydrogen the notation does not write, at a pH the notation does not record.

746. Sixteen Steps, Ten Energies ↩

The question of order

Sections 741 to 745 concern a single pair. This section begins the second question: whether two pairs in one order are the same object as the same two pairs in the other order.

The measurement exists. It is the nearest-neighbor model, in which the stability of a helix is the sum of the stabilities of its overlapping two-pair steps.

The count

possible dinucleotide steps	sixteen
independent measured parameters	ten
steps whose mirror is a different step	six
steps that are their own mirror	four

Reading a duplex from the other strand maps six of the steps onto the other six. Those six are not evidence of anything — the equivalence is bookkeeping.

The four that map onto themselves are where the question has no escape. For those, order is the only variable left.

747. The Four That Cannot Escape ↩

The Watson-Crick numbers

From the Turner 2004 parameter set, free energy change at 37 °C, kilocalories per mole:

step	ΔG°37	ΔH°
5′AU3′ / 3′UA5′	−1.10 ± 0.08	−9.38
5′UA3′ / 3′AU5′	−1.33 ± 0.09	−7.69
5′CG3′ / 3′GC5′	−2.36 ± 0.09	−10.64
5′GC3′ / 3′CG5′	−3.42 ± 0.08	−14.88

What the volume computes from them

A-U above U-A 0.23 kcal/mol same two pairs, opposite order\nG-C above C-G 1.06 kcal/mol same two pairs, opposite order\nfor reference, a whole A-U step is worth 1.10 kcal/mol

The difference made by the order of a guanine-cytosine and a cytosine-guanine pair is 1.06 kilocalories. An entire adenine-uracil step is worth 1.10. Order alone is worth as much as a base pair.

Both uncertainties are under a tenth of a kilocalorie. The separations are nine and twelve standard errors. This is not noise.

The enthalpies dissent

Note that A·U is more stable than U·A in free energy but less stable in enthalpy: −9.38 against −7.69 runs the other way. The ordering effect is partly entropic, and the volume records that without explaining it.

---

748. The Wobble Steps ↩

Two G·U pairs, two orders

step	ΔG°37
5′GU3′ / 3′UG5′	+1.29 ± 0.56
5′UG3′ / 3′GU5′	+0.30 ± 0.48

Both are positive. Both cost energy.

Two adjacent wobble pairs destabilize a helix in either arrangement, and the two arrangements differ by 0.99 kilocalories — as much as an entire adenine-uracil step.

And with a Watson-Crick neighbor

step	ΔG°37
5′GU3′ / 3′CG5′	−2.51 ± 0.25
5′CG3′ / 3′GU5′	−1.41 ± 0.24

1.10 kilocalories apart. The same G·U pair and the same C-G pair, in the two possible orders.

Part Ninety-Two section 731 recorded that G·U and U·G are structurally distinct and cited a sentence. Here is the same statement as a number, four times over.

---

749. What Context Is Worth ↩

The footnote that undoes the model

The Turner tables carry a note. Tandem G·U is generally unfavorable at +0.47 kilocalories, "but is favorable in the one context shown (GC preceding pair and CG following pair). For the favorable case, the single reported parameter (−4.12 kcal/mol) is used for the total of three stacks."

The volume's arithmetic

The favored unit is 5′GGUC3′ / 3′CUGG5′. Its three steps have published values of their own:

5'GG3' / 3'CU5' -1.53\n5'GU3' / 3'UG5' +1.29\n5'UC3' / 3'GG5' -1.53 (the symmetric equivalent of the first)\n----------\nsum of the parts -1.77\nmeasured as a unit -4.12\n----------\nunaccounted for -2.35 kcal/mol

Two and a third kilocalories of stabilization that the sum of the neighbors does not produce. The same four pairs, in the same order, worth something different because of what flanks them.

This computation is the volume's. The source publishes the three step values and the four-pair total; it does not print the difference.

What that means for the notation

The nearest-neighbor model was already an admission that a sequence is not a list of letters but a list of adjacencies. This footnote is an admission that adjacency is not enough either.

---

750. The Distinction the Volume Must Not Blur ↩

Two claims that are not the same claim

There is a temptation, having found the numbers above, to say that A·U and U·A are different objects. They are not, and the volume states the distinction plainly.

level	is order a real difference?
an isolated Watson-Crick pair	no. A:U and U:A name one physical object; which strand is written first is convention
an isolated wobble pair	yes. the displacement is off the pseudo-dyad, so which strand carries the purine is a real asymmetry
a two-pair step in a helix	yes, and measured. 0.23 to 1.10 kcal/mol, section 747 and 748
a step in a longer sequence	yes, and larger. 2.35 kcal/mol unaccounted, section 749

Part Forty-Eight established that four letters close under complement as a unique involution. That closure is a fact about the pairing map and it survives everything in this Part. What does not survive is the further assumption that the map's symmetry passes through to the structure.

The volume claims the second, not the first.

---

751. The Third Position and the Protein Fold: What Is Not True ↩

The proposition to be tested

The third codon position is where wobble pairing occurs. The question is whether the geometry of the pair at that position reaches the tertiary structure of the protein being made.

The answer, stated against interest

It does not, and the volume will not claim that it does.

where the wobble pair exists	between messenger RNA and transfer RNA, inside the ribosomal A site
how long it exists	the duration of one decoding event
what happens to it	it is taken apart when the ribosome translocates
what physical continuity it has with the protein	none

The tertiary structure of a protein is built from the amino acid sequence and the folding environment. There is no covalent path, and no hydrogen-bonding path, from a base pair in a nucleic acid duplex to the fold of the polypeptide that duplex helped specify.

A volume that argued otherwise would be making the error it accuses the notation of: reading a correspondence as a mechanism.

---

752. What Is True, and What This Part Claims ↩

The third position does change the fold — by a different route

Kimchi-Sarfaty and colleagues, in Science in 2007, reported the multidrug resistance transporter MDR1 carrying the polymorphism c.3435C>T.

the codon change	ATC → ATT
the amino acid change	isoleucine → isoleucine. none
the protein sequence	identical
messenger RNA and protein levels	similar to wild type
what differed	an altered conformation, with altered drug and inhibitor interactions

The arithmetic the volume checks

codon 1145 occupies nucleotides 3 x 1145 - 2 = 3433\n3434\n3 x 1145 = 3435\ntherefore c.3435 is the THIRD base of codon 1145

The polymorphism is at a third codon position exactly, by construction.

The path, in four steps, none of them a bond

third position changed\n-> a different isoleucine codon, read by a different tRNA\n-> a different pause length at the ribosome\n-> a different amount of chain folded before more chain arrives\n-> a different tertiary structure

The honest weakening

The proposed mechanism is a rare codon slowing the ribosome. The human usage figures do not show ATT to be rare:

isoleucine codon	per thousand codons
ATC	20.8
ATT	16.0
ATA	7.5

ATC to ATT moves from the most-used isoleucine codon to the second most-used, not to a rare one. The functional result has been reproduced; the rare-codon explanation for it remains one candidate among several, and the volume says so rather than borrowing the paper's confidence.

What this Part claims

1	**A Watson-Crick A:U pair bonds through uracil O4; a G·U wobble pair bonds through uracil O2. Different atom, opposite side of the ring**
2	The metal-binding pocket of section 732 exists because O4 was released. The volume's inference, from two sources neither of which states it
3	The wobble drift is a purine-pyrimidine rule, not a guanine-uracil fact, and C·A^+ is a second chemistry obeying it
4	The order of two base pairs is worth between 0.23 and 1.10 kcal/mol, measured, at nine standard errors or better
5	Flanking context beyond the nearest neighbor is worth a further 2.35 kcal/mol in the one case the tables expose
6	A synonymous change at a third codon position can change a protein's folded structure without changing one amino acid

What this Part does not claim

	that the geometry of the codon-anticodon pair propagates into protein structure. It does not
	that A:U and U:A are different pairs in isolation. They are not
	that the rare-codon mechanism for MDR1 is established. It is contested

	that the geometry of the codon-anticodon pair propagates into protein structure. It does not
	that the 2018 and 2000 angle measurements are a strict replication. They are not like for like

What would refute it

the claim	what would kill it
the O2 / O4 relocation	a G·U structure at comparable resolution bonding through uracil O4
the pocket follows from the release	a wobble pair with O4 engaged that still binds metal in the major groove; or an A:U context that makes the same pocket
order costs energy	a redetermination collapsing the AU/UA and GC/CG separations to within their errors
the 2.35 kcal residue	a corrected value for any of the three published step parameters that closes the gap
third position reaches the fold	failure to reproduce the MDR1 conformational difference under controlled expression

And the falsification this Part most invites: if the O4 release is the reason for the pocket, then any modification that occupies uracil O4 should abolish metal binding at a G·U pair while leaving the pair itself intact. That is a single experiment, and this volume does not know its result.

REVISED IN SECTION 762. That prediction is too strong. Uracil O4 contributes to the negative electrostatic surface but does not hydrogen-bond the metal, so blocking it should weaken binding rather than abolish it. The corrected prediction is stated in section 762.

PART NINETY-FOUR · BOTH FACES

Part Ninety-Four of the evidence volume, sections 753 to 765

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Six papers on the guanine-uracil pair, spanning 1995 to 1997. Part Ninety-Three printed one face of the wobble displacement and called it the account. The minor groove carries the other half, and it is worth two and a half kilocalories. The metal this volume inferred has been seen twice, by crystallography and by NMR. And the reagent that measured the amine is inosine with a sulfur atom on it.

753. The Six Papers ↩

What arrived, and what each settles

source	what it establishes
Strobel and Cech, Science 267(5198):675–679, 1995	the exocyclic amine of G in the minor groove, worth 2 kcal/mol to binding; and the tRNA-Ala synthetase parallel
Strobel and Cech, Biochemistry 35(4):1201–1211, 1996	the amine is worth 2.5 kcal/mol in wobble geometry and under 0.8 in Watson-Crick geometry
Strobel and Shetty, PNAS 94:2903–2908, 1997	which amines, by name, using thio-inosine as the probe
Cate and Doudna, Structure 4(10):1221–1229, 1996	metal bound in the major groove of G·U pairs, at 2.8 Å
Kieft and Tinoco, Structure 5(5):713–721, 1997	the same site in solution, and which atoms actually hold the metal
Gautheret, Konings and Gutell, RNA 1(8):807–814, 1995	about one hundred and twenty conserved G·U sites in ribosomal RNA

The shape of what follows

Two of these papers correct Part Ninety-Three. The volume prints the corrections before it prints the additions.

754. The Correction Owed to Part Ninety-Three ↩

What that Part claimed

Part Ninety-Three, sections 741 to 743, established that the uracil of a wobble pair bonds through O2 rather than O4, that O4 is so released, and that the released O4 joins guanine N7 and guanine O6 to make the negative pocket in the major groove.

Every word of that concerns the major groove. The Part did not mention the minor groove once.

Why that was wrong

Cate and Doudna state the two-sided fact in a single sentence:

"Although long-range RNA-RNA contacts within the molecule primarily involve the minor groove, osmium hexammine binds at three locations in the major groove."

ONE displacement, TWO faces\nmajor groove uracil O4 released -> negative pocket -> divalent metal\nminor groove guanine N2 exposed -> tertiary contact -> 2.5 kcal/mol

The wobble does not do one thing. It rotates the bases, and rotation has two sides. Part Ninety-Three described the face where the metal binds and was silent on the face where the specificity lives. This volume records the omission rather than quietly repairing it.

---

755. The Amine in the Minor Groove ↩

What Strobel and Cech did

They replaced the natural G·U pair with synthetic pairs that keep the wobble geometry but systematically change which functional groups are present.

analog	N2 exocyclic amine	paired against
guanosine	present	U, C, or isocytidine
inosine	absent	U, C, or isocytidine
diaminopurine riboside	present	U, C, or isocytidine
adenosine	absent	U, C, or isocytidine

Inosine is guanosine with the amine removed. Diaminopurine is adenosine with the amine added. The four analogs make a two-by-two design in which the amine is the only variable.

This volume has treated inosine since Part Sixty-Four as the base that reads three letters. Here it is used as a subtraction: the molecule that tells you what an amine is worth by not having one.

The result

"The exocyclic amine of G, when presented on the minor groove surface by the wobble base pair conformation, contributes

substantially (2 kilocalories·mole⁻¹) to binding by making a tertiary interaction with the ribozyme active site."

And the active site also contacts "a tripod of 2′-hydroxyls on the minor groove surface of the splice site helix," which led the authors to conclude that the ribozyme binds the duplex primarily in the minor groove.

---

756. Two and a Half Kilocalories, and Why Geometry Is the Variable ↩

The number, and its control

The following year the same authors measured the rate of 5′-exon miscleavage — cleavage at the wrong phosphate — across the same series of analogs.

the amine is presented by	its contribution
wobble geometry, in all three wobble pairs tested	2.5 kcal/mol
Watson-Crick geometry	under 0.8 kcal/mol

Why this is the strongest measurement in the group

the amine identical atom, identical chemistry, both cases\nthe geometry the only thing that changed\nthe difference more than 1.7 kcal/mol

The chemical group is not what carries the information. The chemical group presented at a particular angle is what carries the information. Move the same amine into a canonical pairing geometry and it stops being read.

This is the volume's thesis in one experiment. A notation that writes G has written the amine. It has not written the angle, and the angle is where the two and a half kilocalories are.

The magnitude it is set against

The Tetrahymena intron defines a single phosphate as the 5′-exon/intron boundary and catalyzes a reaction there with a rate enhancement of 10^{11}. Mutating the G·U pair to C·G reduces reactivity at the correct site by two orders of magnitude and increases cleavage at incorrect ones.

757. The Amine Works Twice ↩

Recognition, and then catalysis

what the amine does	how much
defines the exon/intron boundary — recognition	2.5 kcal/mol
stabilizes the chemical transition state — catalysis	1.0 kcal/mol relative to an inosine-U pair
of that transition-state figure, the portion independent of the neighboring U's 2′-hydroxyl	0.7 kcal/mol

The model the authors rule out

A natural explanation would be a water molecule bridging the guanine amine and the uridine 2′-hydroxyl. If that were the mechanism, removing the 2′-hydroxyl should abolish most of the amine's transition-state contribution.

It does not. Seven tenths of the contribution survives.

The authors' reading: the amine's hydrogen bond to its partner in the active site is slightly improved during the chemical transition. Not a new bond formed — an existing bond tightened.

Part Ninety-Three section 743 recorded that Garg and Heinemann find a water molecule in the major groove of each wobble pair. That water is real and it is on the other face. It is not this water, and the volume does not merge them.

758. The Instrument Is Inosine Carrying a Sulfur ↩

What nucleotide analog interference mapping is

Interference mapping identifies positions where replacing the nonbridging pro-R phosphate oxygen with a sulfur is detrimental to activity. Sites of incorporation are read out by cleaving the phosphorothioate linkage with iodine.

The reagents

reagent	what it is
IMPαS	5′-O-(1-thio)inosine monophosphate — inosine, sulfur-tagged
ITPαS	the triphosphate, synthesized from inosine
DMPαS	5′-O-(1-thio)diaminopurine riboside monophosphate — the amine-bearing control, same tag

What this volume notices

The assay works by exchanging an oxygen for a sulfur at the phosphate. The probe carrying that sulfur is inosine. The result it produced is the value of an amine on a purine ring.

Sulfur, oxygen, inosine, and an amino group — the four subjects of this volume — assembled into a single reagent in 1997, by a laboratory that was not thinking about any of the volume's questions.

Part Thirty-Eight established sulfur and oxygen as a conjugate pair, interchangeable at a position with consequences. Here the interchange is the measuring instrument: where the swap hurts, something was needed.

---

759. Which Amines Are Essential ↩

The scale of the search

There are 106 other guanosines within the intron beyond the ones already studied, several phylogenetically conserved. Testing them one at a time by full-length synthesis had made the question impractical. Interference mapping tests every position in one experiment.

What was found

position	requirement
G111, G112, G303 — three phylogenetically conserved guanosines	amino groups important for 3′ exon ligation
G22, and the amines of the other four guanosines within the P1 helix	essential for ligation of the 5′ exon

And the rescue

Point mutation of either G22 or G303 to adenosine substantially reduces activity. Adenosine, like inosine, lacks the N2 amino group.

Interference rescue was then detected at the site of mutation using DMPαS — diaminopurine, which is adenosine with the N2 amine restored. The G22A mutant could also be rescued by incorporating DMPαS at A24, a different position entirely.

genetics	the chemical equivalent demonstrated here
loss of function	interference
reversion	rescue at the mutated site
suppression	rescue at a different site — A24 rescuing G22A

A full genetic vocabulary, applied to a single chemical group rather than to a gene.

---

760. The Metal, Seen in the Crystal ↩

What Cate and Doudna resolved

The 2.8 Å crystal structure of the 160-nucleotide P4-P6 domain of the Tetrahymena intron — the first detailed view of metal binding in an RNA large enough to pack helices side by side.

"Osmium hexammine binds at three locations in the major groove. All three sites involve G and U nucleotides exclusively; two are formed by G·U wobble base pairs."

In the native RNA, two of the three sites are occupied by fully hydrated magnesium ions.

And the extrapolation the authors make

"The features of the observed metal-binding sites… suggest that some of the conserved tandem G·U base pairs in ribosomal RNAs are magnesium-binding sites."

That sentence is the bridge to section 764, and the authors wrote it before anyone had counted the sites.

761. The Metal, Seen in Solution ↩

The independent confirmation

Kieft and Tinoco solved the solution structure of the P5b stem loop bound to cobalt(III) hexammine, standing in for hexahydrated magnesium. The ion's position is fixed by intermolecular nuclear Overhauser cross-peaks to RNA protons in the major groove.

the binding site	**tandem G-U base pairs, in a run of four consecutive G residues ending in a GAAA tetraloop**
what the major-groove base edges present	"an electrostatically negative face and a variety of hydrogen-bond acceptors"
relation to the crystal	"the structure of the complex in solution is very similar to the structure in the crystal"

Part Ninety-Two section 732 described a region of deep negative electrostatic potential and said a metal binds there. Part Ninety-Three section 743 explained why the region exists. Here the metal is located in solution, atom by atom, by a method that shares no assumptions with the crystallography.

762. A Second Correction: Which Atoms Hold the Metal ↩

What Part Ninety-Three implied

Section 743 named guanine N7, guanine O6 and uracil O4 as the three atoms making the pocket, and said the metal binds there. A reader would take all three to be ligating the metal.

What the solution structure actually shows

"The metal ion ligand is bound near the guanosine nucleotides of the adjacent G-U base pairs, where it makes hydrogen bonds with the N7 and carbonyl groups of both guanines. The carbonyl groups of the uracil residues add to the negative surface of the binding pocket, but do not form hydrogen bonds with the hexammine."

atom	role
guanine N7	hydrogen bond to the metal ligand
guanine O6	hydrogen bond to the metal ligand
uracil O4	contributes to the negative surface — no hydrogen bond

What survives and what does not

SURVIVES uracil O4 is released by the wobble and adds to the negative face\nSURVIVES the pocket exists because the pairing moved from O4 to O2\nDOES NOT the reading that uracil O4 ligates the metal

The correction sharpens the falsification test. Part Ninety-Three section 752 proposed blocking uracil O4 and predicted metal binding would fail. It should not fail outright. It should weaken, because what is being removed is electrostatic attraction and not a hydrogen bond. A prediction of total abolition would have been the wrong prediction, and this volume revises it here.

And one more thing that structure reports

The binding site is preformed in the absence of metal ions, and the structure does not change significantly on binding.

The pocket is a property of the pair, not something the metal carves. Two G·U pairs stacked together make a hole whether or not anything ever occupies it.

---

763. The Synthetase and the Ribozyme Read the Same Amine ↩

The sentence that closes a thread

"The alanyl aminoacyl transfer RNA synthetase recognizes the exocyclic amine of an invariant G·U pair and contacts a similar array of 2′-hydroxyls when binding the tRNA-Ala acceptor stem, providing an unanticipated parallel between protein-RNA and RNA-RNA interactions."

The two readers

the reader	what it is	what it reads
the Tetrahymena ribozyme active site	RNA	the N2 amine of the G in a G·U pair, plus a tripod of 2′-hydroxyls
alanyl-tRNA synthetase	protein	the N2 amine of the G in a G·U pair, plus a similar array of 2′-hydroxyls

A protein and a nucleic acid, unrelated in composition, arrived at the same solution to the same problem: read the amine that the wobble geometry pushes into the minor groove.

The fourth appearance

Yeast transfer RNA for alanine now enters this volume for the fourth time.

Part	what it carried
Seventy-Eight	Leder and Nirenberg found hypoxanthine at the third anticodon position
Eighty-Two	Crick derived its anticodon as IGC
Ninety-Two	its acceptor-helix G·U pair determines which amino acid it accepts
this Part	the chemical group the synthetase actually touches is the N2 amine of that pair

Four Parts, one molecule, and at every appearance the operative feature is one the four letters cannot write: a missing amine, a wobble, an angle, an amine presented at that angle.

---

764. One Hundred and Twenty Sites ↩

The census

Gautheret, Konings and Gutell exhaustively analyzed the sequence alignments and secondary structures of eubacterial and chloroplast 16S and 23S ribosomal RNA, seeking positions with high levels of G·U.

"Approximately 120 such sites were identified."

The rule, and the sites that break it

The expected rule: the side of the wobble pair that loses stacking should sit in a loop, where stacking matters less.

"However, multiple sites violate these rules and display highly conserved G·U pairs in orientations that could cause severe stacking problems."

Conserved despite a structural penalty. That is the signature of a feature being kept for a reason other than stability.

The three recurrent motifs

motif	note
5′UG3′ / 3′GA5′	not previously reported
5′UG3′ / 3′GU5′	not previously reported — tandem G·U, the metal motif of sections 760 and 761
a G·U pair flanked by a bulge loop 3′ of U	

Two of the three motifs had never been described. And the second of them is the tandem arrangement that Cate and Doudna, in the same year, found holding magnesium.

Part Ninety-Two called G·U "the most common mismatch" in ribosomal RNA on the strength of a review sentence. Here is the count, the classification, and the anomaly.

---

765. What This Part Claims ↩

The claims

1	**The wobble displacement acts on both faces at once. Major groove: an oxygen released, a metal bound. Minor groove: an amine exposed, a partner read**
2	The N2 exocyclic amine of guanine is worth 2.5 kcal/mol in wobble geometry and under 0.8 in Watson-Crick geometry. Same atom. Only the angle differs
3	The same amine contributes a further 1.0 kcal/mol to transition-state stabilization, of which 0.7 is independent of the neighboring 2′-hydroxyl
4	The metal-binding pocket inferred in Part Ninety-Three has been observed twice — osmium hexammine at 2.8 Å, cobalt

1	**The wobble displacement acts on both faces at once. Major groove: an oxygen released, a metal bound. Minor groove: an amine exposed, a partner read**
	hexammine by NOE — and is preformed
5	Guanine N7 and O6 hydrogen-bond the metal; uracil O4 contributes to the negative surface only. This corrects Part Ninety-Three section 743
6	A protein and a ribozyme independently converged on reading the same exocyclic amine on the same conserved pair
7	About 120 conserved G·U sites exist in bacterial and chloroplast ribosomal RNA, and some are conserved in orientations that cost stacking energy

What this Part does not claim

	that the minor-groove amine and the major-groove metal are mechanistically coupled. They are on opposite faces and no source links them
	that the water in the major groove of Garg and Heinemann is the water ruled out by Strobel and Cech. Different faces, different waters
	that the 2 kcal/mol of the 1995 paper and the 2.5 of the 1996 paper are the same measurement. They are binding and boundary-definition respectively
	that the ribosomal G·U sites are metal sites. Cate and Doudna suggest it; nobody in these six papers has shown it

The correction record

what was wrong	where	corrected in
Part Ninety-Three treated the major groove as the whole account	sections 741–743	754
Section 743 implied uracil O4 ligates the metal	743	762
Section 752 predicted blocking O4 would abolish metal binding	752	762 — it should weaken it, not abolish it

What would refute this Part

the claim	what would kill it
geometry, not chemistry, carries the amine's value	a construct presenting the N2 amine in Watson-Crick geometry that recovers the full 2.5 kcal/mol
the pocket is preformed	a structure of the same tandem G·U motif, metal-free, showing the negative face absent until the ion arrives
guanine N7 and O6 are the ligands	a metal complex at a G·U site with the ion coordinated through uracil O4

the claim	what would kill it
the two-reader convergence	evidence that alanyl-tRNA synthetase reads something other than the N2 amine of the acceptor-stem pair
120 conserved sites	a re-analysis on modern alignments returning a materially different count

And the experiment this Part most wants run: present the N2 amine on the minor groove surface using a pair that is neither G·U nor Watson-Crick, and see whether the 2.5 kilocalories follow the amine or follow the geometry. Strobel and Cech tested three wobble pairs and one canonical one. A fourth geometry would settle whether the wobble is necessary or merely sufficient.

PART NINETY-FIVE · THE LAST PURINE

Part Ninety-Five of the evidence volume, sections 766 to 780

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Buckley, Barsky, Weinberg and Warburton, 2004. Inosine given to rats breathing ninety percent oxygen cuts DNA damage in the alveolar epithelium by forty percent, doubles their glutathione, and turns on the enzyme that excises oxidized guanine. Its metabolite uric acid does all of it completely. The enzyme that walks the purine square down to uric acid is a molybdenum center held and switched on by sulfur, and one missing sulfur atom separates kidney stones from death in infancy. And uric acid is where the square ends in us — because a methylated cytosine lost an amine, and an arginine codon became a stop.

What it is for in this volume

This volume has treated inosine as a reader. Part Sixty-Four established hypoxanthine as the base that arrives by deamination; Part Eighty-Two recorded Crick's inosine reading three letters; Part Ninety-Four found inosine used as a subtraction to weigh an amine.

Here inosine is none of those things. It is a drug, given by injection, and it works.

The Part follows the molecule to the end of its own pathway, and finds that the end is an antioxidant, and that in our lineage the pathway stops there because a gene was broken.

---

767. The Model and the Dose ↩

The injury

animals	**adult male Sprague-Dawley rats**
chamber	90 × 42 × 38 cm Plexiglas
exposure	humidified greater than 90 percent oxygen for 48 hours
why 48 hours	"reproducible damage to the alveolar epithelium with minimal mortality" — before the infiltrative phase
what happens	alveolar type 1 cells are destroyed within 24 hours; the normally quiescent type 2 cells later proliferate to resurface the denuded wall

The treatment

in vivo	**200 mg/kg inosine intraperitoneally in endotoxin-free PBS, at the start and every 12 hours for 48 hours**
in vitro	1 mM from the time of plating
the titration	0.1, 1 and 10 mM tested. 0.1 mM had virtually no effect; 1 and 10 mM had similar effects

A threshold between one tenth and one millimolar, and then saturation. Not a dose-response curve — a step.

The cells were isolated by elastase digestion and differential adherence, and confirmed as at least 95 percent positive for surfactant protein C. The lavage was over 90 percent macrophages.

768. What Inosine Did to the Damage ↩

The primary result

measure	effect of inosine
hyperoxia-induced DNA damage (TUNEL)	reduced by about 40 percent
given in vivo	~40 percent reduction
added in vitro	a similar reduction
in normoxic animals or cells	no effect

The same magnitude of protection whether the molecule was injected into a rat or added to a dish. That is the paper's first evidence that part of the effect is direct.

The apoptotic profile

protein	direction under inosine
ICE, a caspase	decreased
PARP, the molecular nick sensor activated by oxidative stress	expression and degradation decreased
Bcl-2, protective	increased

The number the volume flags

Normoxic TUNEL labeling is reported as 5 ± 5 percent.

The standard deviation equals the mean. On a baseline that small the volume records the figure and declines to lean on it.

769. A Purine Restores a Sulfur ↩

The measurement

Hyperoxia depletes cellular glutathione, and the DNA damage correlates with the depletion.

condition	glutathione
hyperoxic AEC2	depleted
hyperoxic + inosine in vivo	about 2-fold higher
hyperoxic + inosine in vitro	equally effective
hyperoxic + uric acid, 1 mM, in vitro	completely restored
normoxic, with or without inosine	no significant change

What the volume takes from this

Glutathione is the thiol tripeptide — the working sulfur of the cell, and this volume's molecule since Part One.

a purine is administered\n-> the sulfur pool is refilled\n-> the DNA damage falls

The volume has traced sulfur into cofactors, into methylation, into iron clusters and into the modified bases of transfer RNA. It has not previously had a case where a purine restores a sulfur. Here the restoration is complete, and the restorer is the terminal product of purine degradation.

And uric acid did the other half too: added in vitro at 1 mM it reduced TUNEL labeling to control levels.

---

770. The Enzymes That Do Not Do It ↩

The paper's own opening admission

"Antioxidant therapy would seem to be a logical rationale for treating or preventing hyperoxic lung damage, yet there are currently no antioxidant therapies in routine clinical use, despite decades of research in the field."

What the knockouts showed

Transgenic and knockout mouse models revealed negligible roles for the biological antioxidant enzymes in preventing hyperoxic lung injury:

enzyme	role in preventing hyperoxic lung injury
MnSOD	negligible
CuZnSOD	negligible
glutathione peroxidase	negligible

The inversion the volume records

Three dedicated antioxidant enzymes, each with a gene, each writable in four letters, each knocked out — and the injury proceeds. A purine metabolite, which no gene encodes and which is the waste product of a degradation pathway, works.

The volume states this as an observation about this injury model and claims nothing general about antioxidant defense. But it is the shape of an argument this volume has made before: the thing the notation names is not always the thing doing the work.

---

771. Inosine Turns on the Eraser ↩

The repair enzyme chosen as the marker

8-oxoguanine DNA glycosylase — OGG — a base excision repair enzyme that removes oxidized guanine from DNA. It is activated by hyperoxia.

condition	OGG expression by Western blot
control AEC2	virtually undetectable
hyperoxia	induced
hyperoxia + inosine in vivo	further increased
normoxia + inosine	also induced

The repair enzyme is not standing by. In an untreated cell it is essentially absent, and it has to be called for. Inosine calls for it — and calls for it even when there is no injury.

Where this meets the volume

Part Eighty-Six tested what the nucleotide-pool sanitizer NUDT16 would bind. Among the beads was phosphate-8-oxo-GTP, and the column pulled down nothing.

level	the lesion	what handles it
the nucleotide pool	8-oxo-GTP	not NUDT16 — Part Eighty-Six found no binding
the DNA itself	8-oxo-guanine in the strand	OGG, and inosine induces it

Two sanitation duties for the same damaged base at two different levels. The volume has now met both, and neither of them is expressible in a four-letter alphabet, because 8-oxoguanine is not one of the four letters — it is a G with an extra oxygen that the notation still calls G.

---

772. Protection by Exaggeration ↩

What went up, not down

The obvious expectation is that a protective agent suppresses the injury response. It does the opposite.

in bronchoalveolar lavage	inosine-treated versus hyperoxia alone
active TGF-β	consistently threefold HIGHER
TNF-α	not significantly altered
IL-1β	not significantly altered

And in the cells: hyperoxia activates Smad2; inosine co-administered with hyperoxia gives a further 2-fold activation. Inosine in vitro had no effect on Smad2 — so this arm is indirect.

The mechanism proposed

AEC2 are normally quiescent	majority in G0/G1, only about 6 percent in S and G2/M
during repair after hyperoxia	rises transiently to about 10 percent
with inosine	significantly fewer cells in S and G2/M, accumulation in G0/G1

The authors' reading: more active TGF-β holds the cell in G1, and the arrest is "a time-out for DNA repair." The cell is protected by being stopped.

The paper cites the same result in mink lung epithelial cells, where protection against oxygen-induced DNA damage through G1 blockade is attributed to an enhanced ability to recognize and repair damaged DNA.

The volume records the counter-intuitive shape plainly: the protected animals had more of the cytokine, not less. A model in which protection means suppression would have predicted the wrong sign.

---

773. The Causal Test, and the Honest Split ↩

The signaling result

kinase	effect of in vivo inosine during hyperoxia
ERK 1/2	significant two-fold activation, above hyperoxia alone
JNK	not altered
p38	not altered
inosine added in vitro	did not activate ERK

The activation was present in freshly isolated cells as well as in 24-hour cultures — so it was initiated in the animal and sustained through culture.

The blockade

PD98059, a MEK inhibitor, at 50 μM from the time of plating:

"The protective effect of inosine was abolished, resulting in TUNEL labeling similar to that seen in AEC2 from rats subjected to hyperoxia alone."

That is an intervention, not a correlation. Block the kinase and the protection disappears.

The two mechanisms, separated

DIRECT works in a dish reduces DNA damage, restores glutathione\n-> antioxidant chemistry, and uric acid does it fully\nINDIRECT needs the animal ERK activation, Smad2 activation, TGF-beta rise\n-> paracrine signaling, MEK-dependent

The authors could have reported one mechanism. They ran the same molecule in vivo and in vitro, found that one arm survives the transition and the other does not, and printed both. This volume records that as the correct behavior.

---

774. What they Looked for and Did Not Find ↩

The receptor hunt

Inosine signaling through adenosine A3 receptors had been described in rodent mast cells, and the most abundant expression of human A3 receptors is in lung and aorta.

target	result
A3R at the expected ~52 kD	not detected in AEC2 lysates — though readily detectable in whole rat lung
a band at ~30 kD	seen in AEC2, and in the macrophage-lysate positive control
A2a receptors	not detected, with the caveat that the antibodies were not raised against rat epitopes

"Whether this is a metabolite of the receptor, or an unrelated protein, remains to be determined."

The route by which inosine reaches the cell is therefore unestablished. The paper says so, and proposes the experiment that would settle it: confirm the receptor subtypes by PCR, then block them in vivo with specific antagonists.

---

775. The End of the Purine Square Is an Antioxidant ↩

The pathway, in this volume's own notation

Part Eighty-One established the purine square: IMP to XMP to GMP on one side, IMP to AMP on the other. This paper runs the other direction, down.

IMP -> inosine -> hypoxanthine\n| xanthine oxidoreductase + O\nv\nxanthine\n| xanthine oxidoreductase + O\nv\nuric acid

step	color in this volume's scheme
hypoxanthine	orange
xanthine	indigo
uric acid	the terminus

Two successive oxidations, both by the same enzyme, xanthine oxidoreductase — which this volume has already met in Parts Four, Fifteen, Forty, Forty-Seven and Fifty-Two.

The result

Uric acid is the end product of purine metabolism in humans and is a major antioxidant of human plasma. The degradation pathway that loads two oxygens onto a purine ring terminates in a molecule whose function is to absorb oxidative damage.

And in this paper it is the active agent: uric acid restored glutathione completely and reduced DNA damage to control levels, where inosine only halved the damage and doubled the glutathione.

Inosine, injected or ingested, causes only a minor increase in serum inosine, with a more sustained elevation in serum uric acid. The authors conclude it is likely that uric acid contributes to the protective effect. The drug is a precursor. The agent is the terminus.

---

776. The Enzyme Is Held Together by Sulfur ↩

What xanthine oxidoreductase is made of

The enzyme that performs both oxidations of the preceding section is a homodimer of about 300 kilodaltons. Each half of it carries three prosthetic groups.

per subunit	
one	molybdenum cofactor — the pterin-based Moco, also called molybdopterin
two	[2Fe-2S] iron-sulfur clusters, non-identical
one	FAD

Where the sulfur is

The molybdenum atom is not held by the protein directly. It is chelated by a dithiolene — two sulfur atoms carried on the pterin. And there is a third sulfur beyond those two: a terminal Mo=S sulfido ligand in the equatorial position.

sulfur atoms at one active site\n2 dithiolene, clamping the molybdenum\n1 terminal sulfido, on the molybdenum\n4 inorganic, in the two [2Fe-2S] clusters\n---\n7 before counting the cysteines that hold the clusters in place

And the third one is the one that decides

The terminal sulfido is labile. Treat the enzyme with cyanide and that atom leaves as thiocyanate. What remains is called the desulfo form.

The desulfo form is catalytically dead. The equatorial sulfido ligand is required for the enzyme to hydroxylate hypoxanthine and xanthine at all.

There is an enzyme whose entire job is to put it back

Molybdenum cofactor sulfurase — MOCOS in humans, ABA3 in Arabidopsis — converts the molybdenum cofactor from the desulfo form into the sulfo form.

A gene, a transcript, a folded protein and an active site, maintained by selection across plants and animals alike, existing to reinstall one sulfur atom onto one metal atom.

What the preceding section did not say

It recorded that the purine square ends in an antioxidant. It did not record what walks it there.

The machine that turns hypoxanthine into xanthine and xanthine into urate is a molybdenum center clamped by sulfur, activated by sulfur, and wired to its flavin through two iron-sulfur clusters. Remove one atom of sulfur and the descent stops before it starts.

777. One Atom, Two Phenotypes ↩

The rule that splits the molybdoenzymes

"Xanthine dehydrogenase and aldehyde oxidase, but not sulfite oxidase and nitrate reductase, require the post-translational sulfuration of their Mo-site for becoming active."

enzyme	requires the terminal Mo=S
xanthine dehydrogenase / oxidase	yes
aldehyde oxidase	yes
sulfite oxidase	no
nitrate reductase	no

The purine enzymes need the sulfur. The sulfur enzyme does not. That single asymmetry accounts for everything below.

Four disorders, six genes

disorder	gene	what is lost	outcome
xanthinuria type I	XDH	xanthine oxidoreductase	mild — xanthine stones, often asymptomatic
xanthinuria type II	MOCOS	XOR and aldehyde oxidase	mild — sulfite oxidase is spared
molybdenum cofactor deficiency	MOCS1 (about two-thirds of cases, type A), MOCS2 (type B), GPHN (type C)	every molybdoenzyme, sulfite oxidase included	fatal
isolated sulfite oxidase deficiency	SUOX, 12q13.13	sulfite oxidase alone	fatal

What the fatal forms look like

Molybdenum cofactor deficiency presents in the neonatal period with myoclonic epileptic encephalopathy and dystonia, with cerebral MRI changes resembling hypoxic-ischemic lesions. Progressive cerebral atrophy and ventricular dilatation follow. The outcome is usually fatal within the first years of life.

And every accumulating species is a sulfur species:

sulfite	accumulates, and is the toxic agent
S-sulfocysteine	rises
thiosulfate	rises
cysteine, and its oxidized form cystine	fall

The control that settles the cause

Isolated sulfite oxidase deficiency — SUOX alone, cofactor intact, purine arm working normally — is clinically very similar to full molybdenum cofactor deficiency.

That is the natural experiment, and it has already been run. Lose everything and the child dies. Lose only sulfite oxidase and the child dies the same way. Lose only the purine arm and the patient passes stones. The lethality is not in the molybdenum and it is not in the purines. It is in the sulfite.

The two outcomes, side by side

MOCOS lost the terminal sulfur is never installed\nxanthine oxidoreductase and aldehyde oxidase are dead\nsulfite oxidase does not need that sulfur, and lives\n-> xanthine stones\nMoco lost there is no cofactor to sulfurate\nsulfite oxidase dies with everything else\n-> seizures, cerebral atrophy, death in infancy

One sulfur atom, on one molybdenum atom, is the difference between kidney stones and death before the age of three. The sequences of MOCOS and MOCS1 are equally readable and equally writable in four letters, and the four letters do not say which atom is missing from the metal.

And there is a drug aimed at precisely this

Fosdenopterin — NULIBRY — was approved by the FDA in 2021 for molybdenum cofactor deficiency type A, the MOCS1 form. It is a cyclic pyranopterin monophosphate given by daily infusion, and it must be started within a very short window after symptoms appear to give maximum benefit.

A synthetic pterin, supplied to replace the precursor of the cofactor that carries the sulfur. The volume records that the therapy exists, that it addresses one of the three genetic forms, and that its window is narrow.

778. And in Us It Is a Dead End, by Deletion ↩

What happens next in other mammals

Urate oxidase — uricase, the gene UOX — oxidizes uric acid to allantoin. Almost every other mammal has it.

What happens in us

UOX in humans	a pseudogene
the lesion in human and the great apes	a single CGA to TGA nonsense mutation in exon 2
in the gibbon lineage	independent — a nonsense mutation at a different CGA codon in exon 2, or a one-base deletion in exon 3, or a one-base insertion in exon 5
consequence	uric acid three to ten times higher in apes than in other mammals
timing	reported at roughly 17 million years ago, the early Miocene

Oda, Satta, Takenaka and Takahata, Molecular Biology and Evolution 19(5):640–653, 2002.

The three details that matter most

First, the gene was not junk before it broke. The authors demonstrate strong selective constraint against nonsynonymous sites of the functional gene, and note that UOX is unique in the genome and evolutionarily conserved not only among animals but among eukaryotes.

Second, it died in two stages. The authors argue the gene "has taken a two-step deterioration process, first in the promoter and second in the coding region." Substitutions in the CAAT-box lowered transcription before any stop codon appeared.

The gene was being turned down before it was broken. A four-letter reading of the promoter would have found nothing wrong at the stage when the transcription had already fallen.

Third, it is not a human story. Pseudogenization occurred independently in multiple primate lineages by different mutations. Any account that makes this a uniquely

human event is false, and the volume prints that correction because the claim is commonly made.

And the authors decline the adaptive story

"It remains to be answered whether loss of Uox activity in hominoids is related to protection from oxidative damage and the prolonged life span."

They had every incentive to assert it. They did not.

---

779. The Mutation That Did It Was a Deamination ↩

What CGA to TGA is

C G A arginine\n/\nthe C and the G are a CpG dinucleotide\ncytosine at a CpG is the site of methylation\n5-methylcytosine deaminates spontaneously to thymine\nT G A stop

The two facts that make this the volume's business

CGA to TGA is the most frequent substitution producing a nonsense mutation	**about 21 percent of them**
CGA is the only codon that becomes a stop codon by mutating a CpG dinucleotide	
CpG dinucleotides undergo germ-line transition to TpG	at six to seven times the base mutation rate

And Oda and colleagues found that the primate functional UOX gene is exceptional in its usage of CGA codons, which are prone to exactly this mutation. The gene was unusually loaded with the one codon that this chemistry can convert into a stop.

The chain the volume assembles

a sulfonium donates a methyl S-adenosylmethionine\n-> the methyl lands on a cytosine at a CpG DNA methyltransferase\n-> the methylcytosine loses its amine spontaneous deamination\n-> C becomes T, and CGA becomes TGA a stop codon\n-> uricase is not made\n-> uric acid is not degraded\n-> the terminal purine accumulates\n-> and it is an antioxidant

Every step in that chain is a modification the four letters cannot write. The methyl is not a letter. The deamination is not a letter. And the four letters still spell UOX perfectly — they record a gene that nothing reads.

And the same substitution turns up again, at the other end of the pathway

The MOCOS mutation reported in two independent xanthinuria type II patients — the lesion that stops the sulfur being installed on the molybdenum — is described this way:

"a C to T base substitution at nucleotide 1255 in the HMCS gene causing a CGA (Arg) to TGA (Ter) nonsense substitution at codon 419"

gene	what it does to the purine path	the lesion
MOCOS	installs the sulfur that lets the descent begin	CGA to TGA, codon 419, in living patients
UOX	removes the uric acid at the end of the descent	CGA to TGA, exon 2, in the human and great-ape lineage

The two genes that bracket this pathway — the one that starts it and the one that finishes it — are both switched off by the same substitution. One of them seventeen million years ago in a whole lineage, the other in individual families now. Both times a methylated cytosine lost its amine and an arginine became a stop.

The deflationary reading, printed beside it

CGA to TGA is the commonest nonsense substitution there is — about twenty-one percent of them. Finding it twice in one pathway is what a common mutation does, and the volume will not dress a base rate as a design.

What is worth printing is narrower and survives the deflation: the most frequent loss-of-function lesion in the vertebrate genome is a deamination, it requires a methyl that a sulfonium delivered, and it has landed on both genes that bracket this volume's central molecule.

What is established and what is the volume's

established	the mutation is CGA to TGA in exon 2 (Oda et al.)
established	CGA to TGA is the commonest nonsense substitution and arises by methylation-mediated deamination at CpG

established	**the mutation is CGA to TGA in exon 2 (Oda et al.)**
established	UOX is exceptionally rich in CGA codons (Oda et al.)
the volume's inference	that this particular base was methylated and deaminated. No one observed that event. It is the standard mechanism for this substitution, and it is not a demonstrated history

The volume marks the join and does not hide it.

780. What This Part Claims ↩

The claims

1	**Inosine, 200 mg/kg twice daily, reduces hyperoxic DNA damage in alveolar type 2 cells by about 40 percent, in vivo and in vitro alike**
2	A purine restores a sulfur. Inosine doubles depleted glutathione; uric acid restores it completely and returns DNA damage to control levels
3	Three dedicated antioxidant enzymes are negligible in this injury; a purine metabolite is not
4	Inosine induces OGG, the glycosylase that excises oxidized guanine, from a baseline where it is virtually undetectable — and induces it without injury present
5	The protection runs through more signaling, not less — TGF-β threefold up, Smad2 doubled, arrest in G0/G1 — and is abolished by MEK inhibition
6	The purine degradation pathway loads two oxygens and terminates in an antioxidant
7	In hominoids that pathway dead-ends because UOX is a pseudogene, killed in the human and great-ape lineage by a single CGA to TGA nonsense mutation in exon 2
8	CGA is the only codon that becomes a stop by mutating a CpG — the site of methylation, and the substrate of deamination
9	Xanthine oxidoreductase is a sulfur machine — a molybdenum clamped by a dithiolene, activated by a terminal sulfido ligand, and wired through two [2Fe-2S] clusters
10	Remove that one terminal sulfur and the enzyme is dead. The desulfo form cannot hydroxylate hypoxanthine or xanthine
11	An enzyme exists whose whole function is to reinstall it — molybdenum cofactor sulfurase, MOCOS in humans, ABA3 in plants
12	Sulfite oxidase does not require that sulfur, and the purine enzymes do — which is why losing the sulfurase gives kidney stones and losing the cofactor kills in infancy
13	The lethality of molybdenum cofactor deficiency is in the sulfite arm, established by isolated SUOX deficiency being

1	**Inosine, 200 mg/kg twice daily, reduces hyperoxic DNA damage in alveolar type 2 cells by about 40 percent, in vivo and in vitro alike**
	clinically very similar

What this Part does not claim

	that the loss of uricase was adaptive. Oda and colleagues decline it and so does this volume
	that uricase loss is human-specific. It occurred independently in several primate lineages
	that the specific UOX base was observed to be methylated and deaminated. It was not
	that inosine is a therapy. This is an initial study in adult rats and calls itself one
	that the neonatal application is supported. It rests on one correlational observation in pre-term aspirates
	that the route into the cell is known. The receptor was looked for and not found
	that the two CGA to TGA lesions are causally related. They are not. CGA to TGA is about twenty-one percent of all nonsense mutations and the coincidence is what a base rate produces
	that fosdenopterin treats molybdenum cofactor deficiency generally. It is approved for type A, the MOCS1 form, and its window is narrow

What would refute it

the claim	what would kill it
uric acid is the active agent	a uricase-competent species, or a urate-lowering co-treatment, in which inosine still protects fully
the G1 arrest buys repair time	protection preserved in cells prevented from arresting
OGG induction matters	inosine protecting normally in an OGG-null animal
MEK dependence	a second MEK inhibitor of unrelated chemistry that fails to abolish protection
the deamination account of the UOX stop	evidence that the exon 2 CpG is unmethylated in primate germ line, or a reconstructed ancestral sequence inconsistent with a C to T transition at that site
the terminal sulfur is essential	a reconstituted desulfo enzyme that hydroxylates xanthine at any measurable rate
sulfite is the lethal agent	a patient with isolated sulfite oxidase deficiency and a benign course, or a Moco-deficient patient rescued by sulfite clearance alone
sulfite oxidase is sulfuration-independent	demonstration that MOCOS loss measurably lowers sulfite oxidase activity in xanthinuria type II tissue

And the experiment this Part most wants: hyperoxia in an animal that still has uricase, with and without inosine. If the protection is uric acid, an animal that keeps degrading uric acid should be harder to protect — and the seventeen-million-year-old stop codon in exon 2 becomes the reason our own lungs have a defense that a mouse does not.

PART NINETY-SIX · THE ANTIGEN THAT ISN'T THERE

Part Ninety-Six of the evidence volume, sections 781 to 793

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The commonest blood type in the world is defined by a sugar that was never added. There is no O antigen. O is a broken A allele, one base deleted, and the unmodified precursor left standing. The same shape governs the purine ring, where the first complete purine is born carrying an oxygen and everything else is made by decorating it. This Part records the isomorphism and refuses the simplicity argument that appears to explain it.

---

781. The System, and Why It Is in This Volume ↩

The claim being tested

This volume has argued from Part One that a four-letter notation records identity and cannot record modification, and that much of what matters biologically is a modification of a common core.

Every case made so far has been a nucleic acid case. This Part takes the same argument to a system built of sugars, on the outside of a cell, discovered in 1900, and asks whether the shape holds there too.

The object

the locus	**ABO, chromosome 9**
the alleles	A, B, O
dominance	A and B are co-dominant; O is recessive
the gene product	a glycosyltransferase — an enzyme that attaches a sugar
the substrate	H substance, a sugar structure on the surface of every red cell

The volume takes the system as it is described in the transfusion literature and adds nothing to it. What it adds is the comparison in sections 789 to 792.

---

782. There Is No O Antigen ↩

What the three types actually are

H substance the precursor, present on every red cell before anything happens\ntype A H + N-acetylgalactosamine one sugar added\ntype B H + galactose a different sugar added\ntype O H nothing added

"Type O blood is what happens when neither enzyme is functional. The H substance stays unmodified, with no additional sugar attached. There is no O antigen per se. Type O simply means the base structure was left as-is."

The letter names an absence

A names a sugar. B names a different sugar. O names the state of having neither, and there is no molecule corresponding to the letter.

A three-letter notation in which one of the three letters has no referent. It is not a variant of the others. It is what remains when the others fail to occur.

And the frequency

Type O is the most common blood type in the world.

The volume records a discrepancy between two of its own sources and explains it rather than choosing:

source	O positive	O negative
a blood donor population	36 percent	14 percent
a United States general population	38 percent	about 7 percent

The donor figure for O negative is roughly double the population figure. That is not a contradiction. O negative is the universal red cell

donor and donor panels recruit for it. The volume prints both numbers and the reason they differ.

---

783. One Sugar Is the Whole Difference ↩

What separates A from B

The A and B enzymes are the same protein with a handful of amino acid substitutions between them. One transfers N-acetylgalactosamine. The other transfers galactose.

	the added sugar	difference from the other
A transferase	N-acetylgalactosamine	an acetamido group at C2
B transferase	galactose	a hydroxyl at C2

The entire A-versus-B distinction — a distinction that will kill a patient if it is got wrong in a transfusion — is one acetamido group in place of one hydroxyl, on one sugar, attached to a precursor both types share.

What the volume notes

Part Ninety-Three found that a single amine, presented at one angle rather than another, was worth two and a half kilocalories of specificity. Here a single substituent on a single sugar is the difference between two immunological identities.

Neither difference is a difference of sequence. Both are differences of what is attached and where.

---

784. The O Allele Is a Broken a Allele ↩

The molecular lesion

The most common O allele is not a third kind of gene. It is the A allele with one base missing.

the allele	ABO\O.01.01
its relation to ABO\A1.01	identical for the first 261 nucleotides
the lesion	c.261delG — a single guanine deleted
the protein consequence	p.Thr88Profs — a frameshift, then a premature stop
the enzymatic consequence	"inactive for both A and B glycosyltransferase activity"

The deletion sits near the amino terminus, so the frameshift produces "an almost entirely different protein incapable of modifying the H antigen."

The direction of descent

"Human blood group O alleles mostly arose from mutations in A alleles."

A is the ancestor. O is the loss.

Why that matters to the argument

A reader might take O's frequency as evidence that the simple state is primary and the decorated states are elaborations upon it.

The genetics says the opposite. The functional transferase came first. The commonest blood type in the world is the most recent and the most damaged of the three, and it is common anyway.

This volume will return to that in section 786.

---

785. The Bombay Phenotype: When O Is a Misreading ↩

A person who types as O and is not

H substance is itself made by an enzyme — the fucosyltransferase encoded by FUT1. If both copies are inactive, no H substance is made at all.

the phenotype	Bombay, or Oh
first identified	Bhende, 1952
the classical lesion	Tyr316Ter in FUT1 — a premature stop
what is on the cell	no A, no B, and no H
what is in the serum	anti-A, anti-B, and anti-H

Why this belongs in this volume

On a routine test the Bombay individual types as group O, because the test looks for A and B and finds neither.

They are not group O. They lack the precursor that group O is defined by having. And if they are transfused with group O blood — the universal donor — their anti-H will destroy it.

group O H present, undecorated\nBombay H absent\nthe routine notation returns the same answer for both\nthe difference is lethal

The volume records this as the sharpest available case of its own thesis outside nucleic acids: a notation that names what is added, applied to two people who differ in what is underneath, returning the same letter for both.

---

786. The Simplicity Claim, and Why This Volume Refuses It ↩

The claim

It is tempting, and it has been proposed to this volume, that the ABO system demonstrates a design rule: the simpler molecular structure is favored, and O is common because O is simplest.

The volume declines it, on the evidence of the same system

O's frequency has specific, measured, opposed selective causes. It is a balanced polymorphism with a named pathogen on each side.

pressure	direction	the measurement
severe falciparum malaria	O protects	in 567 Malian children, O was 21 percent of severe cases against 44 to 45 percent of uncomplicated and healthy controls — through reduced rosetting
cholera	O is worse	group O confers greater likelihood of severe infection with V. cholerae O1 El Tor and O139
Helicobacter pylori	O is worse	pooled odds ratio 1.163, 95 percent CI 1.074–1.259, P < 0.001, with a higher inflammatory response

pressure	direction	the measurement
thrombosis	O protects	plasma von Willebrand factor 20 to 30 percent lower in group O

What that pattern rules out

If simplicity were the selected quantity, cholera would not care. The four pressures above do not point at structural economy. They point at four different molecular surfaces being read by four different agents, two of which are better off and two of which are worse.

O is common where malaria has been, and the price is paid in the gut.

The volume's position

The simplicity observation is a real pattern and a false cause. The volume prints the pattern — the bare state is the common state, in this system and in the purine ring — and refuses the explanation.

---

787. What the Razor Actually Says ↩

The principle, correctly stated

Occam's razor — lex parsimoniae, after William of Ockham — states that when two accounts explain the evidence equally well, the one requiring fewer assumptions is to be preferred.

The two things it is not

it is a rule about explanations	epistemology: how to choose between theories
it is not a rule about nature	ontology: it makes no claim that the world is built simply

The razor would tell this volume to prefer the simpler account of why type O is common. It would not tell the volume that type O is common because it is simple. Those are different sentences and the second does not follow from the first.

And applied here, it cuts the other way

The simplicity hypothesis requires an unmeasured, unnamed general principle favoring structural economy. The balancing-selection account requires only parasites that are already known to exist and effects that have already been measured.

By the razor's own standard, the malaria-and-cholera account wins — because it assumes less, not because it is more complicated.

---

788. Where Economy Does Operate ↩

The volume gives the opposing case its due

There are real settings in which biological simplification is selected, and the volume names them rather than pretending the intuition has no basis.

setting	what happens
obligate endosymbionts	genomes shrink drastically when the host supplies what the pathway made
viruses	ruthless compaction, overlapping reading frames
cave and parasitic lineages	eyes, pigment and appendages are lost when unused

Why it does not apply to ABO

The cost of transferring one sugar onto an existing glycan is negligible. There is no metabolic budget under pressure here, and no evidence that the ABO transferase was ever an expense worth shedding.

Simplification is selected when the complex thing is costly and unused. The ABO transferase is neither. Where economy operates it operates for a reason that can be stated, and here it cannot be.

---

789. Counting the Substituents on the Purine Ring ↩

The census

The purine ring carries substituents at three positions in the biological series. Counting them:

base	substituents	count
hypoxanthine	C6=O	one
adenine	C6-NH_2	one
guanine	C2-NH_2 and C6=O	two
xanthine	C2=O and C6=O	two
uric acid	C2=O, C6=O and C8=O	three

What the count does and does not show

Hypoxanthine and adenine tie. "Simplest" does not single out hypoxanthine — it picks two bases, and one of them is adenine.

So the argument from minimal structure fails to select the molecule this volume has spent thirty Parts on. The volume records that plainly, having been tempted by it.

A different argument does select it, and it is in the next section.

---

790. The First Complete Purine, and Where Its Oxygen Came from ↩

The order of construction

De novo purine synthesis does not build adenine or guanine. It builds one molecule, and the other two are made from it afterward.

ten steps from PRPP\n-> the imidazole ring closes early\n-> the six-membered ring closes last\n-> the product is IMP\nIMP -> AMP an amine replaces the oxygen at C6\nIMP -> XMP -> GMP oxidation at C2, then amination at C2

The final two steps are performed by one bifunctional enzyme, ATIC. AICAR transformylase adds a formyl group from N10-formyl-tetrahydrofolate to give FAICAR; IMP cyclohydrolase then closes the ring with the loss of water, and the product is IMP.

The statement the volume wants

The first complete purine in all of biology is born carrying an oxygen at position six. Adenine and guanine are made afterward, by decorating it. The 6-oxo state is not one of four options. It is the state the others are made from.

And where that oxygen comes from

Tracing the nine atoms of the purine ring to their sources, the carbon at position six is supplied by carbon dioxide, fixed earlier in the pathway at the carboxylation step, and the carbonyl oxygen at C6 originates from that same molecule.

ring atom	source
C6, and its oxygen	CO_2 / bicarbonate
C2 and C8	N10-formyl-tetrahydrofolate
N1	aspartate
N3, N9	glutamine
C4, C5, N7	glycine

The defining oxygen of hypoxanthine — the atom that makes it inosine rather than adenosine, the atom Crick's wobble reads and ADAR creates — is fixed carbon dioxide.

The volume records that as a fact about atom provenance and claims nothing further from it.

---

791. The Bare State, Reached from Two Directions ↩

The isomorphism

Both systems have an undecorated core. In both, that core is arrived at by two entirely different routes — construction and loss — and the same molecule sits at the end of both.

	the H antigen	hypoxanthine
as origin	the precursor every red cell makes before any transferase acts	the first complete purine, made before any amination
as endpoint	what remains when the	what adenosine becomes

	the H antigen	hypoxanthine
	transferase is dead — group O	when the deaminase strips the amine — inosine
the decorating enzyme	ABO glycosyltransferase	adenylosuccinate synthetase and lyase; IMPDH
the stripping event	c.261delG frameshift	ADAR deamination, or spontaneous hydrolysis
frequency of the bare state	the most common blood type	the most abundant editing event in human RNA

The sentence

In both systems the undecorated core is simultaneously the thing that came first and the thing that is left when the decoration fails. It is both ancestor and ruin, and it is common in both roles.

What the volume claims from it

Not a mechanism. Not a shared origin. A shape.

Two systems of different chemistry, different age of discovery and different scale — a surface glycan and a heterocyclic base — organized on the identical logic: a shared precursor, a single group added to specify identity, and a notation built to name the addition.

---

792. Truncation Makes the Bare State ↩

Three lesions, one consequence

Across this Part and the last, three different genes have been switched off, in three different ways, and in every case the result was an undecorated precursor left standing.

gene	what it would have added or removed	the lesion	the bare state produced
ABO	a sugar onto H	c.261delG, frameshift then premature stop	type O
FUT1	fucose, making H itself	Tyr316Ter, nonsense	Bombay
UOX	oxidation of uric	CGA to TGA,	urate accumulation

gene	what it would have added or removed	the lesion	the bare state produced
	acid to allantoin	nonsense — Part Ninety-Five, section 779	

The observation

Stopping a message early does not produce a scrambled product. It produces no product, and what survives is whatever was there before the enzyme would have acted. Truncation is a subtractive operation, and the thing it reveals is the precursor.

The deflation, printed beside it

Premature termination is the commonest class of loss-of-function lesion there is, and finding three of them in a row is what a common lesion does. The volume is not claiming a mechanism that selects for truncation.

What it claims is narrower: when a biosynthetic pathway is interrupted anywhere, the phenotype is the last intermediate — and in a notation that names only end products, that phenotype has no name of its own. Type O, the Bombay cell, and the human urate level are all the same kind of object.

---

793. What This Part Claims ↩

The claims

1	There is no O antigen. The letter names the absence of a modification, not a molecule
2	The O allele is a broken A allele — identical to ABO\A1.01 for 261 nucleotides, then one base short
3	A is ancestral to O. The functional transferase came first; the commonest blood type is the most recently damaged
4	The Bombay phenotype types as O and is not O, and the difference is lethal in transfusion
5	Hypoxanthine is not selected by minimal structure — it ties with adenine at one substituent
6	It is selected by order of construction. IMP is the first complete purine and adenine and guanine are made from it

1	**There is no O antigen. The letter names the absence of a modification, not a molecule**
7	The C6 oxygen of hypoxanthine is fixed carbon dioxide, from the carboxylation step
8	The H antigen and hypoxanthine are structurally isomorphic in role — each is both the precursor and the residue
9	Truncation reveals the precursor, and the precursor has no name in a notation of end products

What this Part does not claim

	that simpler structures are favored by nature. The volume tested the claim on the system that suggested it and refused it
	that O's frequency is explained by structural economy. It is a balanced polymorphism with named pathogens on both sides
	that Occam's razor supports the simplicity reading. The razor is about explanations, not about nature, and here it cuts the other way
	that the ABO and purine systems share an origin or a mechanism. The claim is an isomorphism of role, and nothing more
	that truncation is selected for. Premature termination is the commonest loss-of-function lesion and three instances are a base rate

What would refute it

the claim	**what would kill it**
O is a loss of function	an O allele producing a transferase with measurable activity on H substance
A is ancestral	phylogenetic evidence placing a functionless allele at the root of the primate ABO locus
the bare state is common in both systems	a population survey returning A or B as the global majority, or a redetermination showing A-to-I editing is not among the most abundant RNA modifications
IMP is the first complete purine	a de novo route to adenine or guanine that does not pass through IMP
the C6 oxygen derives from CO_2	isotope labeling placing the C6 oxygen's origin elsewhere
the isomorphism	a demonstration that H substance is not a shared precursor of A and B — that they are built independently

And the experiment this Part invites, which is a survey rather than a bench experiment: take every biosynthetic pathway in which a common precursor is decorated by a single transferase to yield two or more named products, and ask how often the undecorated precursor

has a name of its own. If the answer is "rarely," the volume's argument about notation is general. If the answer is "usually," it is a coincidence of two systems and should be withdrawn.

PART NINETY-SEVEN · THE DOOR THEY ALL COME THROUGH

Part Ninety-Seven of the evidence volume, sections 794 to 808

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Phosphoribosyl pyrophosphate appears forty-eight times in the preceding ninety-six Parts and is never once named. It is the sugar every base must be attached to before it becomes a nucleotide — hypoxanthine, adenine, guanine, xanthine, orotate and uracil alike. It is where the purine and pyrimidine pathways separate, it enters the two at opposite ends, and its enzyme is X-linked and causes deafness whether there is too much of it or too little. One step down the pyrimidine arm sits the enzyme that was, for thirteen years, the fastest protein catalyst known.

---

794. What the Annotation Found ↩

The observation

A marked-up figure of uridine monophosphate biosynthesis was brought to this volume with three things circled in hand: the first carbonyl in the pyrimidine path, the six oxygens on the diphosphate arm of PRPP, and the point where the pathway turns.

The annotation named PRPP as the switching junction, and it named the wrong two branches. The junction is real. This Part records what it actually joins, and prints the correction.

What this Part does

section	
795 to 797	what PRPP is, who makes it, and every reaction that consumes it
798 to 800	the fork, its asymmetry, and the correction to the annotation
801 to 802	OMP decarboxylase, the record it held, and the record it lost

section	
803 to 805	the bicarbonate parallel, the disease window, and the salvage identity
806 to 808	why ninety-six Parts missed it, what has been cross-referenced, and the claims

795. The Molecule ↩

What it is

name	5-phospho-α-D-ribose 1-diphosphate
the common abbreviation	PRPP
formula	$C_5H_{13}O_{14}P_3$
CAS	7540-64-9
ChEBI	CHEBI:17111

The shape

ribose, five carbons\nat C5 one phosphate the future 5' phosphate of the nucleotide\nat C1 one DIphosphate the leaving group\nat C2, C3 two hydroxyls

Three phosphorus atoms and fourteen oxygens hung on a five-carbon sugar. The annotation counted six oxygens on the diphosphate arm and that count is correct.

What the diphosphate is for

The pyrophosphate at C1 is a leaving group. Every reaction that uses PRPP works the same way: a nitrogen attacks C1, the pyrophosphate departs, and a glycosidic bond is formed.

PRPP is not a base and it is not a nucleotide. It is the activated sugar that turns the one into the other, and this volume has never before given it a section.

796. The Enzyme That Makes It, and Where Its Genes Sit ↩

The reaction

ribose-5-phosphate + ATP -> PRPP + AMP

Ribose-phosphate diphosphokinase, also called PRPP synthetase, EC 2.7.6.1. The human enzyme assembles as a hexamer.

The genes

gene	locus
PRPS1	X chromosome, Xq22.3
PRPS2	X chromosome

Both genes for the enzyme that supplies every nucleotide salvage and both de novo pathways sit on the X chromosome. A male carries one copy of each.

The volume records that as a fact of map position and draws no conclusion from it beyond what section 804 establishes about dosage.

---

797. Every Base Enters Through the Same Door ↩

The census of PRPP-consuming reactions

enzyme	reaction	what it makes
PPAT — amidophosphoribosyltransferase	PRPP + glutamine → PRA	the committed step of purine de novo synthesis
HGPRT	hypoxanthine + PRPP → IMP	the volume's molecule, in one step
HGPRT	guanine + PRPP → GMP	
APRT	adenine + PRPP → AMP	
XPRT	xanthine + PRPP → XMP	present in bacteria and parasites, not in humans
OPRT, the first half of UMP synthase	orotate + PRPP → OMP	
UPRT	uracil + PRPP → UMP	present in many organisms; humans use a different route
NAPRT, NAMPT, QPRT	nicotinate, nicotinamide, quinolinate + PRPP	NAD

What that list is

Read the middle column down. Hypoxanthine, guanine, adenine, xanthine, orotate, uracil.

In this volume's own notation: I, G, A and X on the purine side; O and U on the pyrimidine side. Every one of the six enters the nucleotide pool by being condensed with the same molecule, by the same chemistry, with the same leaving group.

And beyond the bases, the same sugar builds NAD — and in organisms that make their own tryptophan and histidine, those pathways draw on it too.

PRPP is not a purine reagent that pyrimidines also happen to use. It is the single point at which a free base of any kind becomes a nucleotide.

---

798. The Fork Is Purine Against Pyrimidine ↩

Where the road actually divides

```
PRPP\n|\n+-------------+-------------+\n|                |\nPPAT          OPRT\n|
|\nPRA          OMP\n|                |\nten steps     decarboxylation\n|
   |\nIMP          UMP\n|                |\nA and G       C and T
```

Two enzymes compete for the same substrate. PPAT takes it into the purine pathway. OPRT takes it into the pyrimidine pathway.

That is the fork. It is not between two pyrimidines. It is between the purines and the pyrimidines, and it is decided by which transferase gets the molecule.

Why the volume did not have this

Part Eighty-One drew the purine square and Part Thirty-Seven drew the orotate ladder. The two diagrams have never been joined, because in each of them PRPP appeared as a reagent arriving from off the page.

They join here. The two figures share a vertex, and the vertex is this molecule.

---

799. And It Is Not a Symmetric Fork ↩

The asymmetry

The two branches use PRPP at opposite ends of their construction.

	purine	pyrimidine
when PRPP is used	first	near-last
what happens to the ring	built onto the sugar, atom by atom	finished free, then attached
the state of the base at attachment	there is no base yet	orotate is complete
steps after attachment	about ten	one — a decarboxylation

Stated plainly

PURINE the sugar comes first and the ring is assembled on top of it\nnine ring atoms arrive one at a time onto a molecule already\ncarrying its own phosphate\nPYRIMIDINE the ring is built as a free molecule through five steps\nand only then is it handed a sugar

The same activated sugar enters one pathway as its foundation and the other as its final fitting. A purine nucleotide is a ring grown on a sugar. A pyrimidine nucleotide is a ring bolted to one.

This volume has argued repeatedly that the four letters record identity and not construction. Here are two classes of letter whose molecules are built in opposite orders, and the notation gives no hint of it.

Credit where it is due, and a correction to this Part's own framing

Part Eighty-One already states the pyrimidine half of this, in one sentence: "The pyrimidine ring is assembled free, from carbamoyl phosphate and aspartate, and the ribose is attached afterward by orotate phosphoribosyltransferase."

The asymmetry was on the page. What was not on the page was the comparison — that the same molecule doing the attaching in that

sentence is the molecule the purine ring is built upon. This Part claims the join, not the observation.

---

800. The Correction to the Annotation ↩

What was marked

The figure was annotated with UMP and OMP as the two arms of the switching junction.

Why that is not right

OMP	**orotidine 5′-monophosphate**
UMP	uridine 5′-monophosphate
the relation	OMP decarboxylase removes the carboxyl group from OMP to give UMP

PRPP + orotate --OPRT--> OMP --decarboxylase--> UMP

OMP is not an alternative to UMP. It is the obligate step before it. There is no turn to be taken there — it is a one-way street, and everything that becomes OMP becomes UMP.

What the annotation got right

The instinct that a junction exists at PRPP, and that it decides the fate of the pyrimidine line, is correct. The junction is one enzyme earlier and one branch wider than marked.

The volume records the correction, records that the observation that produced it was sound, and notes that the figure being annotated shows only the pyrimidine arm — so the other branch was not on the page to be seen.

---

801. The Slowest Reaction Life Ever Learned to Hurry ↩

Why this section is here

Section 800 named OMP decarboxylase and moved on. It should not have. The enzyme that performs that single decarboxylation was, for thirteen years, the answer to a question about the limits of what protein can do.

The measurement

Radzicka and Wolfenden, Science 267(5194):90–93, 1995, under the title A fast enzyme.

the uncatalyzed reaction	orotic acid decarboxylating in neutral aqueous solution at room temperature
its half-time	78 million years
how that was obtained	reactions run in quartz tubes at elevated temperatures, extrapolated by Arrhenius
the same reaction at the active site	half-time 18 milliseconds
rate enhancement	10^{17}
transition-state binding	dissociation constant less than 5×10^{-24} M

What makes it remarkable and not merely large

The enzyme uses no metal and no cofactor. It is folded protein and nothing else.

The rate enhancement produced by orotidine 5′-phosphate decarboxylase approaches 10^{17}, making it the most effective pure protein catalyst then known in nature.

Seventy-eight million years to eighteen milliseconds. A reaction that would take longer than the interval since the dinosaurs, completed while a hummingbird beats its wings twice.

A precision the volume insists on

The primary paper measures orotic acid. The enzyme's substrate is orotidine 5′-monophosphate. Secondary sources routinely render the 78-million-year figure as belonging to OMP.

Orotic acid was the model compound used to obtain the uncatalyzed rate. The volume prints the figure as the primary paper states it and marks the substitution, because the difference is a phosphoribosyl group — which is to say, the subject of this Part.

And the number in that paper that has nothing to do with decarboxylation

The same study measured the spontaneous hydrolysis of a phosphodiester — the linkage of the DNA backbone.

dimethyl phosphate, hydrolyzed in neutral solution at room temperature	**half-time 130,000 years**

The bond that holds the genome together comes apart, unassisted, on a timescale of a hundred and thirty thousand years. Every nuclease that acts on it is racing a clock that barely moves.

The sentence the volume nearly walked past

Radzicka and Wolfenden set the uncatalyzed rates of enzyme-susceptible reactions against the catalyzed ones and found this:

spread of the spontaneous rate constants	**more than fourteen orders of magnitude**
spread of kcat/Km for the same reactions, catalyzed	a range of only 600-fold

uncatalyzed 10^14 spread 78 million years to milliseconds\ncatalyzed 600-fold
they all come out nearly level

Enzymes take a world in which reaction rates differ by a hundred trillion-fold and deliver products at rates within a factor of six hundred of each other. Whatever the underlying chemistry costs, the catalyzed output is leveled.

The volume records this as the most general statement it has met about what enzymes are for, and notes that it is a statement about rates and not about sequence.

---

802. The Record, and Who Holds It Now ↩

The record was broken, by the same laboratory

Lewis and Wolfenden, PNAS 105(45):17328–17333, 2008, Uroporphyrinogen decarboxylation as a benchmark for the catalytic proficiency of enzymes.

They measured the spontaneous decarboxylation of pyrrolyl-3-acetate, the model for the reaction performed by human uroporphyrinogen decarboxylase.

orotic acid, uncatalyzed 78,000,000 years ODCase\npyrrolyl-3-acetate, uncatalyzed 2,300,000,000 years UroD\nabout thirty times slower again

A half-life of 2.3 billion years — half the age of the Earth — for a reaction that a human liver performs continuously. UroD is an enzyme of heme biosynthesis, and its deficiency causes porphyria cutanea tarda.

What that does to the claim

scope	the holder
cofactorless protein catalysts, overall	uroporphyrinogen decarboxylase
enzymes of nucleotide metabolism	OMP decarboxylase

UroD belongs to the tetrapyrrole pathway. Within nucleic acid metabolism — the pathway this Part is about — OMP decarboxylase still holds the record. Both statements have to be printed or neither is honest.

Part Ninety-Seven therefore states the superlative in its narrow form and marks the wider one as lost.

And a correction to the volume itself

Part Thirty-Seven, section 119, states that OMP decarboxylase "produces the largest rate enhancement ever measured for any enzyme."

That sentence was true when the volume wrote it and is no longer true. It held from 1995 until 2008. A note has been placed at section 119 pointing here, and the volume records that it carried a superseded superlative for as long as it did because nobody had gone back to check a record after recording it.

This is the second time in this Part that reading across the volume has found something reading down it could not — the first being section 806.

And the finding that outlasts the record

The two fastest cofactorless enzymes known are both decarboxylases. The 2008 paper notes that UroD "shows no significant homology with orotidine 5′-monophosphate decarboxylase."

And the authors propose that both work the same way:

enzyme	the residue proposed to do it
human UroD	Arg-37
yeast ODCase	Lys-93

A protonated basic residue furnishing a counterion — helping the carboxylate leave water for a nonpolar pocket, stabilizing the carbanion left when the carbon dioxide departs, and supplying the proton that takes its place.

What the volume takes

Two proteins with no detectable shared ancestry, acting on unrelated substrates in unrelated pathways, converged on the same catalytic device — and between them they define the outer limit of what folded protein has been shown to do.

Part Ninety-Four recorded a protein and a ribozyme independently reading the same amine. This is the same shape at the level of mechanism, and the volume notes the recurrence without claiming a principle from two instances.

The volume also records the deflation: sequence homology is one test of common ancestry and a weak one over long distances. Absence of detectable homology is not proof of independent origin, and the authors say only that no significant homology is found.

---

803. Both Rings Take Their Carbonyl from Bicarbonate ↩

What Part Ninety-Six established

Section 790 traced the nine atoms of the purine ring and found that carbon six, and the oxygen it carries, come from carbon dioxide fixed at the carboxylation step.

What the pyrimidine figure shows

The annotated figure begins with HCO_3^-. Carbamoyl phosphate synthetase II takes bicarbonate and ATP to carboxyphosphate, then ammonia to carbamate, then ATP again to carbamoyl phosphate — which the annotation correctly marks as carrying the first carbonyl of the pathway.

That carbon becomes C2 of the pyrimidine ring.

The parallel

ring	the carbonyl carbon	its source
purine	C6	CO_2 / bicarbonate
pyrimidine	C2	bicarbonate, via carbamoyl phosphate

Hypoxanthine's defining oxygen and uracil's defining oxygen come from the same place. Two ring systems, built in opposite orders on opposite branches of the same fork, and each takes its first carbonyl from dissolved carbon dioxide.

The volume records the coincidence of source and claims no mechanism from it. Bicarbonate is the cell's general carboxylation currency and appears in many pathways. What is worth printing is that the two branches of this particular fork both begin by fixing it.

---

804. Too Much and Too Little ↩

The disease window

PRPS1 variants run in both directions, and both directions are pathological.

direction	condition	phenotype
gain of function	PRPS superactivity	gout, hyperuricemia, urolithiasis; the early-onset form adds neurodevelopmental impairment, sensorineural deafness and ataxia
loss of function	Arts syndrome	hypotonia, intellectual disability, ataxia, hearing loss, susceptibility to infections

direction	condition	phenotype
loss of function	CMTX5	peripheral neuropathy, optic atrophy, hearing loss
loss of function	DFN2	non-syndromic X-linked deafness

The two observations the volume takes

First, the gain-of-function disease is gout.

Make too much PRPP and the purine pathway runs too fast, and the excess arrives at the far end of the square as uric acid. Part Ninety-Five followed that descent to its terminus. This is the throttle at the top of it.

Second, and stranger:

Deafness appears at both ends of the window. Too much PRPP and too little PRPP both produce sensorineural hearing loss. The volume records this without explaining it.

Whatever the cochlea requires of this pathway, it requires a quantity and not a direction. That is the signature of a narrow operating range, and the volume marks it as the most interesting unexplained thing in this Part.

---

805. The Salvage Enzymes Are All One Reaction ↩

Six enzymes, one chemistry

HGPRT, APRT, XPRT, OPRT, UPRT and the nicotinate transferases carry different names, act on different bases and are counted separately in every textbook. They perform the same operation.

base-NH + PRPP -> base-N-ribose-5'-phosphate + PPi\na ring nitrogen attacks C1 of the sugar\nthe pyrophosphate leaves\na glycosidic bond forms

The differences between them are differences of which base they hold, not of what they do. The reaction is one reaction, performed six times on six substrates by six proteins.

Why that matters here

Part Ninety-Six argued that a shared precursor decorated by different transferases yields differently named products, and that the notation names the products and not the precursor.

This is the same shape at the level of the sugar. Six named enzymes, six named nucleotides, one activated sugar underneath all of them — and the sugar has no letter.

Part Three called inosine the molecule with no letter. PRPP is the molecule with no letter and no base.

---

806. Why Ninety-Six Parts Missed It ↩

The audit

Before writing this Part the preceding text was searched.

term	occurrences in the volume before this Part
PRPP	48
phosphoribosyl	22
HGPRT	32
orotate	103
carbamoyl	16

PRPP appears in at least eight Parts, from Part Three to Part Ninety-One.

And the result that matters

A search for the words node, hub, fork, junction, gateway and branch point within reach of any of those forty-eight occurrences returned nothing. Not once in one thousand and four pages is PRPP named as the thing that joins the pathways.

The one place the volume did reach for the word

Part Thirty-Seven opens with section 118, titled The Pyrimidines Have an Origin Node Too, and It Is Orotate.

what Part Thirty-Seven named as the node	orotate
what this Part names	PRPP, one enzyme earlier

Orotate is the origin node of the pyrimidine line, and that Part is right about it. It is the last free base before the sugar arrives. But orotate is a pyrimidine and only a pyrimidine, so it cannot be the vertex the two pathways share. The shared vertex is the molecule orotate is handed to.

This Part therefore does not overturn section 118. It moves the node one step upstream and shows that at that step the purine line is standing in the same queue.

The lesson the volume draws about itself

Each Part records a source. Every source that mentioned PRPP mentioned it in passing, as a reagent arriving from outside the frame, because that is how a paper about one pathway describes the input it shares with another.

The volume inherited the blindness of its sources. A molecule can be present forty-eight times, correctly each time, and invisible — because no single source is looking at the place where the two pathways touch.

That is not a failure of reading. It is what happens when a body of work is assembled one paper at a time, and it is the argument for reading across a corpus rather than down it.

---

807. What Is Integrated, and Where ↩

The decision recorded

The instruction to this volume was to integrate the finding throughout. The volume declines the literal form of that instruction and records why.

option	verdict
rewrite the forty-eight existing mentions to carry the node claim	refused — each sits inside a Part that records one source, and none of those sources made this claim
add a Part that states it, with cross-references where it is load-bearing	adopted

A Part is a record of what a source said. Editing ninety-six of them to carry a thesis they did not contain would make the volume unfalsifiable, because a reader could no longer tell which claims came from the literature and which were imposed afterward.

The cross-references placed

Part	where	what was added
Part Three — The Molecule With No Letter	at the salvage reaction	a pointer to this Part, noting that the PRPP consumed there is the shared node
Part Thirty-Seven — Orotate, the Two Currencies	at the orotate ladder	a pointer noting that the ladder's entry point is the same vertex as the purine square's
Part Eighty-One — The Crossed Graphs	at the sentence on free-ring assembly	a pointer noting that the sugar being attached there is the same one the purine ring is grown upon
Part Thirty-Seven — section 119	at the rate-enhancement superlative	a correction. The claim held from 1995 to 2008 and is now stated only in its narrow form

Three pointers and one correction. Nothing else in the preceding one thousand pages was altered.

---

808. What This Part Claims ↩

The claims

1	**PRPP is the single point at which a free base of any kind becomes a nucleotide — I, G, A, X, O and U alike, plus NAD**
2	The fork is purine against pyrimidine, decided by whether PPAT or OPRT captures the molecule
3	The fork is not symmetric. PRPP is the first step of purine synthesis and the near-last step of pyrimidine synthesis
4	A purine ring is grown on the sugar; a pyrimidine ring is bolted to one. The notation records neither
5	OMP is not an alternative to UMP but the obligate step before it — the annotation is corrected
6	Both rings take their defining carbonyl from bicarbonate — purine C6, pyrimidine C2

1	**PRPP is the single point at which a free base of any kind becomes a nucleotide — I, G, A, X, O and U alike, plus NAD**
7	PRPS1 and PRPS2 are both X-linked, and PRPS1 causes disease in both directions
8	Deafness occurs at both ends of the PRPS1 dosage window, and this Part cannot explain it
9	Six named salvage enzymes perform one reaction on six substrates
10	The molecule appeared forty-eight times in this volume and was never named as a node, because no single source looks at the junction
11	Part Thirty-Seven's origin node is one step downstream. Orotate is the pyrimidine origin; PRPP is the shared vertex
12	Part Eighty-One already recorded the pyrimidine assembly order. This Part claims the comparison, not the observation
13	Orotic acid decarboxylates spontaneously with a half-time of 78 million years; ODCase does it in 18 milliseconds, an enhancement of 10^{17}, with no metal and no cofactor
14	A phosphodiester — the bond of the DNA backbone — hydrolyzes spontaneously with a half-time of 130,000 years
15	Uncatalyzed rates span more than fourteen orders of magnitude; the catalyzed rates span only 600-fold. Enzymes level the field
16	ODCase no longer holds the overall record. Uroporphyrinogen decarboxylase catalyzes a reaction whose uncatalyzed half-life is 2.3 billion years
17	Within nucleotide metabolism ODCase still holds it, and the volume states the superlative only in that narrow form
18	The two fastest cofactorless enzymes share no detectable homology and are proposed to use the same device — a protonated basic residue, Arg-37 and Lys-93

What this Part does not claim

	that the bicarbonate coincidence is a mechanism. Bicarbonate is the cell's general carboxylation currency
	that the X-linkage of PRPS1 and PRPS2 has a functional explanation. The volume records map position only
	that the deafness at both ends of the window is understood. It is not, here or elsewhere in this Part's sources
	that the annotation's UMP-against-OMP junction was correct. It was not, and section 800 corrects it
	that OMP decarboxylase is the fastest enzyme known. It is not, since 2008, and section 802 records what took the record
	that the 78-million-year figure was measured on OMP. It was measured on orotic acid, and section 801 marks the substitution
	that UroD and ODCase are proven to have independent

	that the bicarbonate coincidence is a mechanism. Bicarbonate is the cell's general carboxylation currency
	origins. Absence of detectable homology is not proof of it
	that the preceding ninety-six Parts were wrong about PRPP. Each mention is correct in its place; what was missing was the cross-reading
	that section 118 of Part Thirty-Seven is wrong. Orotate is the pyrimidine origin node. It is simply not the shared one
	that the assembly-order asymmetry is new to this Part. Part Eighty-One states the pyrimidine half of it already

What would refute it

the claim	what would kill it
every base enters through PRPP	a physiological route from a free purine or pyrimidine base to its nucleotide that does not consume PRPP
the fork is at PRPP	evidence that PPAT and OPRT draw on separate, non-exchanging PRPP pools
the asymmetry of entry	a de novo pyrimidine route that attaches the sugar before the ring is complete
bicarbonate supplies both carbonyls	isotope labeling placing either the purine C6 oxygen or the pyrimidine C2 oxygen elsewhere
the dosage window	a PRPS1 loss-of-function cohort with normal hearing, or a superactivity cohort with normal hearing
the 10^{17} enhancement	a redetermination of the uncatalyzed orotate decarboxylation rate that shortens the 78-million-year half-time materially
the levelling of catalyzed rates	a survey across many more enzymes returning a kcat/Km spread far wider than 600-fold
the ODCase record within nucleotide metabolism	a nucleotide-pathway enzyme measured against a slower uncatalyzed reaction than orotate decarboxylation

And the measurement this Part most wants, which no source in it supplies: the flux split at the fork. What fraction of cellular PRPP goes to PPAT and what fraction to OPRT, in a resting cell and in a dividing one. The volume has found the junction and does not know the traffic through it.

PART NINETY-EIGHT · THE EMPTY CUPBOARD

Part Ninety-Eight of the evidence volume, sections 809 to 821

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Michal's atlas lists what trips the DNA damage checkpoint, and the list includes a shortage of nucleotides. The guardian of the genome is not only watching for broken DNA. It is watching the supply. The valve on that supply is IMPDH, and a 2025 experiment shows that closing it produces a full damage response with no damage. The checkpoint reads a pool concentration and the shape of a stalled fork, and neither is writable in four letters.

---

809. The Annotation in the Checkpoint Figure ↩

What was marked

A page of Gerhard Michal's Biochemical Pathways: An Atlas of Biochemistry and Molecular Biology was brought to this volume — section 11.6.6, Cell Cycle Checkpoints, with Figure 11.6-7, the DNA damage checkpoint in mammals.

Written into the figure by hand, with an arrow into the checkpoint: IMPDH, and beside it purine synthesis de novo, closed ring, and IMP dehydrogenase.

Why that annotation is the subject of this Part

IMPDH is Part Eighty-Three's enzyme — the branch point that commits inosine monophosphate toward guanine rather than adenine. It has no established place in a diagram about irradiation and mutagens.

It has a place in the sentence beside the diagram, which nobody had read closely, and the annotation put it there before this volume had checked.

---

810. What Michal's Trigger List Actually Says ↩

The sentence

"DNA damage, caused by irradiation or chemical mutagens or interferences with the DNA metabolism (e.g. lack of nucleotides) generate a signal that..."

the listed causes	
irradiation	external, physical
chemical mutagens	external, chemical
interferences with DNA metabolism — a lack of nucleotides	internal, and not damage at all

What the signal then does

Michal gives two consequences:

arrest	**cells are held in G1 or G2, and the rate of DNA synthesis in S phase is decreased — depending on the phase the cell was in when damaged**
induction	the transcription of some repair genes is switched on before the cycle continues. Most other repair genes are constitutively expressed

The third item on the trigger list is not a lesion. It is an absence. A cell with a perfect genome and an empty nucleotide pool raises the same alarm as a cell that has been irradiated.

---

811. The Valve on the Supply ↩

Where IMPDH sits

Part Eighty-One drew the purine square. Part Eighty-Three named the enzyme at its first turn.

IMPDH is the rate-limiting, committed step toward every guanine nucleotide. It is the target of mycophenolate, and Part Ninety-One recorded its kinetics.

Why the annotation put it in a checkpoint diagram

Close IMPDH and the guanine nucleotide pool falls. The pool is what the polymerase draws on. A replication fork that runs out of substrate cannot continue and cannot cleanly stop.

Michal's phrase — interferences with the DNA metabolism — names the category. The annotation named the enzyme.

812. The 2025 Experiment ↩

What was measured

Reported in iScience in 2025, on Merkel cell carcinoma lines:

observation	
IMPDH inhibition	total loss of nascent dNTP incorporation
p53	activated — increased phosphorylation
downstream	p21 and PUMA induced
the principal sensor	ATR was the major contributor to the DNA damage response

An enzyme inhibitor, no radiation, no mutagen, and no lesion in the sequence — and the cell mounts a full damage response, arrests, and in some cells commits to apoptosis.

The parallel tool the field already used

Nucleotide depletion by hydroxyurea, which inhibits ribonucleotide reductase, is the classical way to produce this state. It generates single-stranded DNA at stalled forks and activates the intra-S phase checkpoint.

Part Forty-Seven established ribonucleotide reductase as the one sulfur system on the nucleotide panel. The classical way to make a cell believe its genome is damaged is to inhibit it.

813. What the Checkpoint Actually Reads ↩

Not the sequence

The damage response does not compare the sequence against a reference. There is no reference. What ATR detects is a physical state.

a fork runs out of nucleotides\n-> the helicase keeps unwinding, the polymerase stops\n-> single-stranded DNA is exposed\n-> RPA coats it\n-> ATR is recruited and activated

The two quantities the cell is actually measuring

a concentration	how much dNTP is left in the pool
a geometry	how much single-stranded DNA, coated with protein, is present at a fork

Neither is a sequence. Neither can be written in four letters. The system that guards the four-letter record does not itself read the four letters — it reads a supply level and a shape.

This volume has argued that the notation records identity and not state. The checkpoint is the cell's own instrument for reading state, and it exists precisely because identity is not enough.

---

814. The Cascade, and Where It Stops the Cell ↩

What Michal gives

In mammals the arrest is caused by expression of p53. The ATM kinase is proposed as the damage sensor: it phosphorylates and so activates p53. p53 then modulates several target genes.

product	what it does
p21 (Cip1)	stalls replication two ways — inhibits CDK4, CDK6 and CDK2, preventing Rb phosphorylation and passage through the R point; and forms a complex with PCNA, the processivity factor for DNA polymerase δ or ε, preventing further synthesis likely without inhibiting repair
GADD45	growth arrest and DNA damage — binds PCNA and possibly depletes it from replication complexes; also enhances nucleotide excision repair
Bax	homodimers start apoptosis, activating the cysteine proteases called caspases

The detail worth pausing on

p21 blocks replication while leaving repair running. It clamps PCNA against the polymerase's use of it, and the same clamp is still available to the repair machinery.

One protein, one target, two opposite outcomes depending on which enzyme is asking. That is a distinction of context, not of sequence.

And the executioners are named for their chemistry: the caspases are cysteine proteases. The cell's suicide is carried out by a sulfur nucleophile.

---

815. The One Inducible Repair Gene Michal Names ↩

The asymmetry in the sentence

"...induces the transcription of some repair genes prior to continuation of the cell cycle, e.g. DNA ligase or O-methylguanine DNA methyltransferase. Most other repair genes are constitutively expressed."

most repair genes	always on
DNA ligase	induced
O-methylguanine DNA methyltransferase	induced

Two enzymes are singled out as worth switching on, and one of them acts on an atom this volume has spent three Parts on.

---

816. A Suicide Enzyme That Moves a Methyl Onto a Sulfur ↩

What MGMT does

O6-methylguanine DNA methyltransferase removes an alkyl group from the O6 position of guanine — the same oxygen that Part Ninety-Three found released by the wobble, and Part Ninety-Four found hydrogen-bonding the metal in the major groove.

Where the methyl goes

from	guanine O6
to	cysteine 145 of the enzyme itself
the reaction	stoichiometric and irreversible
what happens next	the enzyme is ubiquitinated and digested by the proteasome

It is called a suicide enzyme because it can catalyze one reaction per molecule and is then destroyed. Not a catalyst in any ordinary sense — a consumable.

What the volume takes

a methyl sits on guanine O6 the lesion\na cysteine sulfur takes it off the repair\nthe protein dies of having done so the cost

The volume's methyl, the volume's oxygen, and the volume's sulfur, in one reaction that costs a whole protein per lesion. Four letters record the guanine before and the guanine after, and they are the same four letters.

And the atom that carries the lesion is the atom Part Ninety-Four showed holds the catalytic metal when the same guanine sits in a wobble pair. O6 is load-bearing twice, for unrelated reasons, and the notation has no symbol for it either time.

And a ribozyme performs the same removal, with no sulfur and no protein

Scheitl, Mieczkowski, Schindelin and Höbartner reported the crystal structure of the methyltransferase ribozyme MTR1 at 2.8 ångströms in Nature Chemical Biology 18:547 to 555, March 2022. MTR1 catalyzes the site-specific synthesis of 1-methyladenosine in RNA, and the methyl group donor it uses is O6-methylguanine — the same lesion MGMT exists to remove.

what strips the methyl from guanine O6	where the methyl goes	what happens to the machine	cost
MGMT	a cysteine sulfur, at position 145	the enzyme is ubiquitinated and destroyed	one turnover, ever
MTR1	the N1 of an adenosine	the demethylated cofactor leaves as plain guanine	catalytic

The same bond, broken two ways. One route needs a protein and a sulfur and pays a whole enzyme for each lesion. The other needs neither a protein nor a sulfur, and turns over.

The authors draw the evolutionary inference themselves: that modified nucleotides may have enhanced early RNA catalysis, and that metabolite-binding riboswitches may be inactivated ribozymes that lost their catalytic activity. This volume records the comparison and takes no position on which route is older.

817. The Guardian and Its Failure Rate ↩

What Michal records

"The central role of p53 in protecting a cell from DNA damage is shown by the fact that mutations of p53 occur in more than 50 percent of all human tumors. Lost or defective p53 predisposes cells to gene amplifications and aberrant chromosomal separation during mitosis. Thus, p53 is dubbed the 'guardian of the genome'."

p53 mutated	in more than half of all human tumors
the consequence	gene amplification; aberrant chromosome separation in mitosis

The observation the volume adds

The single most frequently mutated gene in human cancer is not a gene that builds anything. It is the gene that decides whether to stop. The commonest failure is not a failure of construction — it is a failure of the pause.

818. Two Fidelities, Five Orders of Magnitude Apart ↩

The two numbers, from the same atlas

process	error rate
transcription	about 1 per 10^4 nucleotides
DNA replication	about 1 per 10^9 to 10^{10} nucleotides

Michal states the comparison directly: the transcription rate is "considerably higher than in DNA replication."

Where replication's accuracy comes from

He itemizes it, and the first line is the one that matters:

stage	contribution
twofold dNTP base selection by DNA Pol III, at binding and at the catalytic step	error rate about 1 per 10^4
3′→5′ exonuclease proofreading by Pol III and Pol I	200 to 1000-fold improvement
postreplicative mismatch repair	the remainder

What the volume computes from that

base selection alone 1 in 10^4 the SAME as transcription\nx proofreading x 10^2 to 10^3\nx mismatch repair the rest\n---------- \nfinal 1 in 10^9 to 10^10

The polymerase that copies the genome is, at the moment of choosing a base, no more accurate than the polymerase that copies a message. The entire difference between one error in ten thousand and one in ten billion is added afterward, by checking.

Accuracy is not in the reading. It is in the re-reading.

---

819. The Code as an Error Budget ↩

Michal's four reasons transcription can afford to be inaccurate

"This rate is a compromise between speed and accuracy and is apparently tolerable for the following reasons: - The products of transcription are not transferred to the progeny - Transcription of an encoding gene takes place repeatedly - The genetic code contains synonyms for amino acids - Many amino acid substitutions do not affect protein activity"

The third reason, read as this volume reads it

The redundancy of the genetic code is here given as a reason the cell may be careless. The synonyms are not decoration. They are a tolerance budget, and transcription spends it.

Part Ninety-Three ended by establishing that synonymous codons are not in fact equivalent — MDR1's ATC and ATT produce different proteins by different folding kinetics.

So the budget is real and it is not free. The code's redundancy licenses a certain error rate at the transcript level, and Part Ninety-Three showed the license is over-drawn: some of those synonyms cost something after all.

The volume records both statements and does not soften either.

---

820. Where This Meets Part Ninety-Five ↩

The same logic, entered from the other side

Part Ninety-Five recorded that inosine given to hyperoxic rats raised TGF-β threefold, held the alveolar cells in G0/G1, and that the authors read the arrest as "a time-out for DNA repair."

Part	the trigger	the response
Ninety-Five	oxidative injury, glutathione depleted	arrest in G0/G1, repair enzyme induced
this Part	nucleotide supply exhausted	arrest in G1 or G2, repair genes induced

Two different insults — one an excess of oxygen, the other a shortage of substrate — produce the same response: stop the cycle and repair. The cell has one lever and pulls it for many reasons.

And in both cases the arrest is protective. Part Ninety-Five's counter-intuitive finding — that protection came with more signaling rather than less — is the same finding as this one. Stopping is what safety looks like.

---

821. What This Part Claims ↩

The claims

1	**Michal's damage-checkpoint trigger list includes "lack of nucleotides." An absence of substrate is on the same list as irradiation**
2	IMPDH is the valve on that supply, and the annotation that placed it in the checkpoint figure was correct
3	IMPDH inhibition produces a full damage response with no lesion — p53 phosphorylated, p21 and PUMA induced, ATR the major sensor
4	The checkpoint reads a concentration and a geometry, not a sequence
5	p21 blocks replication while leaving repair running, by clamping PCNA against one use and not the other
6	MGMT strips a methyl from guanine O6 onto its own cysteine 145, stoichiometrically, and is then destroyed — one lesion per protein
7	p53 is mutated in more than half of all human tumors — the most frequently broken gene is the one that decides to stop
8	Base selection in replication is as inaccurate as transcription — 1 in 10^4. All the additional accuracy comes from proofreading and mismatch repair
9	Michal cites the code's synonyms as a reason transcription may be careless, and Part Ninety-Three showed that license is over-drawn

What this Part does not claim

	that nucleotide depletion and irradiation activate identical pathways. ATR and ATM are distinct sensors and the volume does not merge them
	that IMPDH inhibition is a general model of DNA damage. The 2025 result is in one tumor type
	that MGMT's suicide mechanism is understood. The literature itself asks why an enzyme would work this way
	that the fidelity arithmetic in section 818 is the whole account. Michal gives three stages; the volume multiplies them and marks the product as its own

What would refute it

the claim	**what would kill it**
nucleotide shortage triggers the checkpoint	dNTP depletion without checkpoint activation in a repair-competent cell
IMPDH is the relevant valve	restoration of the guanine pool by a route bypassing IMPDH that fails to silence the response
the checkpoint reads state, not sequence	demonstration of a sequence-comparison step in checkpoint activation
base selection is the same in both polymerases	a redetermination showing Pol III base selection materially more accurate than RNA polymerase

the claim	what would kill it
MGMT is stoichiometric	recovery of methyl-accepting activity by the same protein molecule after a first transfer

And the experiment this Part wants: hold the nucleotide pool constant while blocking IMPDH by supplying guanosine through the salvage route — the HGPRT reaction of Part Ninety-Seven — and see whether the damage response still fires. If it does, the cell is not measuring the pool. If it does not, the guardian of the genome is, in part, a fuel gauge.

PART NINETY-NINE · THE MAP AND THE MARKS

Part Ninety-Nine of the evidence volume, sections 822 to 834

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Thymine occurs in RNA. It is put there by a sulfonium, at one position, in nearly every transfer RNA on Earth, and the gene that does it is essential. On the same seven-nucleotide loop sits a rotation. The cell's signaling currency is adenine and guanine, so this volume's colors extend into cellular communication without alteration. And a four-way DNA junction can be cut two ways, giving two different outcomes from one structure.

822. The Source, and What the Annotations Asked ↩

The atlas

the work	Gerhard Michal, Biochemical Pathways: An Atlas of Biochemistry and Molecular Biology
origin	the wall chart Michal first compiled in 1965 at Boehringer Mannheim
the book	Wiley, 1999

Nine pages of it were brought to this volume, annotated by hand: bacterial transcription and tRNA modification, regulation of transcription, the cellular communication and protein synthesis overview map, the eukaryotic cell cycle,

protein structure, the DNA damage checkpoint, the Holliday junction, and bacterial DNA replication.

The instruction

The request was for "deeper mappings and color symbol linking for human comprehension and pattern recognition." This Part takes the annotations one at a time and asks, for each, whether the volume's color scheme reaches it and whether the observation survives checking.

Part Ninety-Eight took the checkpoint page. This Part takes the rest.

---

823. Thymine, in RNA ↩

What was marked on Figure 10.4-5

Michal's figure shows three tRNA modifications. Beside the third, written by hand: URACIL → RNA₁ / DNA, and below it an arrow down to RNA₂, and the word thymine.

position	starting base	product	enzyme
A37	adenine	N^6-isopentenyl adenosine	MiaA, from isopentenyl-PP
U55	uracil	pseudouridine	pseudouridylate synthase
U54	uracil	ribothymidine	tRNA (uracil-5-)-methyltransferase

What ribothymidine is

Ribothymidine is 5-methyluridine. Uracil with a methyl at carbon five.

A base with a methyl at C5 of a pyrimidine ring, attached to ribose, is thymine sitting in RNA. The single chemical feature that the textbooks use to separate DNA from RNA at the base level — thymine versus uracil — is not a separation at all. It is a methyl, and RNA carries it too.

Where it sits, and how universally

the position	U54, in the seven-nucleotide T-loop — named for this
how common	invariably found at position 54 in tRNAs of most organisms
the gene in E. coli	TrmA
its status	essential for viability

The loop is called the TΨC loop. The T in its name is this thymine. The Ψ is the next section.

---

824. The Methyl Comes from the Sulfonium Again ↩

The reaction

$$S\text{-}adenosylmethionine + tRNA(U54) \n| \nv \n S\text{-}adenosylhomocysteine + tRNA(ribothymidine\text{-}54)$$

The two substrates are S-adenosylmethionine and a tRNA bearing uridine at 54. The two products are S-adenosylhomocysteine and a tRNA bearing ribothymidine.

Michal's figure prints both, and the annotation highlighted them: the sulfonium arrives, the methyl transfers, the homocysteine leaves. Part Forty-Five's donor, doing the one job that converts a uracil into a thymine.

And the enzyme uses a sulfur to do it

The mechanism proceeds through a covalent intermediate. The sulfhydryl of cysteine 324 attacks carbon six of U54, activating carbon five for the methyl, and a β-elimination releases the product.

the sulfur atoms in one turnover	
the sulfonium of S-adenosylmethionine	carries the methyl in
the cysteine thiolate of the enzyme	holds the substrate while it is transferred

Two sulfurs to move one carbon onto one ring position, and the result is the base that names the other nucleic acid.

The exception the volume prints

Some bacteria make the same modification by a different route: TrmFO uses FAD together with N5,N10-methylenetetrahydrofolate as the one-carbon donor, and no sulfonium at all.

The same product, reached by two chemistries. The volume records that the sulfur route is not the only route, and that both organisms end with thymine in their transfer RNA.

---

825. And the Other Modification on the Same Loop Is a Rotation ↩

Pseudouridine at 55

Immediately beside the thymine, at position 55, the same loop carries pseudouridine — the modification Part Seventy-Five established as an isomer rather than a substitution.

	uridine	pseudouridine
formula	identical	identical
the bond to the sugar	N-glycosidic	C-glycosidic
what changed	—	the base was turned around

The two marks together

position 54 U -> ribothymidine a methyl ADDED from a sulfonium\nposition 55 U -> pseudouridine the base ROTATED nothing added

Two adjacent uridines in one seven-base loop, present in nearly every transfer RNA in every domain of life. One of them is modified by addition and the other by rotation, and the four-letter notation writes U for both, and for the two unmodified uridines beside them.

Four identical symbols. Four different molecules. On one loop, in one turn of one RNA.

---

826. The Second Messengers Are Named After the Bases ↩

What was color-marked on the communication map

On Michal's Cellular Communication overview, the annotation applied this volume's own colors to the signal-processing box: G proteins and guanylate cyclase in green, adenylate cyclase in red.

Why that is not decoration

enzyme	product	the base it is built on
adenylate cyclase	cyclic AMP	adenine
guanylate cyclase	cyclic GMP	guanine
G proteins	bind and hydrolyze GTP	guanine
downstream	protein kinase A, protein kinase G	named for their cyclic nucleotide

The cell's internal messaging system does not use a separate chemical vocabulary. It uses the same four bases the genome is written in, cyclized and phosphorylated. Adenine carries one message. Guanine carries the other.

What the volume takes

Part Ninety-Seven established PRPP as the point where every base becomes a nucleotide. This is where two of those nucleotides go afterward, and it is not into nucleic acid at all.

Adenine and guanine are the letters of the genome and, separately, the two channels of intracellular signaling. The notation names them as letters. It has no way to say that one of them is also a message about glucose.

---

827. And the Stringent Signal Is a Guanine with Four Phosphates ↩

What Michal describes

Under amino acid starvation, ribosomes whose A-sites hold non-aminoacylated tRNA bind the stringent factor, which synthesizes an unusual nucleotide:

the molecule	**guanosine tetraphosphate, written PP-5′-G-2′-PP**
what it does	reduces transcription of rRNA and tRNA genes 10- to 20-fold
how	by decreasing the affinity of RNA polymerase for their promoters
the mechanism	unresolved, in Michal's own word
the other arm	amino acid biosynthesis is stimulated

The shape of it

guanosine\ntwo phosphates on the 5' carbon\ntwo phosphates on the 2' carbon

A guanine nucleotide carrying phosphates at both ends of the sugar, made on the ribosome, that turns down the transcription of the machinery for making more ribosomes. A base used as a throttle.

Part Ninety-Seven counted fourteen oxygens and three phosphorus atoms on PRPP. Here is another purine with four phosphates hung on it, doing a job that has nothing to do with being a letter.

---

828. The Color Scheme Extends Without Modification ↩

The test

This volume's colors were built for a nucleic acid argument: orange for hypoxanthine, green for guanine, red for adenine, blue for cytosine, purple for uracil, yellow for thymine and sulfur, indigo for xanthine and orotate.

The annotated communication map applied them to a signal transduction diagram, which is not a nucleic acid diagram, and they fit.

what was colored	color	why it is correct
guanylate cyclase, G proteins	green	they act on guanine
adenylate cyclase	red	it acts on adenine
methionine → cysteine	yellow	the sulfur amino acids
cytidine, deoxycytidine	blue	cytosine
uridine	purple	uracil
deoxythymidine	yellow	thymine

A scheme derived from base identity turns out to label the second-messenger enzymes correctly, because those enzymes are named after the bases they make. No adjustment was required.

The volume records this as a property of biological naming and not as a discovery about biology: the names already carry the information, and the color makes the naming visible at a glance.

---

829. The Four-way Junction ↩

What it is

named for	Robin Holliday, who proposed it in 1964
what it is	a mobile junction between four strands of DNA
why he proposed it	to account for homologous recombination, observed in yeast
its distribution	"highly conserved structures, from prokaryotes to mammals"

How it moves

Because the junction lies between homologous sequences, it can slide — branch migration. In bacteria this is driven by the RuvABC complex or the RecG protein, molecular motors using the energy of ATP hydrolysis to push the junction along.

A structure that exists only because two sequences are the same, and that can travel because they stay the same. Its position along the DNA is not recorded anywhere in the sequence — the sequence is what allows it to have no fixed position.

The annotation

The junction was hand-colored at its four arms by base — G green, A red, C blue, T yellow — turning the diagram into a four-color object with a fourfold center.

---

830. Two Ways to Cut the Same Structure ↩

The resolution

The junction must be resolved — cut and rejoined — to restore two linear duplexes. There are two planes in which to cut.

cut	result
horizontal plane	two molecules that do not show crossover of the flanking markers
vertical plane	both molecules do show crossover

And Michal's source adds: resolution gives patch products if the cuts are in the same orientation during double-strand break repair, and splice products if in different orientations.

What the volume takes

ONE structure\nTWO cutting planes\nTWO genetic outcomes -- crossover, or not\nand in both cases the region of migration is left HETERODUPLEX

The same four strands, the same sequence, the same junction — and whether the flanking genes recombine is decided by the plane of a cut. Not by the letters. By which way the knife goes.

Part Ninety-Three established that the order of two base pairs is worth up to 1.10 kcal/mol. This is the same kind of claim at a larger scale: an outcome fixed by geometry that the sequence does not determine and cannot record.

And every product, whichever plane is used, carries heteroduplex DNA through the migrated region — two strands that are no longer from the same parent, base-paired anyway.

---

831. The Torsion Arithmetic, and Why the Volume Refuses the Inference ↩

What was marked

On Michal's Figure 2.3-1, the primary structure of a polypeptide in extended conformation, the caption states that the torsion angles are $\Psi = \Phi = 180°$.

Written beside it: $180° \times 4 = 720°$, electron, 2 rotations.

The arithmetic is correct

180 x 4 = 720

And 720 degrees is the rotation a spin-one-half particle requires to return to its original state. Part Fifty-Seven's quaternion material rests on exactly that fact.

The volume declines the inference, and states why

the truth	the extended peptide backbone has Φ and Ψ at 180°
the truth	a spinor requires 720° to return to itself
what does not follow	that the first is an instance of the second

Four torsion angles summing to two full turns is arithmetic. A spinor's double rotation is a statement about how a single object transforms under rotation of the frame. The peptide is not one object being rotated twice — it is four separate bonds each held near a half-turn.

The volume prints the observation because it was made, prints the arithmetic because it is right, and refuses the identification because nothing connects them but the number.

This is the same discipline applied in section 779 to the CGA-to-TGA coincidence and in section 786 to the simplicity argument. A number that appears twice is a number that appears twice.

If a real connection exists it will come from the geometry of the backbone under rotation, not from the product of four angles, and this volume does not have it.

---

832. The Figure-Eight, Held in Abeyance ↩

What was marked

On Michal's Figure 10.2-6, bacterial DNA replication, beside the drawing of the replicating circular chromosome, written by hand: "Loop is ½ figure 8 — ∞ — infinity?"

What is true

The replicating bacterial chromosome is called a theta structure, from its resemblance to the Greek letter. Two forks travel in opposite directions from oriC

around a closed circle and meet at the terminus, where six Ter sites and their Tus proteins arrest them.

The daughter chromosomes are then catenated — interlocked — and must be unlinked by topoisomerase IV before they can separate.

Two interlocked closed loops are a genuinely topological object, and unlinking them requires cutting one and passing the other through. That is a real fact about shape, and it is on the page.

What the volume will not yet say

Whether the theta-to-catenane transition is usefully described as half a figure-eight is a claim about topology, and the volume does not have a formulation of it that could be tested.

The observation is recorded and held. If it is to enter the argument it needs a statement of the form: this structure has invariant X, which the sequence does not determine. The volume invites that statement and does not supply it.

---

833. What Is Omitted ↩

The wheel

One annotation from the nine pages is deliberately not treated here: a hand-drawn wheel of twenty-four triangles, marked 24, with codons written around its circumference, on the bacterial replication page.

Its author is investigating it. The volume does not record an observation it cannot yet state, and will take it when it is stated.

And the standing rule this follows

Every Part of this volume ends with the conditions under which it would be wrong. An observation that cannot yet be put in a form capable of being wrong is not yet evidence, however promising.

It is held, named, and left out.

---

834. What This Part Claims ↩

The claims

1	**Thymine occurs in RNA. Ribothymidine is 5-methyluridine at position 54 of nearly all transfer RNAs**
2	The methyl comes from S-adenosylmethionine, and the enzyme holds the substrate through a covalent bond to cysteine 324 — two sulfurs to move one carbon
3	The gene is essential for viability in E. coli
4	Some bacteria make the same base with FAD and methylene-tetrahydrofolate instead, with no sulfonium
5	Positions 54 and 55 of the same loop carry an addition and a rotation, and the notation writes U for both
6	The second messengers are adenine and guanine derivatives, so this volume's colors label the signal-transduction enzymes correctly with no adjustment
7	The stringent signal is a guanine nucleotide with four phosphates, and Michal calls its mechanism unresolved
8	A Holliday junction can be resolved in two planes, giving crossover or no crossover from one identical structure
9	The volume refuses the 720-degree identification, printing the observation and the arithmetic and declining the inference

What this Part does not claim

	that ribothymidine makes RNA into DNA. It is one base modification; the sugar and the backbone are unchanged
	that the sulfonium route is the only route to m5U54. TrmFO uses a different donor entirely
	that the color correspondence in cellular communication is a discovery about biology. It is a property of how the enzymes were named
	that the peptide torsion angles are a spinor. They are four angles that sum to 720 degrees, and nothing more is established
	that the theta-to-catenane transition is a figure-eight. The claim is held, unformulated

What would refute it

the claim	what would kill it
ribothymidine is near-universal at U54	a survey of tRNA modification finding position 54 unmodified across a broad sample of organisms
the modification is essential	a viable TrmA-null E. coli under standard conditions
two sulfurs per turnover	a mechanism for TrmA that does not require the Cys324

the claim	what would kill it
	covalent intermediate
the two-plane resolution	evidence that one resolution plane is used exclusively in vivo
the color correspondence	a second-messenger enzyme named for a base it does not act on

And the measurement this Part would most like: the fraction of cellular transfer RNA that carries ribothymidine at 54, in a human cell, at one time. The literature says "nearly all" and "invariably." This volume would print a number.

PART ONE HUNDRED · THE SHAPE WITH NO SHADOW

Part One Hundred of the evidence volume, sections 835 to 847

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

There is no sixty-four-cell. But there are exactly sixty-four Bravais lattices in four dimensions, and that number arrives in four dimensions and in no lower one. Part Forty-Nine put the eight symbols on the eight corners of a cube; this Part changes the coordinates and keeps every result, and the eight corners then split by parity into two regular tetrahedra with IXGA on one and UOCT on the other. The labeled tetrahedron has exactly two forms and they are mirror images. The rotation group of that tetrahedron has order twelve, its double cover has order twenty-four, and those twenty-four unit quaternions are the vertices of the one regular four-dimensional figure that has no three-dimensional shadow. That chain is rigorous at every link. The arithmetic that was hoped to close the code is not.

835. The Question, and What Was Already Settled ↩

What was asked

"Two primitive cubes, purines IXGA and pyrimidines UOCT — how many sixty-four-cell structures can be made, four-dimensional codons?"

Four clippings on Bravais lattices came with it: the cubic system with its three lattices, and a page giving the count of lattices in four dimensions.

What this volume had already established, and which this Part does not reclaim

Part	section	what it established
Forty-Nine	199	the eight nucleotides on the eight corners of a cube, each with a three-bit address
Forty-Nine	200	the four body diagonals are A–T, G–C, I–U and X–O, and the fourth is the pair that does not exist
Forty-Nine	201	the cube's twenty-four rotations are the twenty-four permutations of the reading alphabet, and three face half-turns are complement, transversion and transition
Forty-Nine	202	eight by eight is sixty-four
Seventy	448	four symbols in three positions and eight symbols in two positions both give six bits, and both give sixty-four

The cube is not new to this volume and neither is the sixty-four. What follows is what happens when the same cube is given different coordinates, and what happens when the question is genuinely carried into four dimensions.

---

836. There Is No Sixty-Four-cell ↩

The complete list

In 1852 Ludwig Schläfli established that four-dimensional space admits exactly six regular convex polytopes. The list is closed.

the figure	its cells	its vertices	its dual
5-cell	5 tetrahedra	5	itself
8-cell, the tesseract	8 cubes	16	the 16-cell
16-cell	16 tetrahedra	8	the 8-cell
24-cell	24 octahedra	24	itself
120-cell	120 dodecahedra	600	the 600-cell
600-cell	600 tetrahedra	120	the 120-cell

What follows

available cell counts: 5 8 16 24 120 600\nsixty-four is not among them

No regular convex four-dimensional polytope has sixty-four cells. The reason is not that nobody has built one. The reason is that the list is complete and has been for a hundred and seventy years.

Three dimensions has five Platonic solids. Four dimensions has six regular polytopes. Every dimension above four has exactly three. Four is the most crowded floor in the building, and even there, sixty-four is not on it.

---

837. But Sixty-Four Is the Right Number for Something Else ↩

What the clipping said

"In four dimensions, there are 64 Bravais lattices, grouped into 23 crystal families and 33 lattice systems. Of these, 23 are primitive and 41 are centered. 10 Bravais lattices split into enantiomorphic pairs."

The series

dimension	Bravais lattices
one	1
two	5
three	14
four	64

One, five, fourteen, sixty-four. The sequence follows no formula. Each entry is a classification carried out by hand and later verified by machine.

Why this is the stronger fact

a cell count	a property of one figure, which either exists or does not
a lattice classification	a theorem about the whole of four-dimensional space

The sixty-four in four dimensions is not the name of a shape. It is the number of essentially different ways a periodic array of points can fill four-dimensional space. It was proved, it is exact, and it is sixty-four.

And twenty-three of those sixty-four are primitive — the word the question used. Four dimensions admits twenty-three primitive lattices and forty-one centered ones.

838. The Same Cube, Re-coordinatized ↩

What Part Forty-Nine did

Part Forty-Nine gave each corner a three-bit address and used the first bit for ring class: zero for a purine, one for a pyrimidine. That places the four purines on one square face of the cube and the four pyrimidines on the opposite face.

What happens if the classes are chosen by parity instead

Put the corners at the eight points whose coordinates are each plus or minus one, and multiply the three coordinates of each corner together.

the class	the four corners
product = +1	(1,1,1) (1,−1,−1) (−1,1,−1) (−1,−1,1)
product = −1	(−1,−1,−1) (−1,1,1) (1,−1,1) (1,1,−1)

The two placements compared

	Part Forty-Nine, by face	this section, by parity
the four purines form	a square	a regular tetrahedron
pairwise distances within a class	two values, 2 and 2√2	one value, 2√2
body diagonals cross the classes	yes	yes
A–T, G–C, I–U, X–O on the diagonals	yes	yes

Nothing is lost. The antipodal map reverses all three coordinates, and reversing three signs always reverses the product, so every body diagonal still joins a purine to a pyrimidine. Part Forty-Nine's four pairs survive the change of coordinates intact — this was checked corner by corner before the section was written.

And what is gained

IXGA -> the four corners of one regular tetrahedron\nUOCT -> the four corners of the other\nthe two together are Kepler's stella octangula, 1619

Under this placement each class of four is not merely a set of four corners. It is a regular solid in its own right, with all six of its edges equal. The two tetrahedra interpenetrate, and the cube is what their vertices share.

Part Forty-Nine's cube is unchanged as a solid. Only the labeling moved, and the labeling that produces tetrahedra keeps every result the face labeling produced.

---

839. The Labeled Tetrahedron Is Chiral ↩

The computation

Four distinguishable labels on the four corners of a regular tetrahedron, counted up to symmetry. The rotation group of the tetrahedron has order twelve. Allowing reflection, order twenty-four.

	group order	distinct labelings
rotations only	12	2
rotations and reflections	24	1

What that means

4! = 24 ways to write IXGA on four corners\ndivided by the 12 rotations that change nothing\n= 2 arrangements that genuinely differ\nand each is the mirror image of the other

Four distinct bases on a tetrahedron cannot be arranged achirally. There are exactly two arrangements, no rotation carries one into the other, and a reflection carries each into the other. Handedness is not something added to the figure. It is the figure.

This is a result about labels, not about chemistry, and this volume does not claim it explains why biology settled on one sugar enantiomer. It records that the smallest container able to hold four distinguishable symbols cannot hold them symmetrically.

840. And the Labeled Cube Has Forty-Eight Forms ↩

The computation

IXGA on one inscribed tetrahedron and UOCT on the other, counted up to symmetry of the cube.

	group order	distinct labelings
rotations only	24	48
rotations and reflections	48	24

4! x 4! = 576 raw arrangements\n576 / 24 rotations = 48\n576 / 48 rotations + mirrors = 24

The two warnings this section prints against itself

First. The twenty-four in the second row is the cube's rotation-group order appearing as a quotient. It is not the twenty-four of the 24-cell in section 843, and the volume declines to join them.

Second. The forty-eight here is the order of the full symmetry group of the cube. The double cover of the cube's rotation group — the binary octahedral group — also has order forty-eight.

They are not the same group. The full symmetry group of the cube contains a subgroup isomorphic to the symmetric group on four letters, and the binary octahedral group contains no such subgroup. Two groups of order forty-eight, both attached to a cube, and not isomorphic. The volume prints this because the coincidence is exactly the kind that has misled the quaternion literature.

And the groups this Part has been computing in have names

Every count in sections 838 through 840 belongs to Coxeter theory, and naming the groups places this Part in a literature a mathematician can read.

Coxeter group	diagram	order	what it is	which count in this Part
B3 = [4,3]	o--4--o-----o	48	the full symmetry group of the cube and of the octahedron	the 24 labelings of section 840

Coxeter group	diagram	order	what it is	which count in this Part
O, its rotation subgroup	—	24	the cube's rotations, isomorphic to the symmetric group on four letters	the 48 labelings of section 840
A3 = [3,3]	o-----o-----o	24	the full symmetry group of the tetrahedron	the 1 labeling of section 839
T, its rotation subgroup	—	12	the tetrahedron's rotations	the 2 labelings of section 839

A3 sits inside B3 at index two, which is the group-theoretic statement of what section 838 found geometrically: the cube contains two tetrahedra, and the operation that swaps them is the one B3 has and A3 does not.

The Wythoff constructions on B3 generate the cube, the truncated cube, the cuboctahedron, the truncated octahedron, the octahedron, the rhombicuboctahedron, the truncated cuboctahedron and the snub cube. That family is the standard illustration of a rank-three Coxeter group at work, and the solid this volume placed eight nucleotides on sits at one corner of it.

AND A REFUSAL, RECORDED BEFORE ANYONE OFFERS IT. The exceptional Lie algebra E8 has rank eight, and the coincidence with this volume's eight symbols is worth closing off in advance. E8 has 240 roots in eight dimensions - 112 of the form plus or minus one in two coordinates, and 128 of the form plus or minus one half in all eight with an even number of minus signs - and an algebra of dimension 248, with a Weyl group of order 696,729,600. Its eight is the rank: eight independent directions in an eight-dimensional space, not eight objects. And the automorphism group of its Dynkin diagram is trivial, so no two of its eight simple roots can be exchanged - each is distinguishable by its position in the graph. This volume's eight symbols divide four and four, with a pairing relation across the division and interchangeability within each class. The E8 diagram has neither a four-and-four split nor any symmetry that could carry the pairing, so any assignment of bases to its nodes would be arbitrary in the choice of which base sits at the branch. The volume declines the identification for the same reason it declined the 720 degrees, the two twenty-fours, the magic square and the sixty-four Bravais lattices: a number in common and no structure in common. The group this Part is actually working in is B3, four ranks below, and B3 describes the cube exactly.

841. Two Cubes, Offset, Is a Real Crystal ↩

The construction

Take two primitive cubic lattices and displace the second from the first by half a cell along each of the three axes. Every point of one then sits at the body center of a cube of the other.

the name	the caesium chloride structure
the coordination number	8, for both species
what surrounds each point	eight nearest neighbors, all of the other kind

Two interpenetrating primitive cubic arrays produce a solid in which no point of one class has any point of its own class as a nearest neighbor. Every nearest contact crosses the classes.

A lattice in which purine points touch only pyrimidine points, eight at a time, and pyrimidine points touch only purine points. It is the cleanest crystallographic statement of the pairing rule this volume has found, and it required no adjustment to say it.

And what it is not

	a model of DNA. DNA is a helix, and its pairing is one-to-one, not one-to-eight
	evidence that bases are arranged cubically anywhere. They are not
	a claim about caesium or chlorine. The structure is the point, not the elements that first showed it

842. Two Cubes, in Four Dimensions, Is the Tesseract ↩

What "two cubes in four dimensions" actually builds

Take a cube and translate it into a fourth direction, joining each corner to its image. The result is the 8-cell — the tesseract.

vertices	16
cells	8 cubes

vertices	**16**
edges	32
square faces	24

The arithmetic problem this exposes

two cubes = 16 corners\nIXGA plus UOCT = 8 letters

Two cubes have sixteen corners and the alphabet has eight letters. The question's own container is twice the size of what it was asked to hold. Either every letter appears twice, or the right figure was one cube all along — which is what Part Forty-Nine used.

If every letter appears twice

The volume records the count, having computed it, and marks it as arithmetic rather than biology.

raw arrangements, 16! / (2!)⁸	**81,729,648,000**
up to the 192 rotations of the tesseract	425,689,320
up to all 384 symmetries	212,979,060

Two hundred and twelve million arrangements. The number is correct and it is useless. It counts labelings of a figure that nothing in the cell is known to occupy, and it is printed here only so that nobody has to compute it again in order to discover that it leads nowhere.

One reading is available and is offered as a reading, not a result: every letter twice is every base on both strands. The volume does not claim the tesseract is where the strands live.

843. The One Figure with No Shadow ↩

The 24-cell

Five of the six regular four-dimensional polytopes are the four-dimensional versions of things that already exist in three dimensions. One of the six is not.

the 24-cell	has no three-dimensional analog
its cells	24 octahedra
its vertices	24
its dual	itself
its symmetry group	F_4, an exceptional group that exists in four dimensions and nowhere else

The consequence of having no analog

Every other regular polytope has a dual that is a different figure. The 24-cell, having nothing else to become, is its own dual. Twenty-four vertices and twenty-four cells, and the count is the same read either way.

It casts no shadow into three dimensions, in the sense that no three-dimensional regular solid stands to it as the cube stands to the tesseract. It is native to four dimensions and it does not descend.

---

844. And Its Vertices Are the Quaternions ↩

The chain, one link at a time

Part Forty-Nine, section 201, reached the double cover of the cube's rotation group by the unit quaternions and stopped there. This section carries the same construction one step further, using the tetrahedron of section 838 rather than the cube.

step	the statement
1	the rotation group of a regular tetrahedron has order 12 — computed directly in section 839
2	unit quaternions cover three-dimensional rotations two to one
3	the preimage of that order-12 group is a group of order 24 — the binary tetrahedral group, 2T
4	2T consists of exactly 24 unit quaternions: ±1, ±i, ±j, ±k, and the sixteen (±1±i±j±k)/2
5	those 24 quaternions are the 24 Hurwitz units
6	those 24 points are the vertices of the 24-cell

What has been established

The 24-cell's vertex set is not merely representable by quaternions. It is the unit group of the Hurwitz quaternions, as a set and as a group. And that group is the double cover of the rotation group of the very tetrahedron on which IXGA sits.

This is the one place in the whole quaternion correspondence where a four-dimensional figure and a quaternion structure are the same object, rather than two objects declared to correspond. No assignment of i, j and k to particular bases is made, and none is needed. The tetrahedron's own symmetry, doubled, is the figure.

And the number is twenty-four

Twenty-four is the number on the hand-drawn wheel recorded in Part Ninety-Nine, section 833, and still under its author's own investigation.

This Part notes the arithmetic agreement and stops. Section 840 has already produced a twenty-four by an unrelated route, and a forty-eight that belongs to two non-isomorphic groups. Matching integers are not a correspondence.

---

845. The Arithmetic, and What Part Seventy Already Printed ↩

What Part Seventy established, and this Part repeats only to extend

letters	positions	product
4	3	64 — the code as it is
8	2	64 — the eight-symbol alphabet, in a doublet

4 symbols x 3 positions = 2 bits x 3 = 6 bits = 64\n8 symbols x 2 positions = 3 bits x 2 = 6 bits = 64

Section 448 printed both and drew the conclusion this volume still holds: four and eight are the only alphabet sizes that give a whole number of bits per symbol and a clean grid of sixty-four.

What is new here: the fourth position

letters	positions	product
4	4	256
8	3	512
8	4	4096
2	6	64

A four-position codon on four letters is 256, not 64. To reach 64 in four positions the alphabet would need 64^(1/4) ≈ 2.83 letters, which is not a whole number. There is no four-position sixty-four-codon code, and there cannot be one.

The third route to sixty-four

Two symbols in six positions also gives sixty-four — purine or pyrimidine, read six times. Part Forty-Nine's three-bit address for each of eight symbols, taken twice, is exactly this.

$$64 = 4^3 = 8^2 = 2^6$$

Three factorizations of one integer. Section 846 states what may and may not be inferred from that.

---

846. The Coincidence This Part Refuses ↩

The number that turned up twice

The edge of the tetrahedron inscribed in a cube of edge 2 is 2√2, computed in section 838. The fourth root of sixty-four is also 2√2.

$$\text{inscribed tetrahedron edge} = 2\sqrt{2} = 2.828427\ldots \quad 64^{(1/4)} = 2\sqrt{2} = 2.828427\ldots$$

Why it is not evidence

Both statements are true and the agreement is exact. It is also empty. $(2\sqrt{2})^2 = 8$, so $(2\sqrt{2})^4 = 64$ by nothing more than squaring twice. And the cube's edge was set to 2 by the author of that section. Set it to 1, and the tetrahedron edge is √2, and the coincidence disappears.

A quantity that depends on an arbitrary choice of units cannot be a fact about biology. The observation is printed so that a reader who notices it is not left wondering whether it was missed, and the refutation is printed in the same section so that nobody carries it further.

The same ruling, applied to the three sixty-fours

the sixty-four	what it counts
64 codons	words of length three over a four-letter alphabet
64 Bravais lattices in 4D	equivalence classes of periodic point-arrays under affine symmetry
64 = 2^6	six binary choices

Three different objects counted by the same integer. Nothing carries from one to another. The volume prints all three, states that they are unrelated, and declines the identification — as it declined the 720 degrees in Part Ninety-Nine.

---

847. What This Part Claims ↩

The claims

1	**There is no 64-cell. The six regular convex 4-polytopes have 5, 8, 16, 24, 120 and 600 cells, and the list is complete**
2	There are exactly 64 Bravais lattices in four dimensions, in 23 crystal families and 33 lattice systems, of which 23 are primitive and 41 centered, with 10 enantiomorphic pairs
3	Part Forty-Nine's cube can be re-coordinatized so that each class of four is a regular tetrahedron, and all four body diagonals — A–T, G–C, I–U, X–O — survive the change unchanged
4	Four distinct labels on a tetrahedron give exactly 2 arrangements under rotation and 1 under reflection. The labeled tetrahedron is chiral
5	IXGA and UOCT on the two tetrahedra of a cube give 48 arrangements under rotation and 24 allowing reflection
6	Two primitive cubic lattices offset by half a cell is the caesium chloride structure, in which every point has 8 nearest neighbors, all of the other class
7	Two cubes joined across a fourth direction is the tesseract: 16 vertices, 8 cubic cells — twice the size of the eight-letter alphabet

1	**There is no 64-cell. The six regular convex 4-polytopes have 5, 8, 16, 24, 120 and 600 cells, and the list is complete**
8	The 24-cell has no three-dimensional analog, is self-dual, and its 24 vertices are exactly the 24 unit Hurwitz quaternions, forming the binary tetrahedral group, which is the double cover of the order-12 rotation group of the tetrahedron of claim 3
9	$64 = 4^3 = 8^2 = 2^6$, and a four-position code on four letters is 256

What this Part does not claim

	that the 64 codons and the 64 four-dimensional Bravais lattices are the same 64. They count unrelated things and the volume refuses the identification
	that the cube is new to this volume. Part Forty-Nine built it; this Part changed its coordinates
	that the bit arithmetic is new. Part Seventy, section 448, printed 4^3 and 8^2 and drew the conclusion
	that bases occupy a cube, a tesseract or a 24-cell anywhere in the cell. No such geometry has been observed and none is asserted
	that the 24 of the 24-cell is the 24 of the hand-drawn wheel in section 833. Section 840 produces an unrelated 24, which is the point
	that the tetrahedron's chirality explains biological handedness. It is a counting result about labels
	that the CsCl structure models DNA. Pairing in DNA is one-to-one; in CsCl it is one-to-eight
	that the $2\sqrt{2}$ agreement means anything. It follows from setting the cube edge to 2

What would refute it

the claim	what would kill it
no regular 4-polytope has 64 cells	a seventh regular convex 4-polytope, which would overturn Schläfli
64 Bravais lattices in 4D	a recount by the crystallographic tables giving a different total
the parity split into two tetrahedra	a pair of same-parity cube corners at the tetrahedral edge distance, which the coordinates forbid
compatibility with Part Forty-Nine	a body diagonal, under the parity labeling, joining two purines or two pyrimidines
2 and 1 tetrahedron labelings; 48 and 24 cube labelings	a recomputation by Burnside's lemma giving different orbit counts
the 24-cell vertices are the Hurwitz units	a Hurwitz unit that is not a 24-cell vertex, or a vertex that is not a unit

the claim	what would kill it
no four-position 64-codon code	an integer fourth root of 64

And the one measurement this Part would want, if the geometry is ever to be more than geometry: an observed physical arrangement, in any cell, of four purines and four pyrimidines at the corners of a cube. Until then the cube is a container for an alphabet, and the volume says so in those words.

Sections 838 through 842 and 845 were computed in code and the counts reproduced by exhaustive enumeration before being printed. Sections 836, 837, 843 and 844 are standard results, cited to the crystallographic and polytope literature in Appendix A.

PART ONE HUNDRED AND ONE · THE LETTERS AND THE LEDGER

Part One Hundred and One of the evidence volume, sections 848 to 860

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

An eight-letter genetic system exists. It was built in 2019, it obeys Watson-Crick geometry, it was transcribed into eight-letter RNA, and it works. It does not use this volume's eight, and the reason it could not is the argument of this Part. Xanthine and orotate have no complement, so they cannot be copied and therefore cannot be letters. Inosine is read and never written. Meanwhile the path from codon to protein loses count at every step — sixty-four to fifty-one to twenty — and the second half of that path is not base pairing at all. The eight are a ledger of where nucleotides came from. They were never a spelling.

---

848. The Distinction That Preceded the Question ↩

What was put plainly

"I was confusing the alphabet codons with metabolic purines and pyrimidines."

That sentence is the subject of this Part, and it is also the answer to it. The volume had already made the distinction and had not stated it in one line.

Where it was already stated, in the volume's own words

Part	section	the sentence
Seventy	449	"Not a replacement for the codon table. A second index over the same sixty-four cells, in which the two gates that no letter names are given coordinates."
Seventy	449	"The four letters answer: what does this codon specify. The eight symbols answer: where did the parts of this codon come from."
Twenty-Two	48	"The code did not enlarge its alphabet to reach twenty-two. It reused punctuation twice and put the deciding information outside the codon, in a hairpin."

Three sentences, written across three Parts and eight hundred pages, saying the same thing. This Part collects them, tests the alternative, and states the limit.

---

849. The Collapse, Counted ↩

The chain from message to protein

mRNA codons	64
sense codons	61
human cytoplasmic tRNA isoacceptors	51 in a published count
minimum tRNA set under Crick's wobble rules	31 to 32
human mitochondrial tRNAs	22
amino acids, all life	22
amino acids in a human	21
canonical amino acids	20
polypeptide	1

What that does to any geometric model

64 -> 51 -> 20\nthe count falls at every step and never rises

A regular solid has a symmetry group, and a symmetry group permutes parts of equal standing. Nothing that collapses from sixty-four to twenty can be the orbit of a symmetry. The code is not a symmetric object, and any figure offered as a model of it will be modeling something else.

Part One Hundred put eight symbols on the corners of a cube and claimed nothing beyond the alphabet. This section is why that restraint was correct.

---

850. The Degeneracy Blocks Are Not an Orbit ↩

The partition of sixty-four

block size	how many amino acids	codons covered
6-fold	3 — leucine, serine, arginine	18
4-fold	5	20
3-fold	1 — isoleucine	3
2-fold	9	18
1-fold	2 — methionine, tryptophan	2
stop	—	3
total	20	64

Why the three matters most

The block sizes are one, two, three, four and six. A group acting on sixty-four objects partitions them into orbits, and the orbit sizes must divide the order of the group. Five different block sizes, one of them odd and equal to three, in a single partition of sixty-four — which is a power of two.

Three does not divide sixty-four. Isoleucine's three-codon box cannot be an orbit of any group acting on a set of sixty-four by symmetries of a binary structure. The code contains a block that the arithmetic of the cube forbids.

This was computed rather than recalled, and the table above was produced by enumerating the standard code in full.

---

851. The Second Step Is Not Base Pairing ↩

The two halves of translation are not the same kind of operation

step	what performs the reading
codon → anticodon	base pairing. Geometry can model this
anticodon → amino acid	an aminoacyl-tRNA synthetase. A protein reading a folded shape

And the ribosome does not check

By the time a transfer RNA reaches the ribosome it is already charged. The ribosomal RNA catalyzes the peptide bond. It never verifies that the correct amino acid arrived.

The amino acid is not attached anywhere near the anticodon. It is attached at A76, seventy-five ångströms away at the far end of a folded molecule, by an enzyme that spans the distance. Part Thirty-Two established that measurement and this Part now uses it.

So the geometry does not merely run out. It stops at a specific place, for a specific reason: a solid is a model of what sits opposite what, and pairing carries the message only as far as the anticodon. The rest is done by a protein at the other end of the molecule.

---

852. Twenty-Two Does Not Close It ↩

What selenocysteine and pyrrolysine actually are

selenocysteine	the 21st, on UGA, requiring a SECIS element and a dedicated elongation factor
pyrrolysine	the 22nd, on UAG, assisted by a PYLIS element

Neither adds a codon. UGA and UAG were already among the sixty-four. What changed is that the same three letters now mean two different things depending on a hairpin elsewhere in the message — in eukaryotes, out in the three-prime untranslated region.

The notation writes UGA identically in both cases. Nothing inside the triplet says whether it terminates the protein or inserts an atom of selenium. That is this volume's thesis in its shortest available form, and the code supplies the example.

And twenty-two is not a human number

pyrrolysine	**confined to methanogenic archaea, chiefly Methanosarcinaceae, and a few anaerobic bacteria. Not present in humans**
selenocysteine	present across all three domains; 25 human selenoproteins
a human	therefore has 21, not 22

And Part Twenty-Two, section 48, already recorded that there is no twenty-third: sixteen archaeal and one hundred thirty bacterial genomes were mined for transfer RNAs bearing stop-complementary anticodons and none was found.

---

853. The One Amino Acid with No Synthetase ↩

The asymmetry inside the twenty-two

20 canonical each charged onto its tRNA by a dedicated synthetase\npyrrolysine
PylRS - a genuine twenty-first synthetase\nselenocysteine none

How selenocysteine is actually made

It is not charged. It is built in place, on its own transfer RNA, out of a serine that is already esterified there.

domain	the route
bacteria	SerRS, then SelA converts Ser-tRNA(Sec) directly to Sec-tRNA(Sec)
archaea and eukaryotes	SerRS, then PSTK phosphorylates to Sep-tRNA(Sec), then SepSecS converts it

Selenocysteine is the only amino acid synthesized on its transfer RNA in all domains of life, the only one specified by a stop codon, and the only one carrying a dietary trace element as a structural component. Twenty-two amino acids are served by twenty-one synthetases.

The set is not twenty-two of a kind. Twenty are charged, one is charged by a late-evolved enzyme, and one is manufactured on the spot out of a different amino acid. A figure with a symmetry group treats its parts as interchangeable. These are not interchangeable.

And the element at the center of the exception is selenium — indigo in this volume's scheme, and the subject of Part Seventy-One.

---

854. And the Twenty-twos Are Different Twenty-twos ↩

The coincidence, and the refusal

the twenty-two	what it counts
22 human mitochondrial tRNAs	genes in one organelle of one species
22 amino acids	residues across all life, of which a human uses 21
22 nucleotide species	the count established in Part Twenty-Two, section 48

Three twenty-twos counting three different things. The volume prints all three and declines to join them, as Part One Hundred declined the two twenty-fours in section 840 and Part Ninety-Nine declined the 720 degrees.

The test the volume already ran against its own number

Section 48 reported a parameter sweep over bases, sugars, phosphorylation states and wobble species which found twenty-five different settings inside a small box that also total twenty-two, and concluded in the volume's own words that landing on the number is therefore not evidence and is not offered as evidence.

That discipline was applied to the author's own favored count before it was applied to anyone else's. This section only extends it.

---

855. An Eight-letter Genetic System Exists ↩

What was built

Hoshika and colleagues, with Benner, in Science, 22 February 2019.

the name	**hachimoji — Japanese hachi, eight; moji, letters**
the alphabet	eight nucleotide letters forming four orthogonal pairs
the added pairs	P with Z, and B with S

What was demonstrated

structure	**three crystal structures show the synthetic building blocks do not perturb the double helix**
thermodynamics	measured parameters predict duplex stability
information	hachimoji DNA increases the information density of natural DNA
transcription	hachimoji DNA was transcribed into hachimoji RNA
function	the RNA folded into a working fluorescent aptamer
the criterion	the system meets the structural requirements to support Darwinian evolution — a polyelectrolyte backbone, predictable stability, and stereoregular building blocks

So the answer to whether the genetic alphabet can be extended to eight is not a matter of opinion. It has been done, it crystallizes, it transcribes, and the product works.

856. And It Could Not Use This Volume's Eight ↩

What they had to do instead

To reach eight letters they designed four new bases. They did not use inosine, xanthine, orotate and thymine, which are present in every cell on Earth.

Why not — from this volume's own findings

the symbol	**why it cannot be a letter**
X — xanthine	no complement. Part Forty-Nine, section 200, found the X–O body diagonal to be the pair that does not exist
O — orotate	no complement. The same finding

the symbol	why it cannot be a letter
I — inosine	read at anticodon position 34; never written into DNA. ITPase exists to hydrolyze ITP, dITP, XTP and dXTP back to the monophosphate before they can be incorporated
T — thymine	already a letter

The rule this establishes

Replication is pairing. A base with no partner cannot be copied, and what cannot be copied cannot be inherited. Xanthine and orotate can never be coding symbols — not because the experiment has not been tried, but because there is nothing for them to pair with. Which is exactly the property that makes them gates.

CORRECTED. THE CONCLUSION STANDS AND THE REASON CHANGES. The paragraph above gives no partner as the reason, and that reason is wrong. Part Forty-Nine, section 200, now carries the correction in full: xanthine pairs with uridine in distinct wobble geometries and with cytidine in two interconvertible modes, at a strength comparable to a G·U wobble, and orotate presents uracil's own Watson-Crick face. Xanthine and orotate cannot be letters because neither is ever available to be incorporated. ITPA destroys xanthine's triphosphate. OMP decarboxylase converts orotate to uracil before it reaches a diphosphate. That is the eight-ladder result, and it names two enzymes where the paragraph above asserts an absence.

AND THE FINDING THIS VOLUME SHOULD HAVE TAKEN FROM IT. The same 2022 study reports that reverse transcriptases read xanthosine preferentially as G or as A, and that the ratio depends on which reverse transcriptase is used. One base, two readings, and the reading decided by the enzyme rather than by the base. That is this volume's thesis, stated by other people, about a symbol the four-letter notation does not contain.

When chemists actually built the eight-letter genome, the four they had to invent were the four this volume's alphabet could not supply. That is the strongest available confirmation of what the eight-symbol set is for, and it arrives from outside the volume.

857. Nature's One Attempt Was a Substitution ↩

Cyanophage S-2L

Known since 1977; the mechanism resolved in two papers in Nature Communications in 2021.

what it does	every adenine in its genome is replaced by 2-aminoadenine, written Z
the pairing	Z pairs with thymine through a triple hydrogen bond rather than two
the alphabet size	still four — Z, T, G, C

The three genes that do it

gene	function
PurZ	a homologue of adenylosuccinate synthetase; makes the 2-aminoadenine nucleotide, and can use either dATP or ATP as its energy source
DatZ	a dATP-specific triphosphohydrolase — destroys dATP and leaves every other dNTP intact, including dZTP
MazZ	a (d)GTP-specific diphosphohydrolase, supplying PurZ its substrate

And the cluster was moved

The three genes — datZ, mazZ and purZ — were expressed together in Escherichia coli, and 2-aminoadenine was successfully incorporated into the bacterium's chromosomal and plasmid DNA.

Three genes changed the alphabet of a living bacterium. And the alphabet still had four letters.

Nature ran this experiment once. It chose substitution over extension. That is a datum about what the code will tolerate, and this volume records it as such. Experiment One, written before this Part, proposed searching the sequenced virosphere for isoguanine on the reasoning that 2-aminoadenine was hiding in phage genomes until somebody looked. This section is what was found when somebody looked at the one that had already been seen.

858. And the Discrimination Was Not in the Polymerase ↩

The finding that matters most here

A member of the PrimPol family is the sole possible polymerase of S-2L, and its crystal structure at 1.5 ångström resolution shows there is no structural element in the active site that could reject adenine opposite thymine. The enzyme incorporates both A and Z opposite T.

So how does the phage exclude adenine

not by reading better\nby destroying the substrate\nDatZ hydrolyzes dATP and nothing else\nthe pool contains no dATP\nthe polymerase, which cannot tell them apart, has only one choice

The letter is chosen by the composition of the nucleotide pool, not by the fidelity of the reader. The specificity is upstream of the machine, in metabolism.

Where this volume has met that mechanism before

Part Ninety-Eight established that the DNA damage checkpoint fires on nucleotide pool depletion with no lesion present — that the cell reads a pool concentration rather than a sequence. Here the same quantity sets which letter the genome is written in.

A pool level decides what gets built, and no notation of the product records that it was decided that way. This is the connection between the alphabet and the ledger, and it is the reason the volume keeps both.

---

859. What an Index Is and What a Code Is ↩

The two questions

the four letters answer	what does this codon specify
the eight symbols answer	where did the parts of this codon come from, and what gate did they pass

What the eight can and cannot be

cannot	**a fifth through eighth coding letter. Two of them have no complement**
cannot	a replacement for the codon table. Part Seventy, section 449, already said so
can	a provenance tag on each nucleotide of a codon — eight values, carried by the molecule, invisible to the ribosome
can	a second index over the same sixty-four cells, giving coordinates to the two gates no letter names

A code must be copied. An index must only be true. That is the whole difference, and it is why xanthine and orotate can be in the second and never in the first.

The volume has been building an index for a thousand pages and occasionally calling it an alphabet. This section fixes the word.

860. What This Part Claims ↩

The claims

1	**The count falls at every step from message to protein — 64 codons, 51 human cytoplasmic isoacceptors, 31 to 32 minimum tRNAs, 22 mitochondrial tRNAs, 20 canonical amino acids**
2	The degeneracy blocks are of sizes 1, 2, 3, 4 and 6, and three does not divide sixty-four
3	The second half of translation is not base pairing. The amino acid is attached at A76, seventy-five ångströms from the anticodon, by a synthetase, and the ribosome does not verify it
4	Selenocysteine and pyrrolysine add no codons. Both are recoded stops with the deciding information outside the triplet
5	Selenocysteine has no synthetase and is built on its own tRNA from an esterified serine; 22 amino acids are served by 21 synthetases
6	Pyrrolysine is not present in humans; a human uses 21
7	An eight-letter genetic system exists — hachimoji DNA and RNA, four orthogonal pairs, crystallized, transcribed, and functional as an aptamer
8	It required four newly designed bases, because xanthine and orotate have no complement and inosine is never written into DNA
9	Cyanophage S-2L replaces every adenine with 2-aminoadenine by three genes, and the alphabet remains four letters

1	**The count falls at every step from message to protein — 64 codons, 51 human cytoplasmic isoacceptors, 31 to 32 minimum tRNAs, 22 mitochondrial tRNAs, 20 canonical amino acids**
10	The S-2L polymerase cannot tell A from Z. The exclusion is performed by DatZ destroying the dATP pool

What this Part does not claim

	that the eight-symbol set is a coding alphabet. This Part establishes that it cannot be
	that hachimoji has been put into a living organism. It is a chemical system; the incorporation of an unnatural pair into a cell is separate work
	that 2-aminoadenine is a fifth letter. It is a substitution for adenine; the count stays at four
	that the three twenty-twos are related. They count different things and the volume refuses the identification
	that the isoleucine three-box refutes the cube. It refutes the cube as a model of the codon table, which Part One Hundred never claimed it was
	that a published count of 51 isoacceptors is exact. tRNA counts vary with method, and this Part cites one count rather than asserting a constant

What would refute it

the claim	**what would kill it**
xanthine and orotate cannot be letters	a demonstrated, replicable base pair with either one as a partner
inosine is never written into DNA	inosine or its deoxy form found as a templated, inherited residue rather than a lesion or an edit
selenocysteine has no synthetase	a selenocysteinyl-tRNA synthetase, in any organism
the alphabet stayed at four in S-2L	a fifth base pair in the S-2L genome
the discrimination is in the pool, not the polymerase	a structural element in S-2L PrimPol shown to reject adenine opposite thymine
the count collapses	a one-to-one mapping from 64 codons to 64 distinct charged tRNA species in any organism

And the measurement this Part would most like is now Experiment Twenty-eight, in Part Twenty-Eight, section 65: whether a semi-synthetic organism carrying an unnatural base pair shows any change in the nucleotide pool enzymes — the ITPase, the triphosphohydrolases — as the cell attempts to treat the new letter as

an error. S-2L had to destroy dATP to protect its alphabet. A cell given a fifth letter it did not ask for should be expected to do the same thing in reverse.

Czernecki, Bonhomme, Kaminski and Delarue, "Characterization of a triad of genes in cyanophage S-2L sufficient to replace adenine by 2-aminoadenine in bacterial DNA," Nature Communications 12:4710, 5 August 2021	the three genes, and their transfer into E. coli

Sections 849, 850 and 852 were computed or tabulated directly from the standard genetic code before being printed.

PART ONE HUNDRED AND TWO · THE PERIOD BELONGS TO THE PARTICLE

Part One Hundred and Two of the evidence volume, sections 861 to 873

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The seven hundred and twenty degrees is real. It was measured in 1975, twice, by two groups working independently with neutron interferometers, and it is the physical period of anything carrying spin one-half. This Part takes it away from the sugars and gives it to the particles that actually have it. Section 110 assigned the

two circuits of the spinor to deoxyribose and ribose. The sugars fail every requirement a spinor claim has to meet, and the one genuine rotation a sugar ring possesses — the pseudorotation of its pucker — closes at three hundred and sixty degrees, not seven hundred and twenty. The chemistry section 110 was reaching for survives without the spinor and is restated here without it. And there is exactly one place in a nucleobase where a rotation and a spin are locked together by the Pauli principle. It is the methyl group on thymine, and its number is three.

861. What This Part Corrects, and on Whose Instruction ↩

The inconsistency

Two sections of this volume treated the same number by two different standards.

section	the claim	how it was treated
110	the two sugars are the two circuits of one spinor period	accepted
831	four peptide torsion angles summing to 720 degrees are a spinor	refused

The author was shown both and ruled that the volume must hold them to one standard. This Part is that ruling carried out. Nothing in section 110 is deleted. What is removed from it is the inference, and the inference is replaced by the physics that actually supports the number.

What this Part does not do

It does not withdraw the 720 degrees. The 720 degrees is a measured fact about spin one-half and it stays in the volume. It moves.

862. The Seven Hundred and Twenty Degrees Is Real, and It Was Measured ↩

The prediction

Aharonov and Susskind, and independently Bernstein, argued in 1967 that the double-valuedness of a spin-one-half wavefunction should be observable in an interference experiment.

The measurement

1975	**Rauch and colleagues, "Verification of coherent spinor rotation of fermions," Physics Letters A 54:425–427**
1975	Werner, Colella, Overhauser and Eagen, "Observation of the phase shift of a neutron due to precession in a magnetic field," Physical Review Letters 35:1053–1055

Both groups used a three-blade interferometer cut from a single perfect silicon crystal. A neutron beam was split, one arm carried through a magnetic field that rotated its spin, and the two arms recombined.

The interference pattern repeats only after the neutron has been carried through 720 degrees. Rotate a spin-one-half object through 360 degrees and you get the negative of what you started with.

Why an interferometer was required

An overall sign is unobservable on its own. It can only be seen by interfering the rotated system against an unrotated copy of itself.

This is the requirement that governs everything else in this Part.

---

863. What a Spinor Claim Has to Satisfy ↩

The four conditions

1	**a continuous rotation is actually applied**
2	there is a state being rotated
3	the state returns to minus itself at 360 degrees and to itself at 720
4	the sign is detectable, which requires interference against an unrotated reference

These are not a high bar invented for this Part. They are what Rauch and Werner had to build in order to see the effect at all. Condition

four is the one that most analogies fail, because a global sign is invisible without something to compare it against.

---

864. The Sugars Fail All Four ↩

Taken one at a time

condition	deoxyribose and ribose
a continuous rotation	no
a state being rotated	no
720 degrees as a period	no
a detectable sign	no

Why the first one fails, which is enough

Deoxyribose and ribose are two different compounds. They differ by one oxygen atom at the two prime position.

ribose --[ribonucleotide reductase]--> deoxyribose\nan oxygen is REMOVED\nnothing is rotated

No rotation carries one sugar into the other. Part One removed that oxygen with a thiyl radical and a pair of cysteines; it did not turn anything through any angle. There is no rotation, so there is no rotation period, so there is nothing for 720 degrees to be the period of.

---

865. And the Sugar's Real Rotation Closes at Three Hundred and Sixty ↩

The furanose ring does have a rotational coordinate

It is the pseudorotation phase angle P, defined by Altona and Sundaralingam, computed from the five endocyclic torsion angles. The pucker travels around a wheel.

the coordinate	P, the phase angle of pseudorotation
its range	0° to 360°
the wheel	ten puckering modes, at 36-degree intervals
the modes	C3′-endo, C4′-exo, O4′-endo, C1′-exo, C2′-endo, C3′-exo, C4′-endo, O4′-exo, C1′-endo, C2′-exo

P : 0° ----------> 360° and the ring is home

The sugar ring contains one genuine rotation, it has been measured since 1972, and its period is three hundred and sixty degrees. That is not an absence of evidence for the spinor reading. It is evidence against it.

And ten modes on the wheel is not twelve. The tetrahedral coincidence section 110 relied on does not appear in the sugar's own rotation either.

---

866. What Section 110 Keeps ↩

The chemistry stands on its own

Section 110's underlying observation is a fact about the base set, and it needs no physics beyond chemistry.

Two sugars carry the same set of bases. Deoxyribose carries A, G, C and T. Ribose carries A, G, C and U. It is one alphabet written on two backbones, and the alphabet is what this volume has been counting from the first page.

What was removed and why

kept	one alphabet, two sugars, and the whole of Parts Thirty-Five and Twenty-Nine on the pentoses
removed	the assignment of the first circuit to deoxyribose and the second to ribose
the reason	the assignment was carried by a true sentence about spin one-half placed directly above a table about sugars, which have no spin one-half character. The truth of the sentence lent authority to a table it did not license

This is the most instructive error the volume has caught in itself, because the false step was made persuasive by a true statement standing next to it, and not by any false statement at all.

867. The Torsion Claim Scored Higher, and Was Refused First ↩

The comparison the volume owes itself

condition	peptide torsions, refused in section 831	the two sugars, accepted in section 110
a real rotation	yes — a dihedral angle is a rotation about a bond	no
a state being rotated	partly	no
720 as a period	no — it is a sum of four angles	no
a detectable sign	no	no

The claim this volume refused was the better of the two. Torsion angles are at least genuinely rotations. The sugars are two compounds with no rotation between them. The volume applied its strictness to the stronger case and its indulgence to the weaker one, and did so for two hundred pages without noticing.

Section 831's refusal stands, unchanged and correct. It is now applied where it was owed.

868. Where Spin One-half Actually Is in a Nucleotide ↩

The inventory

particle	spin	present in every nucleotide
electron	one-half	yes
proton, ^{1}H	one-half	yes
^{13}C	one-half	at natural abundance, about 1.1 percent
^{15}N	one-half	at natural abundance, about 0.4 percent

particle	spin	present in every nucleotide
^{12}C, ^{16}O, ^{14}N	0, 0, 1	not one-half

The 720 degrees belongs to the electron and to the proton. Those are the objects in a nucleotide that genuinely carry it, and this volume already has three sections about them: section 3 on sulfur and the proton, section 4 on sulfur and the electron, and section 32 on the tunneling calculation. That is where the number now lives.

---

869. But Proton Transfer Is Translation, Not Rotation ↩

The limit that must be stated with the relocation

Moving the 720 degrees to the proton does not license attaching it to proton tunneling in a hydrogen bond.

what a Löwdin proton transfer is	a proton translating through a potential barrier
what sets the rate	barrier height, barrier width, reduced mass — the exponent in the WKB expression
what does not appear in the calculation	spin

The proton crossing from guanine to cytosine does not rotate. Its spin is a spectator. The tunneling work of sections 32 and 39, and the Surrey calculation behind Experiment Two, is correct and is untouched by the spinor argument — and is also not supported by it.

A particle can carry spin one-half and still perform an act in which its spin plays no part. The 720 degrees is a fact about rotating a proton, not about moving one.

---

870. The Methyl Group Is the Exception ↩

Where a rotation and a spin are genuinely locked together

A methyl group tunnels between its three equivalent orientations. Its three protons are identical fermions. A rotation by one hundred and twenty degrees permutes them.

rotate the CH3 by 120 degrees\n-> the three protons are exchanged\n-> the Pauli principle constrains the total wavefunction\n-> the SPATIAL rotational state is locked to the NUCLEAR SPIN state

What this produces, and what is measured

the states	classified A and E by symmetry
the observable	a tunneling splitting, measured in microelectronvolts by inelastic neutron scattering
the strange consequence	A and E populations do not equilibrate on their own
why not	converting between them requires changing a nuclear spin. It needs a paramagnetic center
the name	spin-symmetry conversion, or A–E conversion, studied since 1973

Here, and essentially nowhere else on a nucleobase, a rotation and a spin are not two separate things. The Pauli principle makes them one object. This is standard condensed-matter physics with a Chemical Reviews compilation behind it, and it is the first place in this volume where the author's instinct that rotation and spin meet in a base has turned out to be literally correct.

---

871. And Its Number Is Three, Not Seven Hundred and Twenty ↩

The correction that comes with the finding

The methyl rotor's symmetry group is C_3. Its period is one hundred and twenty degrees and its order is three. The 4π period belongs to spin one-half under spatial rotation and is not the methyl's period.

methyl rotor C3 order 3 120 degrees\nspin one-half SU(2) 720 degrees

Which is the better outcome

where three has already	

where three has already appeared in this volume	
appeared in this volume	
three bivectors	the even part of the Clifford algebra of three-space
three generators	of SO(3), one per plane
three positions	in a codon
1, 3, 3, 1	the grading of the eight cube corners by weight, in Part One Hundred

The methyl group's number is three, and three is the number this volume keeps arriving at by routes that do not depend on each other. The volume states that and makes no further claim, having spent Part One Hundred learning what matching integers are worth.

---

872. The Measurement Nobody Has Made ↩

What the search found, and did not find

The methyl tunneling literature is fifty years deep and has its own review compilation. A search for a measured tunneling splitting for the C5 methyl of thymine returned nothing.

Why thymine should be a favorable case

the position	C5 of thymine, a methyl on an aromatic carbon
the barrier	aryl-methyl rotational barriers are low
the consequence	low barrier gives a large tunneling splitting, which is the easy case to observe
and it is not inert	the thymine C5 methyl is already known to alter spontaneous base-pair breathing in DNA

So the one methyl group this volume has spent five Parts on sits at a position where the measurement should be easy, has a documented effect on the pair it belongs to, and has never been looked at with the instrument that would settle it.

This is Experiment Twenty-nine, in Part Twenty-Eight, section 65.

---

873. What This Part Claims ↩

The claims

1	**The 720-degree period of spin one-half is a measured physical fact, confirmed independently by two groups in 1975 using neutron interferometry**
2	The sign is only observable by interference against an unrotated reference
3	Deoxyribose and ribose differ by an atom, not by a rotation, so no rotation period can be assigned to the pair
4	The furanose ring's one genuine rotation is pseudorotation, whose phase angle closes at 360 degrees across ten puckering modes
5	Section 110's chemistry survives without the spinor: one alphabet on two backbones
6	The peptide-torsion claim refused in section 831 satisfied more of the conditions than the sugar claim that was accepted
7	The electron and the proton are the spin-one-half objects in a nucleotide, and the 720 degrees belongs to them
8	Proton transfer across a hydrogen bond is translation, and spin does not enter its rate
9	Methyl rotational tunneling locks the rotational state to the nuclear spin state by the Pauli principle, giving A and E species that do not equilibrate without a paramagnetic center
10	The methyl rotor's symmetry is C_3, of order three, not 4π
11	No tunneling splitting for the thymine C5 methyl appears in the literature

What this Part does not claim

	that the 720 degrees is withdrawn from the volume. It is relocated, not deleted
	that spin one-half plays a role in base-pair proton tunneling. Section 869 states the opposite
	that methyl tunneling has a known biological consequence. It has a known physics; the biology is unexamined
	that the three of the methyl rotor is the three of the codon or the three of SO(3). Section 871 declines that, as Part One Hundred declined the twenty-fours
	that section 110 was dishonest. It was persuasive, which is worse, and the mechanism is described in section 866 so that a reader can recognize it elsewhere

What would refute it

the claim	what would kill it
the sugars are not related by a rotation	a rotation operation carrying ribose to deoxyribose
pseudorotation closes at 360 degrees	a measured 720-degree period in the pucker coordinate
spin does not enter H-bond proton transfer	a measured dependence of the transfer rate on nuclear spin state
methyl tunneling is spin-locked	A–E conversion proceeding at equilibrium rate with no paramagnetic center present
the thymine methyl splitting is unmeasured	a published inelastic neutron scattering spectrum showing it — which the volume would welcome and would print

And the honest summary of this Part: the volume held a true statement about physics next to a false inference about chemistry for two hundred pages, and caught it only when a reader asked which of two contradictory rulings was correct. The number was never wrong. Its address was.

PART ONE HUNDRED AND THREE · THE MARK DECIDES WHERE

Part One Hundred and Three of the evidence volume, sections 874 to 886

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Both epigenetic currencies are carried on sulfur. A methyl on cytosine does not tell the genome what to become — but it decides where the genome is most likely to change, because a methylated cytosine deaminates to thymine rather than to uracil, and thymine is not foreign. The rate runs ten to fifty times other transitions and about a third of the mutations behind human genetic disease sit at these sites. This volume has already printed two worked examples of the mechanism and filed them under disease. This Part files them under evolution, and refuses the stronger claim that usually gets made here.

---

874. The Claim This Part Refuses, and the One It Makes ↩

Refused

That epigenetic reprogramming is the instrument of evolutionary adaptation — that an organism under stress marks its genome and so directs an advantageous change in its own sequence.

No mechanism is known by which a methyl mark steers mutation toward what an organism needs. Transgenerational epigenetic inheritance is well supported in plants and in Caenorhabditis elegans, thin and contested in mammals, and in no organism does it aim. This volume does not carry that claim and will not.

Made

That the epigenetic mark is not neutral with respect to where mutation occurs. It biases the location. The methyl writes the mutational landscape without writing the mutation.

That is quantitative, it is measured, and two of its clearest consequences are already in this volume under a different heading.

---

875. Both Currencies Are Carried on Sulfur ↩

the mark	the donor	the sulfur
methylation	S-adenosylmethionine	a sulfonium, S^+
acetylation	acetyl-CoA	a thioester, S–C(=O)

Every methyl group written onto DNA, RNA, or a histone comes off a sulfonium. Every acetyl comes off a thioester. Part Thirty-Nine established both and Part Forty-Five traced them across the amino acid panel.

The entire writing apparatus of epigenetics has two hands and both of them are sulfur.

---

876. What the Methyl Actually Does to the DNA ↩

The two deaminations, side by side

cytosine --*deamination*--> *URACIL*\n5-*methylcytosine* --*deamination*--> *THYMINE*

And the difference is everything

uracil in DNA	**foreign. It does not belong there. Uracil-DNA glycosylase finds it and cuts it out**
thymine in DNA	native. It is a normal base in a normal position

Deaminating an unmethylated cytosine produces a lesion the cell can see. Deaminating a methylated cytosine produces a base that is chemically indistinguishable from one that was supposed to be there. The methyl group converts a repairable error into an invisible one.

The mark that regulates the gene is the same chemical event that hides the damage.

---

877. The Numbers ↩

C→T at methylated CpG, versus other transitions	**10 to 50 times the rate**
share of mutations in human genetic disease at CpG substitutions	about one third
observed frequency versus chance expectation	about fifteen-fold

CpG dinucleotides are the best-characterized mutational hotspot in the human genome, and the cause is the methyl.

Two percent of the genome carries the mark, and one third of the inherited disease comes from where it sits. That is not adaptation and it is not neutrality. It is a bias, and it is large.

---

878. And the Repair That Almost Works ↩

The cell is not defenseless. Two glycosylases recognize the T:G mismatch that results.

MBD4	**the methyl-CpG binding domain glycosylase, which binds the product of deamination at methylated CpG**
TDG	thymine DNA glycosylase

Both must distinguish a thymine that is wrong from the thymines that are right, using only the mispairing with guanine as evidence — and they must do it before replication fixes the change.

The repair enzyme has to read a state, not a letter. It cannot ask what the base is; it must ask what the base is paired with. This is the volume's argument arriving in a repair pathway.

---

879. The First Worked Example — Uricase ↩

Part Ninety-Five records that the human uricase gene, UOX, is a pseudogene, disabled by a nonsense mutation in exon 2.

the lesion	**CGA → TGA**
what that is	a C→T transition at a CpG
the consequence	arginine becomes a stop codon; the protein is never finished

And the codon arithmetic Part Ninety-Five prints: CGA is the only codon in the genetic code that becomes a stop codon by mutating a CpG. The one codon that can be silenced this way, and it is the one that silenced uricase in our lineage.

---

880. The Second — Mocos, at the Other End of the Same Pathway ↩

Part Ninety-Five also records MOCOS R419X — the molybdenum cofactor sulfurase, the enzyme that installs the terminal sulfur on xanthine oxidoreductase.

the lesion	**the same CGA → TGA**
where	the enzyme that puts the sulfur into the purine pathway
the other end	uricase, the enzyme that takes urate out of it

The same chemical event, at both ends of one pathway, in the enzyme that installs the sulfur and in the enzyme that disposes of the product. Two independent disablements by one mechanism, and this volume printed them fifty pages apart without connecting them to the methyl.

---

881. And the Third Example Is This Volume's Own Color Scheme ↩

5-methylcytosine deaminating to thymine is cytosine becoming thymine.

cytosine BLUE ----> thymine YELLOW

In the shader that runs across all 886 sections, this mutation is a color change. The base goes from the carbon color to the sulfur color, and the notation writes C before and T after — two letters for what is chemically one atom's departure and one methyl's arrival.

The color scheme records the event. The four letters record only the endpoints.

---

882. Why This Is Not Lamarck, Stated in Full ↩

the claim	the status
marks respond to environment and stress	established
marks can be inherited across generations	established in plants and C. elegans; thin and contested in mammals
marks bias where mutation occurs	established, and quantified in section 877
marks direct which mutation occurs	not established. No mechanism is known
marks produce adaptive sequence change on demand	not established, and this volume refuses it

The distinction is between a landscape and a destination. Methylation tilts the surface that mutation rolls across. It does not choose where

the ball stops. Everything in this Part lives on the first side of that line and nothing on the second.

---

883. And Why Off-target Is the Same Problem in Reverse ↩

A genome editor — CRISPR-Cas9, or an ADAR-based RNA editor — is targeted by sequence. It reads letters.

But the mutational landscape is not written in letters. It is written in methyl marks, which the notation does not carry and the guide RNA cannot see. An editor aimed by sequence is aimed at the one layer that does not encode the risk.

This volume takes no position on the safety of any editing platform. It records that the targeting problem and the notation problem are the same problem: a system aimed by identity, in a genome whose behavior depends on state.

---

884. What the Notation Loses Here ↩

the molecule	what the notation writes
cytosine	C
5-methylcytosine	C
the thymine it becomes	T

Three chemically distinct states. Two letters. And the transition between the first two is the most consequential regulatory event in the vertebrate genome, while the transition between the second and third is its most common mutation.

---

885. The Experiment This Part Generates ↩

Experiment Thirty, for Part Twenty-Eight, section 65.

The question. If the methyl writes the mutational landscape, then genes whose disabling lesions are CpG transitions should be enriched for CpG sites in their coding sequence relative to matched controls — and the sulfur-pathway genes this volume tracks should be testable as a set.

Method. Take the volume's own gene set — UOX, MOCOS, XDH, MTHFR, CBS, and the rest of the sulfur panel. Count CpG dinucleotides per coding kilobase. Compare against length-matched and GC-matched controls drawn from the same genome. Then ask whether the observed disease-causing lesions in those genes fall at CpG sites more often than the gene's own CpG density predicts. Public sequence, public variant databases, no bench.

Falsification condition, written before the answer. If the sulfur-pathway genes show no CpG enrichment and their lesions fall at CpG sites no more often than density predicts, then this Part has found two coincidences rather than a pattern, and section 880 should say so.

---

886. What This Part Claims ↩

The claims

1	**Both epigenetic currencies are sulfur-borne — the sulfonium of SAM and the thioester of acetyl-CoA**
2	Cytosine deaminates to uracil, which the cell can see; 5-methylcytosine deaminates to thymine, which it cannot
3	C→T at methylated CpG runs 10 to 50 times other transitions, and about one third of human inherited-disease mutations are CpG substitutions
4	MBD4 and TDG must read a mispairing rather than a base to find the damage
5	Uricase was disabled by CGA→TGA at a CpG, and CGA is the only codon that becomes a stop by mutating one
6	MOCOS carries the same lesion at the other end of the same pathway
7	The mutation is a color change in this volume's own scheme — blue to yellow — and the notation writes only the endpoints

 · © 2026 Dr. John Allen Berger, PhD · CC BY-NC-ND 4.0

What this Part does not claim

	that epigenetic marking directs adaptive mutation. Section 882 refuses it explicitly
	that transgenerational epigenetic inheritance is established in mammals. It is contested
	that the uricase and MOCOS lesions were selected for. They are two lesions at a hotspot, and section 885 is written to test whether that is more than chance
	any position on the safety of genome editing platforms. Section 883 makes a claim about targeting layers, not about clinical risk

What would refute it

the claim	what would kill it
the deamination asymmetry	a routine glycosylase that removes thymine from DNA as efficiently as UNG removes uracil
the 10-to-50-fold rate	a recount of transition rates finding methylated CpG no faster than other sites
the two worked examples	evidence that either lesion arose by a non-deamination route
the enrichment claim of section 885	the permutation test returning null, which this Part has written the condition for in advance

And the measurement this Part would most like: the CpG density of the sulfur panel against the genome, computed once. It needs no laboratory, it takes an afternoon, and it would tell this volume whether it has found a mechanism or two anecdotes.

PART ONE HUNDRED AND FOUR · THE STEP WHERE THE CHEMISTRY IS CONVERTED

Part One Hundred and Four of the evidence volume, sections 887 to 899

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Standard RNA sequencing does not read RNA. It converts RNA into DNA with a reverse transcriptase and reads the DNA. Every modified base that the enzyme copies faithfully is written back as one of four canonical letters before any computer sees the data. A modification is therefore detectable only if it makes the enzyme fail — which means the epitranscriptome is mapped through the defects of a protein rather than read off the molecule. The field states this itself, in print, and has built the instrument that fixes it.

887. The Pipeline, and Where It Is Drawn ↩

The standard diagram

in vivo DNA gene -> pre-mRNA -> [intron splicing] -> mature mRNA\nin vitro fragmentation -> RNA fragments\n-> REVERSE TRANSCRIPTION\n-> double-stranded cDNA fragments\n-> high-throughput sequencing -> sequences\nin silico sequence processing -> alignment -> genome -> splice variants

Every published RNA-seq schematic contains that third arrow, and every one draws it as a simple conversion.

It is not a conversion. It is a translation between two chemistries, performed by an enzyme, and the target chemistry has fewer symbols than the source.

888. The Step Where the Chemistry Is Converted ↩

What reverse transcription is being asked to do

RNA carries, in the current census, well over a hundred distinct chemical modifications. DNA carries four bases and one common modification.

what enters the enzyme	**a ribonucleotide, possibly methylated, thiolated, isomerized, deaminated, or hydroxylated**
what leaves the enzyme	A, C, G or T

The alphabet is reduced at the moment of copying, by a protein, in a tube, before the sequencer is switched on.

889. The Field's Own Statement of the Problem ↩

Motorin and Helm, in Accounts of Chemical Research 57:275 to 288, December 2023, set out the limitations of modification detection by sequencing. Their statement of the mechanism is exact.

"Current Illumina RNA-Seq protocols require prior conversion of RNA into DNA. This conversion relies on reverse transcription to create cDNA... Thus, a particular behavior of RNA modified nucleotides during the RT-step is a prerequisite for their detection and quantification by deep sequencing, and RT properties have great influence on the detection efficiency and reliability."

And on the state of the resulting literature:

"While more and more different modifications were reported to occur in mRNA, conflicting reports and controversial results pointed to a number of technical and theoretical problems rooted in analytics, statistics, and reagents."

And their warning to newcomers:

"Many life scientists freshly entering the field confuse the accuracy and precision of modification mapping with that of normal sequencing, which already features numerous caveats by itself."

Their own image for the difficulty is the one this volume would have chosen:

"Rather than finding the proverbial needle in a haystack, the tasks were to determine how many needles of what color in what size of a haystack one was looking at."

---

890. What Each Modification Becomes ↩

present in the RNA	recorded in the cDNA	what is lost
inosine	G	the entire ADAR editing layer — Parts Fifty-Nine through Sixty-Eight
N6-methyladenosine	A	the most abundant internal mRNA mark

present in the RNA	recorded in the cDNA	what is lost
pseudouridine	U	the rotation. Part Seventy-Five's isomer, invisible without added chemistry
2′-O-methyl	the base alone	the sugar modification snoRNAs install
xanthosine	G or A, depending	see section 892

Inosine behaves like guanosine during reverse transcription. N6-methyladenosine is not converted and continues to be read out as adenosine. One is a substitution and the other is a silence, and neither is a measurement of what was there.

---

891. And the Error Rates Were Measured ↩

Potapov, Fu, Dai, Corrêa, Tanner and Ong, at New England Biolabs, in Nucleic Acids Research 46:5753 to 5763, June 2018, measured how modified bases affect the fidelity of RNA polymerase and reverse transcriptase using single-molecule real-time sequencing.

modification	effect
5-hydroxymethyluridine	increased the combined error rate of T7 RNA polymerase and reverse transcriptases
N6-methyladenosine	increased the combined error rate
pseudouridine	increased the error rate of RNA synthesis by T7 RNA polymerase specifically

The distortion is not hypothetical. It has been quantified, by the company that sells the enzymes.

---

892. The Enzyme Decides the Letter, Not the Molecule ↩

Part Forty-Nine, section 200, and Part One Hundred and One, section 856, already carry the finding. It belongs here too.

Mair and colleagues report that reverse transcriptases read xanthosine preferentially as G or as A, and that the ratio depends on which reverse transcriptase is used.

One molecule. Two letters. And which letter reaches the database is a property of the reagent in the tube.

---

893. Which Makes Detection a Side Effect of a Defect ↩

This is the consequence the volume takes from Motorin and Helm's sentence, and it is the sharpest statement of the problem available.

the enzyme copies the modification faithfully -> the modification is INVISIBLE\nthe enzyme stumbles on the modification -> the modification is DETECTED

A modification can only be mapped if it makes the enzyme fail. The epitranscriptome is therefore charted through the errors of a protein, and every mark that a reverse transcriptase handles cleanly is absent from the record — not because it was looked for and not found, but because looking for it this way cannot find it.

The most faithfully copied modifications are the least visible ones. The method is biased against exactly the marks that do not disturb replication, which are the marks most likely to be tolerated, conserved and functional.

---

894. The Correction the Field Has Already Built ↩

Nanopore direct RNA sequencing reads the native molecule. No reverse transcription. No amplification. No chemical intermediate.

what is sequenced	the RNA itself, single molecule, full length
how a modification is seen	it changes the ionic current through the pore
what is preserved	modifications, transcript architecture, splicing, poly(A) tails — in the same molecule

Because the method never converts the RNA, it never erases what the conversion would have erased. In principle it can detect any modification that changes the current, without a separate assay for each mark.

This volume records that the field identified the problem and built the instrument. The argument of this Part is not that anyone has been careless. It is that the installed base of transcriptome data was produced by the method that erases, and that every database built on it inherits the erasure.

---

895. The Error Is Type Two ↩

A correction the volume makes to its own author's framing.

type I	a false positive — reporting an effect that is not there
type II	a false negative — failing to detect an effect that is there

The failure described in this Part is type II. Modifications that are present are not detected, because the method that would detect them destroys them first. Calling it a false positive understates it: a false positive can be caught by replication, and a systematic false negative cannot, because every replicate uses the same enzyme.

---

896. What This Part Refuses to Claim ↩

The temptation here is to extend the argument to drug development, and it does not reach.

the claim	the status
RT conversion erases modifications from the record	established, and cited above
the resulting databases are blind to the epitranscriptome	follows directly
this is why no drug is free	refused

the claim	the status
of side effects	

Side effects arise from target promiscuity, off-target binding, metabolite toxicity, and the expression of intended targets in unintended tissues. A complete epitranscriptome map would not produce a side-effect-free drug, and no argument in this volume supports that it would. The sequencing claim stands entirely on its own and is weakened by being attached to a claim it cannot carry.

---

897. What the Notation Loses Here ↩

Part One Hundred and Three, section 884, made this point about three states and two letters. This Part makes it about an industry.

the molecule that existed	one of over a hundred chemical species
the letter in the database	one of four
the step between them	an enzyme, chosen by the laboratory

Every alignment, every splice variant call, every miRNA target prediction and every differential expression analysis in the RT-derived literature operates on the reduced alphabet, and no downstream method can recover what the reduction removed.

---

898. The Experiment This Part Generates ↩

Experiment Thirty-one, for Part Twenty-Eight, section 65.

The question. How much of a real transcriptome is invisible to the standard method — not in principle, but in count?

Method. Take one tissue. Sequence it twice: once by standard Illumina RNA-seq with reverse transcription, once by nanopore direct RNA sequencing on the native molecule. Align both to the same reference. Then count the positions at which the direct method reports a modification and the RT method reports a canonical base

with no anomaly. Report that count as a fraction of transcript positions, and separately for each modification class.

Falsification condition, written before the answer. If the two methods agree at essentially every position, and the direct method finds no modifications the RT method missed, then reverse transcription is not erasing anything at detectable frequency, this Part has overstated a theoretical concern, and section 893 should be withdrawn. Commercial platforms, one tissue sample, no novel reagents. Comparisons of this kind have been published for individual modifications; this volume has not found one that reports the total invisible fraction as a single number.

899. What This Part Claims ↩

The claims

1	**Standard RNA-seq converts RNA to cDNA before reading, and the conversion reduces a hundred-plus symbol alphabet to four**
2	Detection of a modification requires it to perturb the reverse transcriptase — the field's own statement of the prerequisite
3	Inosine is read as G; N6-methyladenosine is read as A — a substitution and a silence
4	The distortion has been measured: 5-hydroxymethyluridine and m6A raise the combined polymerase and RT error rate
5	Xanthosine is read as G or as A depending on which reverse transcriptase is used
6	Therefore the epitranscriptome is charted through the failures of a protein, and faithfully copied marks are systematically invisible
7	Nanopore direct RNA sequencing removes the conversion step and preserves the modifications
8	The failure is type II, not type I

What this Part does not claim

	that the field is unaware. Sections 889 and 894 show it identified the problem and built the fix
	that RT-based sequencing is invalid for its designed purpose. Alignment, expression and splicing analysis work; the modification layer is what is absent
	that this explains drug side effects. Section 896 refuses it explicitly

	that the field is unaware. Sections 889 and 894 show it identified the problem and built the fix
	that nanopore sequencing is free of error. It has its own basecalling and benchmarking problems, actively worked on

What would refute it

the claim	what would kill it
RT erases modifications	a demonstration that standard cDNA retains modification information recoverable downstream
detection requires disturbance	a modification routinely mapped by Illumina RNA-seq that does not alter RT behavior in any way
the invisible fraction is material	Experiment Thirty-one returning near-total agreement between the two methods

And the measurement this Part would most like is the one nobody appears to have published as a single number: what percentage of the modified positions in one real transcriptome are absent from its own RT-derived sequence. Until that number exists, the size of the haystack is unknown — which is the point Motorin and Helm were making.

PART ONE HUNDRED AND FIVE · THE MAP HAS NO THIRD DIMENSION

Part One Hundred and Five of the evidence volume, sections 900 to 912

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Every metabolic map in common use records what connects to what and nothing else. There are no coordinates, no volume, no distance. A three-dimensional, spatially resolved, fully dynamic whole-cell model does exist and has been built — for a minimal bacterium whose genome was reduced until it could no longer make a nucleotide at all. The one cell that has been modeled in three dimensions is the one cell that deleted the pathway this volume is about. And gravity, which the question naturally reaches for, moves nothing inside a cell — the number is five hundred thousand to one against it.

900. What a Metabolic Map Actually Records ↩

The maps this volume has annotated

Michal's atlas, KEGG, Reactome — Part Ninety-Eight and Part Ninety-Nine were written from pages of the first of these.

what they encode	what they do not
topology — which metabolite feeds which reaction	position
the enzymes at each step	distance
the cofactors consumed	volume
stoichiometry	concentration

Move any node anywhere on the sheet and the map means exactly the same thing. The x and y of a printed pathway chart are page layout. They carry no information. A reader who colors such a map, as this volume has, is coloring a graph, not a space.

And the genome-scale models are no different in this respect

Recon3D, Human-GEM and the rest are stoichiometric matrices. Flux balance analysis returns rates through reactions with no geometry at all.

The three in Recon3D refers to the inclusion of protein structures, not to spatial metabolism. The metabolism in it is as flat as the wall chart.

---

901. The Question This Part Answers ↩

Does a three-dimensional metabolic map exist — one with depth, in which the position of a molecule is part of the data rather than part of the drawing?

Yes. It has been built, it is published, and the code is public. And it is not applicable to this volume, for a reason worth the whole Part.

---

902. The Model That Exists ↩

JCVI-syn3A. A synthetic minimal bacterium with a reduced genome of 493 genes.

the model contains	
metabolites	148
proteins and mRNAs	452
transfer RNAs	29
ribosomes	503, tracked individually
reactions	over 7,000, with kinetics
the geometry	from cryo-electron tomography — real cell shape and real ribosome positions
the method	reaction-diffusion master equations, coupled to chemical master equations, coupled to ordinary differential equations

A four-dimensional version now runs the entire 105-minute cell cycle — expression of all 493 genes, the whole metabolic network, ribosome biogenesis, chromosome dynamics, DNA replication, and the morphological change through division.

That is a metabolic map with depth, volume, diffusion and time. The thing does exist. It is simply not in the literature this volume has been reading, because it lives in computational biophysics rather than in pathway biology, and it produces a simulation rather than a chart.

---

903. And Why It Cannot Be Applied Here ↩

Syn3A is a Mycoplasma

And mycoplasmas cannot make nucleotides.

"Mycoplasmas are unable to synthesize purine and pyrimidine bases de novo. Therefore, salvage of existing nucleosides and bases is essential for their survival."

In the genomes of Mycoplasma genitalium, M. pneumoniae, Ureaplasma urealyticum and M. pulmonis, no genes for the de novo biosynthesis of purines or pyrimidines were found. They are salvage-only, and they take their nucleotides from a host.

What that removes

the subject of this volume	present in syn3A
PRPP as the fork — Part Ninety-Seven	no
IMP as the hub — the purine square of Part Eighty-One	no
XMP, the xanthine gate to guanine	no
orotate and OMP, the gate to uracil	no
dihydroorotate dehydrogenase wired into respiration — Part Thirty-Seven	no, and no respiratory chain either

The two gatekeepers this volume is built on do not exist in the only cell that has been modeled in three dimensions. The most complete spatial model of metabolism ever constructed is of an organism chosen for being simple enough to model — and for a mycoplasma, simple means it threw away nucleotide synthesis.

904. The Scale Gap, Measured ↩

syn3A, diameter 0.4 µm	volume 0.034 µm³
a human cell, diameter 15 µm	volume 1,767 µm³
ratio	about 52,700 to one
genes	493 against roughly 20,000 — about 41 to one

905. But Compartmentation Is the Gap That Matters ↩

Syn3A has geometry and almost no compartments. It is one bag inside one membrane.

syn3A	one compartment
a human cell	cytosol · nucleus · mitochondrial matrix · intermembrane space · ER lumen · Golgi · lysosome · peroxisome

And nucleotide pools are compartment-specific in exactly the way that matters

The mitochondrion runs its own deoxynucleotide pool with its own salvage enzymes — thymidine kinase 2 and deoxyguanosine kinase — separate from the cytosolic pool.

The mitochondrial DNA depletion syndromes are what happens when that separate pool fails. A one-compartment model cannot represent a metabolite that exists at one concentration in the cytosol and another in the matrix, with a transporter setting the ratio. That is not a detail. It is the disease.

---

906. Gravity Does Nothing, and Here Is the Number ↩

The intuition that a three-dimensional map would show gravity acting on metabolite pools is natural and it is wrong. Computed at body temperature, the height each species would have to be raised for its gravitational potential energy to equal one unit of thermal energy kT:

species	height
water	14 kilometers
glucose	1.5 kilometers
ATP	518 meters
a 50 kDa enzyme	5.3 meters
a ribosome	10 centimeters
a mitochondrion	0.26 micrometers

A cell is about ten micrometers across.

Across the whole width of a cell, thermal motion beats gravity by roughly five hundred thousand to one for a mid-sized protein. This is why bacteria do not sediment and why organelles do not fall. Gravity is the one force in the question that can be dismissed by arithmetic.

Only at the scale of a whole organelle does the ratio begin to close, and even there it does not close far enough to matter over a cell's lifetime.

907. What Does Dominate Instead ↩

diffusion	the actual transport mechanism at this scale
macromolecular crowding	changes effective diffusion by orders of magnitude
compartment boundaries	membranes and their transporters, which set concentration ratios
water	the medium, and the reactant in every hydrolysis

These are precisely the four things the syn3A model computes, and precisely the four things a flat pathway chart cannot express.

908. And the Sensing the Question Was Reaching for ↩

The question asked whether a three-dimensional model could tell an organelle when there was too much or too little of a precursor.

That is allosteric regulation, and it operates on concentration — amount per volume. Concentration is a spatial quantity. A map without volume cannot express it, and a model with volume must.

And this volume already documented the cell doing it

Part Ninety-Eight established that the DNA damage checkpoint fires on nucleotide pool depletion with no lesion present. The 2025 iScience result: inhibit IMPDH, lose nascent dNTP incorporation, and the cell mounts a full damage response with ATR as the principal sensor.

The cell reads a concentration, not a sequence. Section 813 of this volume named the two quantities it actually measures — how much dNTP is left in the pool, and how much protein-coated single-stranded DNA is present at a fork. Neither is a letter. Both are spatial.

The sensing described in the question is real, it is documented, and it is documented in this volume. What is missing is the model that could predict it.

909. The State of the Field, Stated Plainly ↩

flat topological maps of human metabolism	many, and excellent for what they do
genome-scale stoichiometric models of human metabolism	several, and no geometry
spatially resolved whole-cell models	one organism, and it is a nucleotide auxotroph
a compartment-resolved three-dimensional whole-cell metabolic model of a human cell	none found

The syn3A work is the proof that the method exists. It is not a proof that the method scales. The open question is whether cryo-electron tomography geometry coupled to reaction-diffusion master equations can be carried to a compartmented eukaryote fifty thousand times the volume, and at what computational cost.

910. What This Part Does Not Claim ↩

	that flat maps are wrong. They record topology correctly and this volume has used them throughout
	that nobody has done three-dimensional metabolic modeling. Section 902 records that it has been done, well, and published
	that gravity has no biological role. It has one at the organism scale — bone loading, vestibular function, fluid distribution — and none at the molecular scale, which is the scale of the question
	that a spatial model would predict disease. It would predict concentrations. What concentrations mean clinically is a separate problem

911. The Experiment This Part Generates ↩

Experiment Thirty-two, for Part Twenty-Eight, section 65.

The question. What does the syn3A approach cost when carried to a compartmented cell that actually makes its own nucleotides?

Method. Take the smallest eukaryote with a complete de novo purine and pyrimidine pathway — Saccharomyces cerevisiae is the obvious candidate — and scope a spatially resolved model of nucleotide metabolism alone, not the whole cell. Four compartments: cytosol, nucleus, mitochondrial matrix, and the membrane transporters between them. Geometry from published cryo-electron tomography. Pool concentrations from published metabolomics. Then report the computational cost as a function of compartment count and volume, and compare against the published syn3A figures.

Falsification condition, written before the answer. If the cost scales such that a four-compartment eukaryotic nucleotide model is tractable on existing hardware, then the absence of such a model is a matter of nobody having done it, and this Part's framing of an open problem is too generous. If the cost is prohibitive, the barrier is computational rather than conceptual and should be stated as such. Either answer is worth having, and neither requires a laboratory.

912. What This Part Claims ↩

The claims

1	**Standard metabolic maps encode topology only. Position on the page carries no information**
2	Genome-scale stoichiometric models have no geometry either
3	A three-dimensional, spatially resolved, fully dynamic whole-cell model exists — JCVI-syn3A, with geometry from cryo-electron tomography, now extended to four dimensions across a full cell cycle
4	Mycoplasmas cannot synthesize purines or pyrimidines de novo. No de novo genes were found in the sequenced genomes of four species
5	Therefore PRPP, IMP, XMP and orotate are all absent from the model — the entire subject of this volume
6	A human cell is about 52,700 times the volume of syn3A and

1	Standard metabolic maps encode topology only. Position on the page carries no information
	has at least eight compartments to its one
7	Mitochondrial deoxynucleotide pools are separate from cytosolic ones, with their own salvage enzymes, and their failure is a named disease class
8	Gravity is negligible at molecular scale — thermal motion exceeds it by about five hundred thousand to one for a mid-sized protein across a cell's width
9	What dominates is diffusion, crowding, compartment boundaries and water
10	No compartment-resolved three-dimensional whole-cell metabolic model of a human cell was found

What would refute it

the claim	what would kill it
mycoplasmas lack de novo nucleotide synthesis	identification of the de novo genes in a sequenced mycoplasma genome
the gravity arithmetic	a recomputation giving a different ratio, which would require different values of kT or g
no human spatial whole-cell metabolic model exists	the publication of one, which this volume would welcome and would cite
compartmentation is the decisive gap	a demonstration that single-compartment models reproduce compartment-specific pool measurements

And the observation this Part exists to record: the question was asked by someone reading flat maps, and answering it honestly required finding that the three-dimensional work has been done on the one organism to which this volume's subject does not apply. That is not a gap in the literature. It is a gap between two literatures, and naming it is worth more than filling it badly.

PART ONE HUNDRED AND SIX · THE ATOM THAT HOLDS THE CHARGE

Part One Hundred and Six of the evidence volume, sections 913 to 925

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

This volume undercounted magnesium. The correction is printed here rather than absorbed quietly. Magnesium sits at the center of the molecule that captures light and inside the molecule that spends it — the true substrate of every ATP-consuming enzyme is not ATP but magnesium-ATP. The figure of three hundred magnesium-

dependent enzymes, repeated for forty-five years, is an estimate from 1980 and the databases now list more than six hundred. And the reaction that hydrates magnesium silicate releases enough heat to sustain a hydrothermal field with no volcano beneath it. None of this is sulfur, and this volume is better for saying so.

913. The Correction This Part Exists to Make ↩

The volume's seven-color scheme names seven atoms and magnesium is not among them. That was correct as a statement about the nucleotide, in which magnesium is not covalently present. It was wrong as a statement about what a nucleotide requires in order to do anything.

Magnesium is not in RNA. Nothing in RNA works without it.

This Part places magnesium where the evidence puts it and states, in the same breath, that placing it there weakens no claim this volume has made about sulfur.

914. The Number That Was Written Down Once ↩

The figure everyone cites

about 300 magnesium-dependent enzymes	Theodor Günther, 1980 — offered as a rough estimate

It entered the textbooks. It entered the reviews. It is on supplement labels and in clinical handbooks and it is still being repeated.

The figure the databases actually hold

de Baaij, Hoenderop and Bindels, Physiological Reviews 95:1 to 46, 2015:

enzymes for which Mg^{2+} serves as cofactor	more than 600
enzymes in which Mg^{2+} may act as activator	a further 200

Their own assessment of the older figure is that it was an underestimation, because many magnesium-dependent enzymes have been described in the decades since 1980.

A rough estimate was written down once, was copied forward for forty-five years, and became a fact by repetition while the count it summarized more than doubled. This volume's argument is that a system of record can carry a symbol forward without carrying the thing forward. Here is the same failure in a citation chain rather than in a genetic code.

Both numbers belong in print, each with its date. The correction is worth more than the count.

---

915. The Substrate Is Not ATP ↩

What enzymes actually bind

Most intracellular ATP is complexed with magnesium. The species that enzymes bind, that drives active transport, and that powers muscular contraction is not the free nucleotide.

$$ATP^{4-} + Mg^{2+} \rightarrow MgATP^{2-} \backslash n \text{the actual substrate}$$

The energy currency of the cell is a magnesium salt. Every diagram in this volume that writes ATP has written a shorthand, and the shorthand omits the atom without which the molecule is not the substrate of anything.

This is the volume's own thesis arriving at its own diagrams. A notation wrote the letters and lost the metal.

And the same is true of the machinery

ATP synthase	requires Mg^{2+}; the bound nucleotide is the magnesium complex
every kinase	transfers a phosphate from MgATP, not from ATP
every ribozyme	requires divalent metal, and in the cell that metal is magnesium
the ribosome	a magnesium-stabilized structure; its folding does not survive

ATP synthase	requires Mg^{2+}; the bound nucleotide is the magnesium complex
	magnesium removal

916. The Atom at the Center of the Light ↩

Chlorophyll is a chlorin ring with a single magnesium ion held at its center. The molecule that captures sunlight for the whole biosphere is built around one magnesium atom.

Magnesium sits at the center of the molecule that takes the light in, and inside the molecule that pays the light out. Capture and expenditure, the same element at the middle of both.

A precision the volume owes its own color scheme: chlorophyll is green because it reflects green and absorbs red and blue. The association of magnesium with white light is conceptual — the additive whole — and not a statement about the absorption spectrum of chlorophyll.

917. The Heat That Is Not a Volcano ↩

Serpentinization

Olivine is $(Mg,Fe)_2SiO_4$ — magnesium iron silicate, and one of the most abundant minerals in the Earth's upper mantle. When seawater reaches it:

$$olivine + water \rightarrow serpentine + magnetite + H_2 + HEAT$$

the products	
hydrogen gas	the reductant
strongly alkaline fluid	the pH gradient
heat	the reaction is exothermic
mineral surfaces	the catalysts

The reaction is exothermic and, once initiated, may heat the fluid enough to allow serpentinization to continue in the absence of any external heat source. This is a rock that warms itself by getting wet.

918. And the Field That Proves It ↩

Lost City

discovered	4 December 2000
where	the Atlantis Massif, near the Mid-Atlantic Ridge
depth	about 900 meters
the structures	carbonate towers up to 60 meters above the seafloor
fluid temperature	roughly 40 to 77 °C
what vents	hydrogen, methane and low-molecular-weight hydrocarbons
the power source	serpentinization alone — no active magmatism

Unlike the black smokers, Lost City is not driven by magma. It is driven by the hydration of a magnesium mineral. The heat, the hydrogen, the alkalinity and the mineral catalysts all come out of one reaction, and a microbial community lives on them.

This is why serpentinization is now argued as a source of energy, electrons, organics, catalysts, nutrients and pH gradients for the origin of life and for the last universal common ancestor.

919. And the Pacific ↩

The Atlantic field is the famous one. The Pacific has its own, and they are larger.

the Mariana forearc	sixteen large active serpentinite mud volcanoes
diameters	up to 50 kilometers
heights	up to 2 kilometers
South Chamorro Seamount	about 78 kilometers from the trench; drilled at ODP Hole 1200C
further drilling	IODP Expedition 366 — Yinazao, Fantangisña and Asùt Tesoru

Slab-derived fluids from the dehydrating subducted Pacific plate serpentinize the forearc mantle, and the resulting mud rises along faults and extrudes onto the seafloor.

The 2018 Philosophical Transactions of the Royal Society A paper on this system is titled for the implication directly: Mariana serpentinite mud volcanism exhumes subducted seamount materials, with implications for the origin of life.

The intuition that produced this Part placed the chemistry in the Pacific, between the volcanoes and the deepest trench. The famous field is Atlantic and shallow. The Pacific systems are real, they are enormous, they sit on the Mariana forearc beside the trench, and the origin-of-life literature on them is current.

---

920. What Each Atom Can and Cannot Do ↩

The comparison this Part is obliged to make, because a reader who has just been given the figure of eight hundred enzymes will ask why this is not a magnesium volume.

	magnesium	sulfur
how it takes part	coordinated — held and released, never bonded	covalently incorporated
the count	about 800 enzymatic relationships	fewer
what it does	shields negative charge · coordinates phosphate · stabilizes the transition state · holds the fold	methyl transfer · acyl transfer · electron routing · structural bridging · radical generation
the variety	essentially one job, performed everywhere	several distinct chemistries

Magnesium is required in more places. Sulfur does more different things. Eight hundred enzymes need magnesium in order to hold a negative charge steady so that chemistry can happen upon it. No enzyme requires magnesium in order to donate a methyl group, because magnesium cannot donate one.

Neither statement diminishes the other. They are different claims about different kinds of participation, and a volume that made only the first would be as incomplete as one that made only the second.

921. Why This Volume Is Not a Sulfur-only Volume ↩

The instruction that produced this Part is recorded in the author's own terms: focus on sulfur, but not to the detriment of the other atomic elements, cofactors, coenzymes and partners.

where the answer is not sulfur	what it is
folding RNA and running every ribozyme	magnesium
the first long oligomers	montmorillonite clay — no sulfur at any step
the backbone and the energy bond	phosphorus
every hydrogen bond in every base pair	nitrogen and oxygen
capturing sunlight	magnesium, at the center of chlorophyll
the heat at Lost City	magnesium silicate hydration

The claim of this volume was never that sulfur is primary. It is that sulfur is the element the notation loses. That claim survives magnesium entirely, and it is strengthened by a volume willing to name the places where sulfur is not the answer.

922. The Band ↩

The volume's scheme assigns seven colors to seven atoms that are covalently present in the nucleotide. Magnesium is not one of them and will not be given a hue.

band		
WHITE	magnesium	the additive limit. Light captured and energy held — chlorophyll, MgATP, the wholeness that everything

band		
		else stands on
ULTRAVIOLET	—	light that breaks. Sulfite photolysis, the hydrated electron, the bond destroyed
BLACK	—	the subtractive limit. Absence
gray, bordered	Fe · Mo · Ni · Zn · Mn · Co	coordinated, not bonded — the trace metal centers

Two kinds of light and one absence. Ultraviolet takes apart; white holds together; black is what is not there. Magnesium is removed from the trace-metal register because it is not a trace metal — it is the most abundant divalent cation in the cell and the one condition every phosphate transaction depends on.

923. What This Part Refuses ↩

the claim	the status
serpentinization produces heat, hydrogen, alkalinity and catalysts	established, and cited
magnesium therefore caused the origin of life	refused
MgATP is the substrate of ATP-dependent enzymes	established
magnesium is therefore the true energy currency and ATP a misnomer	refused. The bond that stores the energy is the phosphoanhydride. Magnesium makes it usable; it does not make it
the 300 figure is outdated	established by the 2015 review's own statement
therefore the older literature citing 300 is unreliable	refused. It is dated, not wrong, and it was labeled an estimate when it was made
magnesium is the conductor rather than sulfur	not adjudicated here. Section 920 gives both counts and both kinds of participation and leaves the reader to weigh them

924. The Experiment This Part Generates ↩

Experiment Thirty-three, for Part Twenty-Eight, section 65.

The question. How many of the volume's sulfur reactions also require magnesium — and is the overlap larger than either atom's advocates would guess?

Method. Take the volume's own sulfur enzyme panel — the methyltransferases running on SAM, the acyl transferases running on CoA, ribonucleotide reductase, MOCOS, the sulfite oxidase family, the cysteine desulfurases. For each, retrieve the cofactor annotation from the enzyme databases and record whether Mg^{2+} or another divalent cation is required. Then compute the fraction of the sulfur panel that cannot operate without magnesium. Public databases, no bench, one afternoon.

Falsification condition, written before the answer. If the overlap is small — if most sulfur-dependent chemistry runs without a magnesium requirement — then the two atoms occupy genuinely separate systems and section 920's framing of complementary roles is too generous. If the overlap is large, then the volume's sulfur reactions are magnesium reactions as well, and every mechanism in this book has a second required atom that the book has not been naming.

The second outcome would be the more interesting one and the more embarrassing, and it is written here in advance so that it cannot be quietly declined.

---

925. What This Part Claims ↩

The claims

1	**The figure of about 300 magnesium-dependent enzymes is Günther's 1980 estimate, still widely repeated**
2	Enzymatic databases now list more than 600 enzymes for which Mg^{2+} is a cofactor, and about 200 more where it acts as activator — de Baaij, Hoenderop and Bindels, 2015
3	$MgATP^{2-}$, not ATP, is the species enzymes bind
4	Chlorophyll holds a single magnesium at the center of its ring
5	Serpentinization of olivine — a magnesium iron silicate — is exothermic and can sustain itself without an external heat source
6	Lost City is powered by serpentinization alone, with no active magmatism, at about 900 meters on the Atlantis Massif, discovered in December 2000

1	**The figure of about 300 magnesium-dependent enzymes is Günther's 1980 estimate, still widely repeated**
7	The Mariana forearc carries sixteen large active serpentinite mud volcanoes, up to 50 km across and 2 km high, drilled at ODP Hole 1200C and on IODP Expedition 366
8	Magnesium is required in more reactions; sulfur performs more distinct chemistries
9	Magnesium takes the white band — captured light and held energy — and is removed from the trace-metal register

What would refute it

the claim	what would kill it
the enzyme count	a database audit returning a figure near 300 rather than above 600
MgATP as the bound species	a demonstration that free ATP^{4-} is the physiological substrate of the major kinases
serpentinization is self-sustaining	a thermal budget showing the reaction cannot maintain the observed fluid temperatures without magmatic input
the complementarity of section 920	Experiment Thirty-three returning a large overlap, which would mean this volume has been describing magnesium reactions and calling them sulfur reactions

And the admission this Part exists to record: the author of this volume changed his mind about magnesium after learning more about it, and instructed that the change be printed. A volume that could not survive the promotion of a second atom would not have been worth writing. This one survives it, and is more honest at 938 sections than it was at 925.

PART ONE HUNDRED AND SEVEN · THE CARRIER IS ALWAYS ADENOSINE

Part One Hundred and Seven of the evidence volume, sections 926 to 938

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Experiment Thirty-three was written in the previous Part and partly run before this one. The result does not divide along the line anyone expected. Magnesium is not required by sulfur chemistry in general — the redox enzymes and the pyridoxal enzymes do without it entirely. It is required wherever sulfur is attached to an adenosine. And every sulfur currency in this volume is an adenosine conjugate. The

methyl donor, the acyl carrier and the sulfate donor are all built by bolting a sulfur atom onto a nucleotide, and every such bolting runs on magnesium-ATP. Two of the enzymes carry magnesium in their formal names.

---

926. The Question, and Why It Was Asked ↩

Section 924 of the preceding Part set the condition. If most of this volume's sulfur chemistry also requires magnesium, then the book has been describing magnesium reactions and calling them sulfur reactions.

The author's stated intuition was that sulfur and magnesium are intertwined at the deepest levels. This Part records what was found when that intuition was checked, including the part that costs the volume something.

---

927. The Enzyme That Makes the Sulfonium ↩

Methionine adenosyltransferase

S-adenosylmethionine is the volume's central sulfur currency. Part Thirty-Nine established it, Part Forty-Five traced it, and Part One Hundred and Three found both epigenetic marks hanging off it.

the reaction	**methionine + ATP → SAM + phosphate + pyrophosphate**
the requirement	dependent on the presence of K^+ and Mg^{2+}

The sulfonium at the center of this volume cannot be assembled without magnesium. Every methyl group written onto a cytosine, an adenosine or a histone in this book comes off a molecule that a magnesium-dependent enzyme built.

---

928. And the Two Enzymes with Magnesium in Their Names ↩

Sulfate activation

Inorganic sulfate is unreactive. To be used it must be adenylylated, and that takes two enzymes and two molecules of ATP.

enzyme	its systematic name
ATP sulfurylase	MgATP : sulfate adenylyltransferase
APS kinase	MgATP : APS 3′-phosphotransferase

sulfate --ATP sulfurylase--> APS --APS kinase--> PAPS\nthe universal sulfate donor

These are not annotations. They are the formal enzyme names, and magnesium is inside both of them. The route from inorganic sulfate to the universal sulfate donor is named for magnesium at every step it has.

In metazoans the two activities sit on one bifunctional polypeptide, the PAPS synthase.

---

929. The Complication, Which Is the Interesting Part ↩

The relationship is not monotonic. The kinetic literature reports that ATP sulfurylase requires MgATP as its substrate while free Mg^{2+} inhibits the activity.

form	effect
Mg^{2+} bound to ATP	required — it is the substrate
free Mg^{2+}	inhibitory

More magnesium does not mean more sulfur chemistry. There is an optimum, and the cell sits on it. That is the signature of a regulated relationship rather than an incidental cofactor dependency, and it is a better argument for interweaving than a simple requirement would have been.

---

930. The Third Currency ↩

Coenzyme A

Coenzyme A is assembled from pantothenate in five enzymatic steps, and cysteine — the sulfur — is added at the second.

step	enzyme	
1	pantothenate kinase	phosphorylation, ATP
2	phosphopantothenoylcysteine synthetase	the cysteine is added here
3	phosphopantothenoylcysteine decarboxylase	
4	phosphopantetheine adenylyltransferase	the adenosine is added here, from ATP
5	dephospho-CoA kinase	phosphorylation, ATP

Three of the five steps consume ATP, and one of them is the step that attaches the adenosine. Kinases and adenylyltransferases act on MgATP rather than on free ATP — which this volume states as an inference from the general case in section 915, not as a measurement made on these particular enzymes. The specific determination is one of the things Experiment Thirty-three still has to do.

---

931. And the Negative Controls, Which Are What Make This a Finding ↩

If magnesium were required by everything, the observation would be worthless. It is not.

sulfur enzyme	what it requires	magnesium
cystathionine β-synthase	heme and pyridoxal phosphate — the only known PLP enzyme that also carries heme b	no
sulfite oxidase	the molybdenum cofactor, and a heme	no
cysteine desulfurase	pyridoxal phosphate	no

The enzymes that perform redox chemistry on sulfur, and the enzymes that perform pyridoxal chemistry on sulfur, do their work without magnesium. The dependence is not general. It has a shape.

---

932. The Shape ↩

The rule the data suggest

Magnesium is required wherever sulfur is attached to a nucleotide. Where sulfur does redox or pyridoxal chemistry, magnesium is absent.

nucleotide conjugation	magnesium required
redox and PLP chemistry	magnesium absent

The division is not between sulfur and magnesium. It runs through the middle of sulfur biochemistry, and it separates the making of the carriers from the work the carriers do.

---

933. And the Observation This Part Exists for ↩

Every sulfur currency in this volume is an adenosine conjugate

the currency	what it is	the sulfur
S-adenosylmethionine	adenosine + methionine	the sulfonium
coenzyme A	adenosine + pantetheine + cysteine	the thiol, which becomes the thioester
PAPS	adenosine + sulfate	the sulfate

Sulfur does not travel through the cell as sulfur. It travels bolted to an adenosine. The methyl donor, the acyl carrier and the sulfate donor are three nucleotides carrying three different sulfur species, and the bolting is done by magnesium.

This is the deepest level the intuition was reaching for, and it is stronger than expected:

sulfur *--needs a carrier-->* *ADENOSINE* *--needs magnesium-->* *the bond is made*

Which lands inside this volume's own subject

This book is about what a four-letter notation loses. It has argued that the notation records identity and not modification, rotation, absence or orientation.

Here the notation loses something else. SAM, CoA and PAPS are adenosine derivatives — they are nucleotides — and none of them appears in any nucleotide notation anywhere. The letter A covers adenine. It does not cover the three molecules that carry every methyl, every acyl and every sulfate in the cell, all of which are built on it.

934. What This Costs the Volume ↩

Stated plainly, because section 924 committed to stating it.

where this volume says sulfur and means a currency being made	it should say sulfur and magnesium
where this volume says sulfur and means redox or PLP chemistry	it was right as written

The revision is real and it is not a footnote. It does not sink the argument, because a notation that loses sulfur also loses magnesium, and a finding that the two are inseparable makes the indictment broader rather than narrower. But the volume was imprecise in a way that mattered, and the imprecision is now on the record with its correction beside it.

935. And the Same Pairing, in the Rock ↩

Part One Hundred and Six established that Lost City is powered by the hydration of a magnesium mineral rather than by magma. What lives on it completes the pattern.

The hydrogen and the deeply-sourced formate produced by serpentinization fuel sulfate-reducing bacteria in the Lost City chimneys.

the energy source	serpentinization of a magnesium silicate
the metabolism it feeds	sulfate reduction
the sunlight involved	none
the volcano involved	none

Magnesium chemistry powering sulfur chemistry, in the dark, in the rock, with no biology required to start it.

936. And in the Salt ↩

Magnesium sulfate is one compound containing both atoms. It is the salt sold as Epsom salt, and it is the form in which most people encounter either element knowingly.

This volume notes it as a curiosity rather than as evidence. Two atoms sharing a crystal is not a biochemical relationship, and nothing in this Part rests on it.

937. What This Part Refuses ↩

the claim	the status
MAT requires K^+ and Mg^{2+}	established
ATP sulfurylase and APS kinase are formally named as MgATP enzymes	established
CBS and sulfite oxidase do not require magnesium	established
the CoA pathway's kinases require magnesium	inferred from the general case, not measured here. Section 930 says so
magnesium is therefore as important to this volume as sulfur	refused. Section 932 shows the dependence is partial and structured; a claim of equal standing would erase the structure that makes the finding interesting

the claim	the status
the Epsom salt observation is evidence	refused in section 936
sulfur and magnesium co-evolved as a functional pair	not established. The pattern reported here is a present-day biochemical one. Nothing in this Part is a historical claim

938. What This Part Claims ↩

The claims

1	**Methionine adenosyltransferase makes SAM in a reaction dependent on K^+ and Mg^{2+}**
2	ATP sulfurylase is systematically named MgATP : sulfate adenylyltransferase
3	APS kinase is systematically named MgATP : APS 3′-phosphotransferase
4	Free Mg^{2+} inhibits ATP sulfurylase while MgATP is its substrate — the relationship has an optimum
5	Coenzyme A biosynthesis is five steps, three of them ATP-consuming, with cysteine added at step two and adenosine at step four
6	Cystathionine β-synthase requires heme and pyridoxal phosphate, and sulfite oxidase requires the molybdenum cofactor — neither requires magnesium
7	Therefore the dependence is structured: magnesium where sulfur is joined to a nucleotide, absent where sulfur does redox or PLP chemistry
8	All three sulfur currencies — SAM, CoA and PAPS — are adenosine conjugates, and none appears in any nucleotide notation
9	Serpentinization-derived hydrogen and formate fuel sulfate reducers at Lost City — magnesium-driven geology feeding sulfur metabolism

What would refute it

the claim	what would kill it
the structured dependence	a magnesium requirement demonstrated for cystathionine β-synthase or sulfite oxidase, which would make the dependence general and the pattern meaningless
the adenosine rule	a sulfur carrier in central metabolism that is not a nucleotide conjugate and is nonetheless magnesium-dependent
the MAT requirement	a demonstration of SAM synthesis at physiological rates with magnesium removed

the claim	what would kill it
the inference of section 930	a direct determination that the CoA kinases act on free ATP rather than MgATP

And the note this Part ends on. The finding was produced by an intuition that could not have been derived from the volume as written, and it was checked because the condition for checking it had been written down in advance. Neither half would have been sufficient. The hunch found the vein; the falsification condition determined whether there was anything in it. This volume has argued throughout that the record must carry what the notation drops. The record now carries the occasion on which the author's own framework was found to be incomplete, and the correction is printed in the same book as the claim it corrects.

PART ONE HUNDRED AND EIGHT · SPEED OR RECORD

Part One Hundred and Eight of the evidence volume, sections 939 to 949

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Artificial intelligence has raised the success rate of Phase I trials from roughly half to roughly nine in ten, and has not moved Phase II at all. Phase I is chemistry and Phase II is biology. That single split is the sharpest published test of what this volume argues, and it is a test the volume did not design. The field's own diagnosis of its bottleneck is speed, and its proposed remedies are faster sites, faster approvals and lighter preclinical requirements. This volume's diagnosis is representation, and its remedy is to record what the current methods discard. The two diagnoses imply opposite actions, and this Part sets out what would decide between them — including the condition under which this volume is the one that is wrong.

---

939. The Two Diagnoses ↩

	the field's diagnosis	this volume's diagnosis
the bottleneck	the process is too slow	the representation is too poor
the remedy	move faster — better trial infrastructure, quicker approvals, lighter preclinical requirements	record more — read the molecule rather than its transcription
if it is right	acceleration helps	acceleration produces wrong answers sooner

These are not two versions of the same complaint. They prescribe opposite actions, and only one of them can be the principal explanation.

---

940. The Number That Separates Them ↩

Jayatunga, Ayers, Bruens, Jayanth and Meier, Drug Discovery Today 29(6), 2024 — the first systematic analysis of how AI-discovered drugs perform in the clinic.

	AI-discovered molecules	historical industry average
Phase I success	80 to 90 percent	40 to 65 percent
Phase II success	about 40 percent	about 40 percent

The improvement is large, real, and confined entirely to the first phase. In the second phase the advantage vanishes.

---

941. What Each Phase Actually Measures ↩

Phase I	safety and tolerability in healthy volunteers. Does the molecule behave as a molecule — absorption, distribution, metabolism, excretion, toxicity
Phase II	efficacy in patients with the disease. Does the target matter, and does hitting it change the illness

Phase I is a chemistry question. Phase II is a biology question.

The methods have become markedly better at generating molecules with drug-like properties and have not become better at knowing what to aim them at. That is the shape this volume predicts: a representation that carries structure well and carries state badly will improve the chemistry and leave the biology where it was.

---

942. Where the Methods Are Actually Being Applied ↩

From the same analysis, of about 6,147 drugs in clinical development:

AI-discovered molecules	67	about 1 percent
involving an AI-discovered target	24	about 0.4 percent
involving a genuinely novel AI-discovered target	3 to 9	0.05 to 0.1 percent

The methods are being used to design ligands for targets that people chose. They are almost never being used to choose the target.

---

943. And the Target Is the Layer This Volume Is About ↩

Part One Hundred and Three, section 883, made the argument before these figures were consulted: an editor or a drug aimed by sequence is aimed at the one layer that does not encode the risk. Part One Hundred and Four established that the sequence databases were produced by a method that converts RNA to DNA and discards the modifications on the way.

what target selection is done from	sequence, expression and pathway topology
what those records contain	letters, counts and edges
what they do not contain	modification, rotation, orientation, absence, concentration, position

Between three and nine drugs in clinical development were aimed at a target that a machine proposed. Whatever is limiting that number, it

is not molecular design, which is working. The constraint sits upstream of the design, in what the machine was given to look at.

This volume does not claim to have shown that the representation is the constraint. It claims that the constraint is upstream of chemistry, that the published figures locate it there, and that representation is one candidate which has not been tested.

944. The Remedies Point in Opposite Directions ↩

the proposal	what it assumes
faster trial infrastructure	the science is sound and the pipeline is congested
faster approval pathways	the evidence is adequate and the review is slow
replacing preclinical animal studies with human volunteers in emerging jurisdictions	the preclinical layer is a delay rather than a source of information
direct sequencing of the native molecule	the preclinical layer is producing an impoverished record

The first three treat the preclinical stage as a queue. The fourth treats it as a measurement. If the measurement is the problem, shortening the queue moves the same error into humans earlier.

This volume takes no position on the ethics or the regulation of any of these proposals and makes no recommendation about any of them. It records that they assume the opposite of what this volume argues, and that the assumption is testable.

945. What This Part Refuses, Including Vindication ↩

the claim	the status
the Phase I and Phase II figures	published, and cited above
the pipeline proportions	published, and cited above
that this volume has therefore been vindicated	refused
that impoverished representation explains the	refused as unproven. It is one candidate among several: biology is genuinely hard, target validation was always the

the claim	the status
Phase II plateau	weak step, and Phase II failure has a long history that predates any of these methods
that this explains why drugs have side effects	refused, again. Section 896 of this volume already refused it and that refusal stands unmodified

A finding that shares a shape with an argument is not evidence for the argument. This volume has spent a hundred and seven Parts insisting on that distinction and does not abandon it when the resemblance is flattering.

---

946. And a Caution About Agreement Among Machines ↩

A form of reasoning is now appearing in public commentary in which several large language models are asked the same question, their answers are found to agree, and the agreement is reported as support for the conclusion.

It is not support. Frontier models are trained on heavily overlapping corpora. When they agree, they are reproducing the corpus, not measuring the world. Consensus among such systems is a statistic about their training data.

This is the volume's own thesis in a new location. A record that reproduces itself and is mistaken for an independent observation is exactly the failure the preceding Parts describe in sequence databases — and here it appears in the instruments being used to reason about them.

---

947. The Field's Own Unease, Recorded Without Weight ↩

Senior figures within the sector have publicly raised the question of whether private valuations in this field have outrun therapeutic output, and whether a correction is coming.

This volume records that such commentary exists and assigns it no evidential weight. It is commentary by interested parties, published

outside peer review, and it proposes no mechanism. The figures in sections 940 and 942 are the evidence. The commentary is the weather.

One clinical result should be recorded alongside it for accuracy, because the strongest public statements of the negative case do not accommodate it. A generative-AI-discovered TNIK inhibitor reached a randomised Phase IIa trial in idiopathic pulmonary fibrosis, published in Nature Medicine in June 2025 — 71 patients, 22 sites, forced vital capacity improving by 98.4 milliliters on the highest daily dose against a decline of 20.3 milliliters on placebo.

No drug discovered by these methods has yet been approved. Both statements are true and this volume prints both.

---

948. The Experiment This Part Generates ↩

Experiment Thirty-four, for Part Twenty-Eight, section 65.

The question. Are the targets of failed Phase II trials enriched for genes whose regulation depends on features the sequence record does not carry?

Method. Take a set of drug targets that passed Phase I and failed Phase II for lack of efficacy. Take a matched set that succeeded. For each target gene, retrieve from published maps the density of RNA modifications on its transcripts, the extent of ADAR editing, and the CpG methylation density of its promoter. Then ask whether the failed set is enriched for any of these relative to the successful set. Public trial registries, public epitranscriptome and methylome maps, no laboratory.

Falsification condition, written before the answer. If the failed and successful targets are indistinguishable on these measures, then the layer this volume is about does not predict clinical failure, section 943's framing is unsupported, and this Part should say so in a later edition. If the failed set is enriched, that is a correlation and not a mechanism, and it would justify one prospective study rather than a conclusion.

This is the first experiment in the volume that could connect the notation argument to a clinical outcome. It is also the one most likely

to return nothing, and it is written here so that a null result is recorded rather than quietly abandoned.

949. What This Part Claims ↩

The claims

1	**AI-discovered molecules succeed in Phase I at 80 to 90 percent against a historical average of 40 to 65**
2	They succeed in Phase II at about 40 percent, which is the historical rate
3	Phase I tests chemistry; Phase II tests biology. The improvement is confined to the chemistry
4	About 1 percent of drugs in clinical development are AI-discovered molecules; about 0.4 percent involve an AI-discovered target; between 3 and 9 involve a genuinely novel one
5	The methods are designing ligands for targets that people chose
6	The field's principal proposed remedies address speed; this volume's addresses the record
7	The two diagnoses imply opposite actions and are therefore distinguishable
8	Agreement among language models is a statistic about training data, not evidence about the world
9	That caution applies to this volume, which was assembled with such a model, and is the reason every Part carries a refutation condition

What would refute it

the claim	what would kill it
the Phase I / Phase II split	a larger or later analysis finding Phase II success improved for AI-discovered molecules
the target-layer scarcity	a current count showing AI-discovered targets are now a substantial fraction of the pipeline
the framing of section 943	Experiment Thirty-four returning no difference between failed and successful targets
the two diagnoses being opposed	a demonstration that acceleration and better representation are complementary rather than alternative, which would make this Part's central contrast false

And the discipline this Part exists to enforce. The temptation, on finding that a well-placed figure in a field has publicly said something

that rhymes with one's own argument, is to call it confirmation. This volume declines. What supports the argument here is a table of trial success rates that nobody assembled with this book in mind, and what would overturn it is a second table of the same kind. Neither has anything to do with who agrees.

PART ONE HUNDRED AND NINE · THE CHAIN IS HELD ON A SULFUR

Part One Hundred and Nine of the evidence volume, sections 950 to 962

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The fourth family of building blocks has a monomer, and it is not a fat. A fatty acid is assembled two carbons at a time from an acetyl group, and for every step of that assembly the growing chain is covalently bonded to a sulfur atom — first on coenzyme A, then on the phosphopantetheine arm of the acyl carrier protein. Of the four biomolecule classes, lipid is the only one built on a sulfur tether. And the finished lipids carry sulfur too: half the sulfur in the biosphere is estimated to sit inside one sulfolipid, and the two sulfurs of lipoic acid are installed by an enzyme that destroys one of its own iron-sulfur clusters to supply them.

---

950. The Monomer the Series Was Missing ↩

The four families, and their units

family	the monomer
nucleic acids	mononucleotide
proteins	amino acid
carbohydrates	monosaccharide
fats and lipids	see below — there are two answers and both are correct

The first answer — the naming mono

Dietary fat arrives as triacylglycerol. Pancreatic lipase does not take it apart symmetrically.

where the enzyme cuts	sn-1 and sn-3 only
what is released	2-monoacylglycerol and two free fatty acids
what crosses into the enterocyte	the 2-monoacylglycerol, within minutes of appearing in the lumen

Monoacylglycerol is not a teaching convenience. It is the physical unit in which every fat you have ever eaten entered your body.

The second answer — the repeating unit

A fatty acid is not built from fatty acids. It is built two carbons at a time.

acetyl-CoA → malonyl-CoA → +2 carbons per cycle → palmitate, C16\neight acetyl units, seven cycles

The monomer of a lipid chain is the acetyl group.

---

951. And the Chain Is Never Free ↩

What carries it

stage	the carrier	the bond
the primer	coenzyme A	thioester on the terminal thiol
the extender	malonyl-CoA	thioester
every intermediate	acyl carrier protein	thioester to the terminal sulfhydryl of a 4′-phosphopantetheine arm

The phosphopantetheine group is attached to the protein by a phosphodiester to a serine, and every acyl intermediate of fatty acid biosynthesis is bound to its terminal sulfhydryl.

From the first two carbons to the last, the growing fatty acid is covalently attached to a sulfur atom. It does not exist as a free molecule until a thioesterase releases it at the end.

---

952. Which Makes Lipid the Odd One of the Four ↩

family	the monomer	what carries it during assembly
nucleic acid	nucleoside triphosphate	nothing — added directly, magnesium-catalyzed
protein	amino acid	an ester to the tRNA ribose hydroxyl
carbohydrate	monosaccharide	a nucleotide-sugar — UDP-glucose and its kin
lipid	acetyl	a thioester, on two successive sulfur carriers

Proteins are assembled on an oxygen. Nucleic acids are assembled on nothing. Carbohydrates are assembled on a phosphate. Fat is the only one of the four assembled on a sulfur.

---

953. And the Tether Is the Adenosine Carrier, Grafted ↩

Part One Hundred and Seven established that every sulfur currency in this volume is an adenosine conjugate. The acyl carrier protein is that finding in a new form.

coenzyme A	adenosine + pantetheine + cysteine
the ACP arm	the pantetheine-and-thiol end of coenzyme A, transferred onto a serine

The sulfur atom that holds every fatty acid you make originated in a cysteine, was delivered by way of an adenosine conjugate, and is bolted to a serine on a protein. The carrier was cut down and mounted, and the sulfur came along.

---

954. The Gap at Section 5, Now Closed ↩

Section 5 of this volume set out the bond sulfur makes in each of the four families and recorded the lipid row as not found in the sources searched, stating it as a gap in the search rather than a fact about nature. The row is now filled, and the entry is larger than the other three.

955. The Sulfolipid, and the Proportion of the Biosphere It Holds ↩

Sulfoquinovosyl diacylglycerol

what it is	a glycerolipid whose head group is a sugar carrying a sulfonate — a direct carbon-sulfur bond
where it is	the thylakoid membrane of every plant, alga and cyanobacterium, and some fungi
what it does	required for full function of photosystem II

It is estimated that half of the sulfur in the biosphere is present within sulfoquinovosyl diacylglycerol.

Half the sulfur in the living world is in a lipid — and this volume's own section 5 recorded the lipid row as empty. Part Thirty-Five already had the molecule under a different heading, as the sulfonated sugar of the thylakoid. It belongs in both places.

956. The Sulfatide, in the Brain ↩

in the myelin sheath	share of total lipid
galactosylceramide	23 percent
sulfatide — its 3-O-sulfated form	4 to 6 percent

Sulfatide is a sulfate ester on the sugar head of a sphingolipid, highly enriched in myelin in both the central and peripheral nervous systems.

Between four and six percent of the lipid in the insulation around every axon in a human being carries a sulfate group. That is a structural role for sulfur in a lipid, at scale, in the organ this volume returns to most often.

957. And Lipoic Acid Is a Fatty Acid with Two Sulfurs ↩

The direct answer to whether sulfur appears within a fatty acid itself.

the backbone	an eight-carbon chain — octanoic acid
the sulfurs	two, at C6 and C8, closing a dithiolane ring
what it does	the swinging arm of pyruvate dehydrogenase and α-ketoglutarate dehydrogenase

Lipoic acid is not a sulfur compound that resembles a fatty acid. It is a fatty acid, and the sulfurs are inserted into a chain that was already built.

---

958. And the Enzyme That Installs Them Destroys Itself to Do It ↩

Lipoyl synthase

LipA is a radical S-adenosylmethionine enzyme carrying two [4Fe-4S] clusters, and the two clusters do different jobs.

the cluster	the job
the radical SAM cluster	binds SAM and donates the electron for its reductive cleavage, generating two 5′-deoxyadenosyl radicals which abstract hydrogen atoms from C6 and C8 of the octanoyl chain
the auxiliary cluster	is the sulfur donor. Two of its own bridging μ3-sulfido ions recombine with the substrate radicals

The auxiliary cluster is degraded during turnover. The enzyme is limited to a single turnover in vitro, because it has consumed part of itself. An iron-sulfur cluster is dismantled to build a fatty acid.

The fourth ligand to that auxiliary cluster is a serine, which is unusual, and it is held by a CX4CX5C motif found in no other radical SAM enzyme.

Three of this volume's threads meet inside one protein: the sulfonium of SAM, the iron-sulfur cluster, and the insertion of sulfur into a lipid.

---

959. The Row as It Now Reads ↩

family	bond sulfur makes	where it is found	what it does there
proteins	S–N and S–S	cysteine, methionine, the sulfenyl-amide switch, every disulfide	shape, catalysis, switching
sugars	S–N	N-sulfoglucosamine in heparan sulfate	decides which proteins the chain binds
nucleic acids	S–P	phosphorothioate in the backbone; thiolated bases in transfer RNA	redox, gene regulation, reading the code
fats and lipids	S–C and O–S, and S–C(=O) throughout assembly	lipoic acid, two sulfurs on an eight-carbon chain; sulfoquinovosyl diacylglycerol, holding an estimated half the sulfur in the biosphere; sulfatide, 4 to 6 percent of myelin lipid; and the thioester tether at every step of synthesis	cofactor catalysis, photosystem II function, myelin structure, and carrying the chain during assembly

All four families carry sulfur, and in the family the earlier survey found empty it makes three different bonds and holds half the element in the living world.

---

960. And the Clinical Axis, Which Is Eighty Years Old ↩

Toohey, Molecules 19:8334 to 8349, 2014, reviewing a relationship established in the 1930s.

the amino acid	the effect on diet-induced fatty liver
methionine	lipotropic — prevents it
cystine	hepatosteatogenic — promotes it

Two sulfur amino acids, opposite effects, on the deposition of fat in the liver.

The proposed mechanism

The lipotropic effect of methionine may be mediated by sulfane sulfur, and the steatogenic effect of cystine may be related to the removal of sulfane sulfur by cysteine catabolites.

The proposed link between sulfur amino acid metabolism and monounsaturated fatty acid synthesis is stearoyl-CoA desaturase-1. Its substrate is stearoyl-CoA — another thioester.

And the wider metabolic route

methionine and cysteine determine	homocysteine, hydrogen sulfide, taurine, glutathione
the route into lipid	global hypomethylation disturbs phosphatidylcholine synthesis, and PC synthesis is lipid metabolism
impaired H_2S synthesis from cysteine	favors atherosclerosis and steatosis in animal models
betaine supplementation	lowers homocysteine and raises total and LDL cholesterol

That last line is printed as it stands. A treatment that improves one sulfur marker worsens a lipid one, and the volume does not resolve it.

---

961. The Experiment This Part Generates ↩

Experiment Thirty-five, for Part Twenty-Eight, section 65.

The question. Is the methionine-versus-cystine effect on liver fat traceable to stearoyl-CoA desaturase-1, as proposed, or does it run through phosphatidylcholine?

Method. Four dietary groups in a standard rodent fatty-liver model: control, methionine-loaded, cystine-loaded, and cystine-loaded with a sulfane sulfur donor. Measure hepatic triglyceride, SCD-1 expression and activity by the desaturation index, phosphatidylcholine to phosphatidylethanolamine ratio, and bound sulfane sulfur. Then ask which of the two proposed routes tracks the liver fat.

Falsification condition, written before the answer. If liver fat tracks the PC/PE ratio and not the desaturation index, the SCD-1 hypothesis is not the route and section 960 should record that. If neither tracks, the sulfane sulfur proposal does not survive in this model. If the sulfane sulfur donor rescues the cystine group, that is

the strongest available support for Toohey's proposal and would justify a human study.

962. What This Part Claims ↩

The claims

1	**Pancreatic lipase cuts sn-1 and sn-3 only, releasing 2-monoacylglycerol and two free fatty acids, and the monoacylglycerol is the absorbed unit**
2	The repeating unit of a fatty acid chain is the acetyl group — two carbons per cycle, eight for palmitate
3	Every acyl intermediate is bound as a thioester to the terminal sulfhydryl of the 4′-phosphopantetheine arm of the acyl carrier protein
4	Lipid is the only one of the four biomolecule families assembled on a sulfur
5	The phosphopantetheine arm is the thiol end of coenzyme A, mounted on a serine — the adenosine carrier of Part One Hundred and Seven, cut down
6	Sulfoquinovosyl diacylglycerol is estimated to hold half the sulfur in the biosphere and is required for full photosystem II function
7	Sulfatide is 4 to 6 percent of myelin lipid; galactosylceramide is 23 percent
8	Lipoic acid is an eight-carbon fatty acid with sulfurs at C6 and C8
9	Lipoyl synthase supplies those sulfurs from its own auxiliary [4Fe-4S] cluster, which is destroyed in the process, limiting the enzyme to one turnover in vitro
10	Methionine prevents and cystine promotes diet-induced fatty liver, a relationship established in the 1930s

What this Part does not claim

	that sulfur is incorporated into ordinary fatty acids. The tether is on the carrier, not in the product; lipoic acid, the sulfolipid and the sulfatide are the cases where sulfur is in the finished molecule
	that 2-hydroxy fatty acids are sulfur fatty acids. They are not — the substituent is oxygen
	that the sulfane sulfur mechanism of section 960 is established. It is a proposal, and section 961 is written to test it
	that betaine is harmful. The volume prints one reported effect on two markers and draws no clinical conclusion

What would refute it

the claim	what would kill it
the thioester tether	a demonstrated fatty acid synthase pathway in which intermediates are carried as oxygen esters
the biosphere estimate	a re-inventory placing the SQDG fraction of biospheric sulfur well below one half
the auxiliary cluster as sulfur donor	isotopic labeling showing the C6 and C8 sulfurs arriving from a free sulfide pool rather than from the cluster
the SCD-1 route	Experiment Thirty-five returning a phosphatidylcholine correlation and no desaturation-index correlation

And the observation this Part records. The fourth family was entered in this volume as the one with no sulfur found. It turns out to be the family in which sulfur holds the chain from the first carbon to the last, appears in three different bond types in the finished molecules, and accounts for an estimated half of the element in the living world. The lipid row is now the largest of the four.

PART ONE HUNDRED AND TEN · AIMED BY LETTERS

Part One Hundred and Ten of the evidence volume, sections 963 to 975

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Every editing tool now in clinical use is aimed by sequence. A guide RNA is designed as a string of letters and scored for uniqueness against a string of letters. What it enters is not a string. It is a torsionally stressed physical object in which a guanine and a thymine can pair in wobble geometry, and in which negative supercoiling alone raises off-target cleavage a thousandfold at sites the software scored as safe. On the RNA side the whole engineered repertoire is two reactions, both of them the removal of an amino group, and the two reverse reactions do not exist. And the product of the most widely used RNA edit is inosine, which every sequencing readout writes down as guanosine. None of this makes the tools invalid. All of it is outside the notation they are designed in.

963. The Claim This Part Declines ↩

An argument is available here and this volume does not make it.

That the CRISPR-Cas systems are therefore suspect or invalid.

the record	
Casgevy — exagamglogene autotemcel, a Cas9 edit of the BCL11A erythroid enhancer	approved 8 December 2023 for sickle cell disease
transfusion-dependent beta thalassaemia	approved 16 January 2024
children aged two and older	approved 1 July 2026

A method that has cured a genetic disease in human beings is not invalid. It is a method with a measured specificity limit, and this Part is about the physical causes of that limit and about the fact that none of them appear in the representation the method is designed in.

---

964. And First, Four Molecules Sharing One Name ↩

A reader entering this field meets the term guide RNA applied to four unrelated things.

what is called a guide RNA	what it is	when
CRISPR gRNA	directs a Cas protein to DNA	2012
kinetoplastid gRNA	template for uridine insertion and deletion in trypanosome mitochondria	1990
snoRNA guides	direct 2′-O-methylation and pseudouridylation of ribosomal RNA	
ADAR-recruiting guides	direct A-to-I editing to a chosen site	2017

Four chemistries, four fields, one term. The maxicircles and minicircles that appear in discussions of guide RNA belong to trypanosome mitochondrial DNA and have no connection to Cas9. This volume's argument about notation applies to the names of things as readily as to the letters in a codon.

965. The Guide Is Designed as a String ↩

what guide design software does	
takes a target sequence	twenty letters
searches the genome	for letter-by-letter matches and near-matches
scores a candidate site	by counting mismatched letters and their positions
what it does not represent	base-pair geometry, hybrid stability, or DNA topology

The design object is a string. The target is a molecule. The remainder of this Part is the difference between them.

966. The First Difference — the Wobble in the Hybrid ↩

Cas9 pairs an RNA guide against a DNA target strand. That heteroduplex admits a pairing the letters call a mismatch.

The rG:dT mismatch can overcome the energy barrier by positioning the bases in a wobble geometry, and the formation of the rG:dT pair in the RNA-DNA hybrid is associated with the energetically favorable melting of the dT:dA pair in the DNA duplex.

what the software records	G against T — a mismatch, penalized
what the chemistry does	a wobble pair, stabilized by the duplex it displaces
the same is documented for	rU:dG
what it depends on	position in the heteroduplex, local sequence context, neighboring mismatches

Part Sixty-Nine of this volume established the wobble position in translation. It is the same geometry, in a laboratory reagent, deciding where a nuclease cuts a human genome.

967. The Second Difference — Topology, and It Is a Thousandfold ↩

Cas9 must open the duplex to let the guide pair with the target strand. That is R-loop formation, and it is mechanical.

the finding	
supercoiled plasmid versus linear or nicked circular DNA	cleaved more than fifty times faster
negative supercoiling and off-target cleavage	accelerated a thousandfold
Cas9 on underwound DNA	complete R-loop formation and efficient cleavage in the presence of multiple mismatches
the state of DNA inside a living cell	globally underwound

Negative supercoiling dramatically reduces Cas9 specificity, and cellular DNA is negatively supercoiled everywhere. Local topological stress is generated dynamically by transcription and by every process that mechanically deforms the double helix.

Two identical target sequences, one in a relaxed region and one under torsional stress, are not equivalent targets. In the design file they are the same twenty letters.

---

968. What the Notation Loses Here ↩

the physical variable	represented in guide design
wobble geometry in the RNA-DNA hybrid	no
supercoiling state at the target locus	no
chromatin occupancy and accessibility	partially, in some tools
modified bases in the guide or the target	no
letter identity and position	yes — this is the whole model

A guide unique in the four-letter genome is not necessarily unique in the physical one.

969. The RNA Side — Two Reactions, and Both Are Subtractions ↩

The natural repertoire in mammals is exactly two edits.

edit	enzyme	the chemistry
A → I	ADAR, adenosine deaminase acting on RNA	removes an amino group
C → U	APOBEC, cytidine deaminase	removes an amino group

APOBEC1's best-characterized edit is CAA to UAA in apolipoprotein B messenger RNA — the creation of a stop codon, which truncates apoB100 to apoB48.

Every engineered RNA editor in existence is a redirected deaminase. Nobody has built a new reaction; two existing subtractions were pointed at new addresses. Part Nine of this volume argues that biology proceeds by removal. So does the biotechnology built on it.

970. And the Two That Are Missing ↩

The field states the gap in its own terms.

Enzymes to perform guanosine-to-adenosine and uridine-to-cytidine editing are still lacking to complete the set of transition reactions.

the two available	A→I and C→U — deaminations
the two missing	G→A and U→C — each would require putting the amino group back

The only route yet found to U-to-C runs through the DYW:KP domains of seedless plants. Seven consensus DYW:KP domains were designed and fused to a programmable pentatricopeptide repeat binding domain; three of them edited a targeted uridine to cytidine in bacteria and in human cells.

A plant enzyme family, borrowed to attempt the reverse of the only reaction mammalian editing knows how to run.

971. Uridine Is the Hinge of the Whole Field ↩

what uridine does here	
it is the product	C-to-U deamination makes it
it is the insertion unit	kinetoplastid editing inserts and deletes uridylates by the hundred, guided by minicircle-encoded RNAs, in an editosome of roughly twenty polypeptides
the inserting enzyme	terminal uridylyl transferase — TbRET2 inserts at editing sites, TbRET1 uridylates guide RNA 3′ ends
it carries the sulfur	2-thiouridine at wobble position 34 — Part Sixty-Nine
it has an isomer	pseudouridine — the same atoms, rotated — Part Seventy-Five
and it cannot be edited back	U→C is one of the two missing reactions

Uracil is the only base that is made by editing, inserted by editing, deleted by editing, thiolated at the wobble, isomerized in place, and cannot be reversed. This volume's indigo band already marks the gate it comes through, at orotate.

972. The Edit Is Inosine. The Record Says Guanosine. ↩

Part One Hundred and Four established that reverse transcription reads inosine as guanosine and that the letter reaching the database is a property of the reagent. Applied to a therapeutic A-to-I editor, that becomes a question about validation.

the molecule the enzyme produces	inosine
the letter the sequencing readout reports	G
are they the same molecule	no

inosine	guanosine
no exocyclic amine at C2	has one
reads three codons at the wobble	reads one
hydrogen-bonds accordingly	differently

inosine	guanosine
recognized differently by RNA-binding proteins	

A site-directed A-to-I therapy is assessed by a method that cannot distinguish its product from a different molecule. The edit made is inosine. The evidence of success is a guanosine in a database. Part One Hundred and Four's nanopore direct sequencing is the instrument that would close the gap, and it is not the instrument the field validates with.

973. What This Part Does Not Claim ↩

	that the Cas systems are invalid. Section 963 declines it, and an approved therapy is the reason
	that off-target activity is unknown to the field. It is the field's principal engineering concern, and high-fidelity variants, base editors and prime editors all exist because of it
	that RNA editing does not work. It works, at the sites and efficiencies reported
	that inosine and guanosine are functionally unrelated. Inosine reads as guanosine at many positions, which is why the substitution is useful; the claim is that they are not identical and the readout cannot tell them apart
	that the maxicircle and minicircle literature bears on CRISPR. Section 964 separates them explicitly

974. The Experiment This Part Generates ↩

Experiment Thirty-six, for Part Twenty-Eight, section 65.

The question. Are the off-target sites that guide-design software fails to predict enriched for either of the two physical variables the software does not represent?

Method. Take a published set of experimentally measured Cas9 off-target sites — from GUIDE-seq, DISCOVER-seq or equivalent — together with the in-silico predictions for the same guides. Partition the measured sites into predicted and

unpredicted. For each site score two variables: first, whether the mismatches are rG:dT or rU:dG capable of wobble geometry rather than non-wobble mismatches; second, the local transcription-generated negative supercoiling, estimated from published GapR-seq or psoralen crosslinking maps. Then ask whether the unpredicted sites are enriched for either. Public datasets, no bench.

Falsification condition, written before the answer. If unpredicted off-target sites are no more likely than predicted ones to carry wobble-capable mismatches and no more likely to sit in underwound DNA, then neither variable explains prediction failure, and this Part's central claim that the missing physics is the problem does not hold. A positive result on either variable is a correlation and would justify adding that variable to a prediction model, not a conclusion about clinical safety.

975. What This Part Claims ↩

The claims

1	**Guide design software models letter identity and position, and does not model hybrid geometry or DNA topology**
2	rG:dT pairs in wobble geometry in the RNA-DNA heteroduplex, stabilized by the melting of the dT:dA pair it displaces; the same is documented for rU:dG
3	Supercoiled DNA is cleaved more than fifty times faster than linear or nicked circular DNA
4	Negative supercoiling accelerates off-target cleavage a thousandfold, and cellular DNA is globally underwound
5	Mammalian RNA editing is two reactions, A-to-I and C-to-U, and both are deaminations
6	G-to-A and U-to-C editing enzymes are absent, and the only U-to-C route found runs through plant DYW:KP domains
7	Uracil is made, inserted, deleted, thiolated and isomerized by editing, and cannot be edited back
8	A-to-I editing produces inosine and is validated by a readout that writes guanosine
9	Four unrelated molecules are called guide RNA, and the circular-DNA literature belongs to only one of them

What would refute it

the claim	what would kill it
the wobble tolerance	structural or biochemical work showing rG:dT is not

the claim	what would kill it
	accommodated in the heteroduplex
the topology effect	a repetition finding no supercoiling dependence of off-target cleavage in cells
the missing reactions	publication of an efficient mammalian G-to-A or U-to-C RNA editor, which this volume would record and cite
the readout claim	a demonstration that standard RNA-seq distinguishes inosine from guanosine without added chemistry
the framing of section 968	Experiment Thirty-six returning no enrichment on either variable

And the statement this Part exists to make. The tools work. They are aimed by a notation that records which letter is present and nothing about how it pairs, how the molecule is wound, or which of two chemically distinct nucleosides the enzyme actually produced. Every mechanism in this Part was known to somebody before this volume printed it. What this volume adds is the observation that all four failures have the same shape, and that the shape is the one described in the first ten Parts of this book.

---

y

---

976. And the One Approved Cure Did Not Correct a Letter ↩

What Casgevy actually edits

The approved Cas9 therapy for sickle cell disease and beta thalassaemia does not touch the mutation that causes either.

what the guide targets	the erythroid-specific enhancer of BCL11A
what BCL11A does	represses fetal hemoglobin at the developmental switch after birth
what the cut accomplishes	disables the repressor, and gamma-globin returns
the HBB sickle mutation	present, unaltered, in every cell
fetal hemoglobin at six months	43.9 percent of total, sustained beyond twenty-four months

Fetal hemoglobin cannot sickle because it carries no beta chain at all, and therefore no valine at position six.

The patient is not repaired. The patient is returned to a program they ran until roughly six months of age and then switched off. The defective letter remains in the book; the cell has been instructed to read a different chapter.

And the strategy was taken from healthy people

Hereditary persistence of fetal hemoglobin is a naturally occurring human condition. Those who carry it are well, and when it is co-inherited with sickle cell disease or beta thalassaemia the severity is reduced. A genome-wide association study reported BCL11A variants associated with persistent fetal hemoglobin and with the mild form of beta thalassaemia.

The therapy did not design a cure. It identified people who were already protected, established which gene was responsible, and reproduced their condition with a nuclease.

What this Part takes from it

the therapeutic content	was not in the letters of HBB
what changed	which of two hemoglobin programs an erythroid cell executes
what a four-letter readout shows before and after	the same mutation, in the same place

Two qualifications this volume states plainly. The edit is still aimed by sequence, so everything in sections 966 and 967 applies to the targeting. And the choice of compensation over correction is partly an engineering matter — a knockout uses non-homologous end joining, which is efficient in blood stem cells, while correcting a base requires homology-directed repair, which is not. Base editors aimed at HBB itself are in trial.

With both qualifications allowed, the fact remains. The first approved genome-editing cure works by changing a state rather than by correcting information, and the difference between the treated and untreated patient is invisible in the notation.

PART ONE HUNDRED AND ELEVEN · THE ANTICODON IS A GUIDE

Part One Hundred and Eleven of the evidence volume, sections 977 to 989

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

A transfer RNA is a guide RNA with three letters instead of twenty, and two of those three positions are chemically rewritten after transcription. The modifications expand the reading, restrict it, bias it, or invert it. In bacteria one anticodon written CAU delivers methionine to AUG or isoleucine to AUA, and which it does is decided by a single modification the letters do not carry. And two human mitochondrial diseases are caused by point mutations that are nowhere near the wobble position, which prevent a modifying enzyme from recognizing the tRNA, so that a sulfur atom is never installed and specific codons stop being read at all.

977. The Anticodon Is a Guide, and It Is Shorter ↩

	a CRISPR guide	an anticodon
length	twenty nucleotides	three
target	a DNA duplex	a codon in messenger RNA
what the notation records	the letters	the letters
positions chemically rewritten before use	none by design	two of the three neighbor hood — 34 and 37

Part One Hundred and Ten set out what a twenty-letter guide fails to carry. This Part sets out the same failure in a three-letter one, where the proportion of the molecule that is modified is far higher.

Position 34 is the most heavily modified position in the transcriptome, and it is the position that decides which codons a transfer RNA answers.

978. The Table Every Textbook Prints ↩

Crick's wobble hypothesis, 1966 — anticodon position 34 against the third position of the codon.

written at 34	reads
C	G
A	U

written at 34	reads
G	U and C
U	A and G
I	U, C and A

Every entry is a statement about a letter, and the molecule at position 34 is very often not the letter written there.

979. The Derivatives, and They Do Four Different Things ↩

the modification	made from	what it then reads	the operation
I — inosine	A	U, C, A	expands one to three
cmo⁵U	U	A, G, U and C	expands to all four
Q — queuosine	G	U in preference to C	biases
τm⁵U	U	UUA and UUG	required, or the codon fails
τm⁵s²U	U	AAA and AAG	required, or both fail
k²C — lysidine	C	A rather than G	inverts

Expand, restrict, bias and invert. Four distinct operations on the reading rule, and the notation carries the letter the position started as.

980. Lysidine — One Anticodon, Two Amino Acids ↩

The bacterial isoleucine problem

The AUA codon has to be read as isoleucine and AUG as methionine. Both begin AU. The tRNA that reads AUA carries an anticodon written CAU — which is the methionine anticodon.

	as written, C34	modified to lysidine, k²C34
the codon it reads	AUG	AUA
the amino acid it carries	methionine	isoleucine

The precursor bearing C34 has no isoleucine-acceptance activity and behaves as a methionine acceptor. After modification the tRNA becomes specific for isoleucyl-tRNA synthetase and can no longer be recognized by methionyl-tRNA synthetase.

The enzyme is TilS, tRNA-isoleucine lysidine synthetase. It attaches a lysine to C2 of the cytidine, using ATP, and it distinguishes tRNA-Ile from the structurally similar tRNA-Met carrying the same anticodon loop by reading the anticodon loop, the anticodon stem and the acceptor stem together.

---

981. Which Means the Modification Sets Identity, Not Only Reading ↩

Two things change at once, and this is the point of the example.

codon specificity	AUG becomes AUA
aminoacylation specificity	methionyl-tRNA synthetase becomes isoleucyl-tRNA synthetase

One chemical modification at one position changes both which codon the molecule answers and which amino acid it delivers. The three letters CAU are identical before and after. A reader working from sequence cannot determine either property.

Part Thirty-Two of this volume named the aminoacyl-tRNA synthetases as the unique covalent junction between nucleic acid and amino acid. Here that junction is assigned by a modification rather than by a sequence.

---

982. And the Position Next Door ↩

Position 37 sits immediately 3′ of the anticodon and is not read by anything. It decides whether the reading stays in frame.

modification at 37	
t⁶A — N6-threonylcarbamoyladenosine	stabilises the codon-anticodon interaction at the first position
i⁶A — isopentenyladenosine	enhances binding
yW — wybutosine	
m¹G	prevents +1 frameshifting

Part Ninety recorded the frameshift measurements. The relevant fact here is that a position which pairs with nothing determines whether the three positions that do pair are read in register.

---

983. The First Worked Mistranslation — MERRF ↩

the mutation	m.8344A>G
the molecule	mitochondrial tRNA-Lys
what is lost	τm⁵s²U34 — 5-taurinomethyl-2-thiouridine
the consequence	the tRNA cannot translate AAA or AAG — a complete loss of codon-anticodon pairing on the ribosome

The 2-thio modification of the wobble base is critical for decoding the AAR codons. Without it both lysine codons go unread, and MERRF patients show a marked defect in whole mitochondrial translation.

The atom that fails to arrive is sulfur.

---

984. And the Second — MELAS ↩

the mutation	m.3243A>G
the molecule	mitochondrial tRNA-Leu(UUR)

the mutation	m.3243A>G
what is lost	τm⁵U34 — 5-taurinomethyluridine
the consequence	a UUG decoding deficiency

Two of the most common mitochondrial disease mutations in medicine, and in both the proximate lesion is a missing wobble modification rather than a missing or wrong amino acid.

985. And the Mutation Is Not at the Position That Fails ↩

This is the detail that carries the argument.

where the mutation is	position 8344, or position 3243
where the failure is	position 34
the mechanism	the mutation prevents recognition by the tRNA-modifying enzyme, so the modification is never installed

A base change at one place in the molecule abolishes a chemical group at another place, and the clinical result is that two specific codons stop being translated. Nothing in the sequence at position 34 has changed. No comparison of the anticodon letters before and after would show anything at all.

986. The Misreadings This Predicts ↩

what is lost	what follows
I34, the adenosine deamination on tRNA	the anticodon reverts to reading U alone; the C-ending and A-ending codons go unanswered
lysidine	tRNA-Ile2 reverts to a methionine acceptor — methionine inserted where isoleucine belongs
τm⁵s²U34	AAA and AAG unread — stalling, and elevated frameshift risk
m¹G37	+1 frameshift, and everything downstream is a different protein

987. What the Notation Loses Here ↩

the molecule at position 34	what the notation writes
adenosine	A
inosine, made from it	A, in the gene; G, in a cDNA readout
cytidine	C
lysidine, made from it	C
uridine	U
2-thiouridine	U
5-taurinomethyl-2-thiouridine	U

Seven chemically distinct molecules. Three letters. And the differences between them decide which codon is read, which amino acid arrives, and whether the reading stays in frame.

988. What This Part Refuses ↩

the claim	the status
modifications at 34 and 37 determine codon reading and frame	established, and cited
lysidine switches both codon and amino acid specificity	established
MERRF and MELAS involve loss of wobble modification	established
that translation is therefore unreliable in healthy cells	refused. The modifications are installed accurately; the point is that the accuracy lives in chemistry the notation does not record
that mistranslation explains disease generally	refused. Two mitochondrial diseases are documented here and no general claim is made
that the genetic code is wrong	refused. The code is a correct account of which codon specifies which amino acid. It is not an account of how the reading is accomplished

989. What This Part Claims ↩

The claims

1	**An anticodon is a three-letter guide, and two positions in its neighbor hood are modified after transcription**
2	Position 34 is the most heavily modified position in the transcriptome
3	Modifications at 34 expand, restrict, bias or invert the reading rule
4	Lysidine converts a tRNA reading AUG as methionine into one reading AUA as isoleucine
5	The same modification switches the charging enzyme from MetRS to IleRS
6	Position 37 pairs with nothing and determines frame
7	MERRF m.8344A>G abolishes τm⁵s²U34, and the tRNA then reads neither AAA nor AAG
8	MELAS m.3243A>G abolishes τm⁵U34, producing a UUG decoding deficiency
9	In both, the mutation is remote from position 34 and acts by preventing enzyme recognition
10	Seven distinct molecules occupy position 34 and the notation has three letters for them

What would refute it

the claim	what would kill it
the lysidine identity switch	a demonstration that unmodified C34 tRNA-Ile2 is charged with isoleucine
the MERRF mechanism	measurement showing τm⁵s²U34 present at normal levels in m.8344A>G tRNA-Lys
the remoteness of the lesion	evidence that these mutations alter position 34 directly
the framing of section 987	a sequencing method in routine use that distinguishes all seven position-34 species

And the sentence this Part exists to leave with the reader. Part One Hundred and Ten showed a twenty-letter guide aimed by a notation that omits the physics of pairing. This Part shows the cell's own guide, three letters long, in which the notation omits the chemistry at two of the three positions that matter — and in which one unwritten modification decides whether a codon means methionine or isoleucine.

PART ONE HUNDRED AND TWELVE · THE SEQUENCE HAS NO SHAPE

Part One Hundred and Twelve of the evidence volume, sections 990 to 1002

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

An antisense oligonucleotide is designed by Watson-Crick complementarity against a target that is folded. A sequence does not have a structure; it has an ensemble, and the same twenty bases sit in an open loop in one conformer and buried inside a stem in another. Complementarity does not vary with conformation, so the design metric is blind to the one variable that decides whether the drug can reach its site. The remedy now being proposed is to design around triple base pairs — an interaction of three bases that a pairwise notation has no symbol for. And in an RNA virus the structure is the function, which is why the first antisense drug ever approved was aimed at a virus and why so few have followed.

990. The Sentence This Part Is Built on ↩

Hörberg, Carlesso and Reymer, in a 2024 study of ASO-RNA complexation, state the problem in their own abstract.

"Current oligonucleotide drug design strategies prioritize full Watson-Crick base pair complementarity, overlooking mRNA target 3D shapes."

No part of this volume was consulted in writing that sentence. It is the argument of this book, arrived at independently, inside the field it applies to.

991. The Arithmetic of the Field ↩

proteins classified as undruggable by conventional small molecules, which oligonucleotides were meant to reach	**about 10,000**
oligonucleotide drugs approved by the FDA since	18

proteins classified as undruggable by conventional small molecules, which oligonucleotides were meant to reach	**about 10,000**
the 1990s	
of those, antisense oligonucleotides	about half
the first, fomivirsen, approved 1998	for cytomegalovirus retinitis

Thirty-five years, ten thousand promised targets, eighteen drugs.

This volume takes that ratio as a fact about the field rather than as an indictment of it, and asks what the design method is not seeing.

992. A Sequence Does Not Have a Structure ↩

It has an ensemble

A folded RNA is not one shape. It is a population of conformers exchanging on timescales from nanoseconds to seconds.

the same twenty bases	
in one conformer	exposed in a loop, and available
in another	paired inside a stem, and unavailable
in the sequence record	identical

The letters are the same in both. The drug can bind one and not the other.

993. What the Design Metric Cannot See ↩

The study's own finding is that ASO-mRNA complex stability is governed by three quantities.

the quantity	in a complementarity score
ASO length	yes
the number of common triple base pairs	no
the dynamic accessibility of bases in the hairpin loop	no

Two of the three determinants of binding are invisible to the method used to design the molecule.

And the authors note where the accessible regions are: hairpin motifs, which they describe as highly accessible regions for interactions. Accessibility is a property of the fold. It is not recoverable from the sequence by inspection.

994. The Remedy Being Proposed Is a Triple ↩

The recommendation of the paper is to incorporate common triple base pairs into ASO design, and to use pseudoknots in the training data for the machine learning models that will design the next generation.

a Watson-Crick pair	two bases
a base triple	three bases, one of them contacting an existing pair

The third contact is typically made on a face the pairing rules do not use — the Hoogsteen edge or the sugar edge rather than the Watson-Crick edge.

995. And the Notation Has No Symbol for It ↩

Watson-Crick notation is irreducibly pairwise. A goes with T. G goes with C. The scheme has one slot for a partner and there is no way to write a third.

This volume has recorded four things the four-letter notation loses — modification, rotation, absence and orientation. The base triple is a fifth and it is of a different

kind. It is not a property of a base that the letter fails to carry. It is an entire class of contact for which the scheme provides no notation at all.

And the field's proposed fix for its most disappointing drug class is to design around it.

996. RNA Viruses, Where the Structure Is the Function ↩

In a viral genome, shape does work that sequence does not.

the element	what it does	what conserves it
the frameshifting pseudoknot	sets the ratio of two proteins made from one message by stalling the ribosome at a fixed frequency	the fold, not the letters
the internal ribosome entry site	recruits the ribosome without a cap	the fold
structured untranslated regions	replication and packaging signals	the fold

Sequences in these elements are conserved because of the structure they produce. An antisense oligonucleotide designed against the sequence of a pseudoknot is aimed at the one region of the molecule whose meaning is not in its sequence.

997. And the First One Ever Approved Was Aimed at a Virus ↩

Fomivirsen, 1998, for cytomegalovirus retinitis — the first antisense oligonucleotide to reach the clinic anywhere.

Eight more ASOs followed over the next quarter century.

998. What Else Is Wrong, Stated So the Claim Is Not Oversold ↩

Structural accessibility is one cause among several, and this volume names the others.

delivery	**the field's most cited obstacle. Oligonucleotides reach liver, kidney and the central nervous system; other tissues remain difficult**
nuclease susceptibility	ASOs must carry backbone modifications to survive, and those modifications produce their own off-target effects
toxicity, potency and specificity	named together in the field's own reviews as the causes of clinical setbacks

This Part claims that structure is a real and under-modeled variable. It does not claim that structure explains the whole of the field's difficulty, and a reader who takes it that way has taken more than is offered.

---

999. And the Linker Is a Thioether ↩

In the siRNA-ASO conjugates now being built, the two oligonucleotides are joined chemically. The common linkage is a maleimide reacted with a thiol, producing a thioether. The alternative is a triazole from azide-alkyne cycloaddition.

The chemistry that staples two nucleic acids together reaches for a sulfur first. Nothing in this Part depends on that. It is recorded because it is the fourth time in this volume that a carrier, a tether or a junction between two molecules has turned out to be made at a sulfur atom.

1000. The Five Mechanisms, Together ↩

Parts One Hundred and Ten through One Hundred and Twelve set out five ways a modern sequence-directed tool is aimed at something the sequence does not describe.

	the tool	what the notation omits
1	Cas9 guide RNA	rG:dT pairs in wobble geometry — scored as a mismatch, behaves as a pair
2	Cas9 target site	DNA topology — negative supercoiling raises off-target cleavage a thousandfold
3	A-to-I RNA editing	the product is inosine and the readout writes guanosine
4	the anticodon	seven molecules occupy position 34 and there are three letters
5	the antisense oligonucleotide	the target's fold, and the base triple, for which there is no symbol

And section 976 records a sixth of a different kind: after a somatic edit a patient carries two genomes, and the record format has one slot per person.

Six failures, one shape. In every case the instrument is aimed by identity and the molecule responds by relation, geometry or state.

1001. The Experiment This Part Generates ↩

Experiment Thirty-seven, for Part Twenty-Eight, section 65.

The question. Do ASOs that failed in the clinic differ from those that succeeded in the predicted accessibility of their target sites?

Method. Assemble the target sites of the approved antisense oligonucleotides and of a matched set of ASOs that reached clinical trials and failed for lack of efficacy. For each target site compute a structural accessibility score from published chemical probing data — SHAPE or DMS — and, where no probing data exists, from ensemble folding predictions rather than a single minimum-free-energy structure. Then ask whether the successful set is enriched for accessible sites. Public sequence, public probing datasets, public trial records, no bench.

Falsification condition, written before the answer. If accessibility does not separate the two sets, then either the accessibility measures available are inadequate or structure is not the discriminating variable at the clinical scale, and section 993's framing is stronger than the evidence supports. A positive result would be a

correlation across a small sample — there are fewer than twenty approved oligonucleotide drugs in total — and would justify a prospective comparison rather than a conclusion.

The sample size is the honest weakness of this experiment and it is stated here rather than discovered later. Eighteen approved drugs is not a population.

1002. What This Part Claims ↩

The claims

1	**Current oligonucleotide design prioritises full Watson-Crick complementarity and overlooks the target's three-dimensional shape — the field's own statement**
2	Eighteen oligonucleotide drugs have FDA approval, about half of them ASOs, against roughly ten thousand targets the class was meant to reach
3	The first, fomivirsen, was approved in 1998 for cytomegalovirus retinitis
4	A sequence corresponds to an ensemble of structures, not to one
5	Complex stability depends on ASO length, the number of triple base pairs, and dynamic accessibility in the hairpin loop — and two of the three are absent from a complementarity score
6	Hairpin motifs are the accessible regions, and accessibility is a property of the fold
7	A base triple is a three-base contact and Watson-Crick notation is pairwise, with no symbol for a third partner
8	In RNA viruses the functional elements are conserved for their fold rather than their letters

What would refute it

the claim	what would kill it
accessibility governs ASO binding	demonstration that measured binding in cells tracks complementarity alone, independent of probing-derived accessibility
the triple has no notation	an established sequence notation in routine use that records base triples
structure is under-modeled in design	a survey showing that current commercial ASO design pipelines already incorporate ensemble accessibility as a primary criterion
the framing of section 993	Experiment Thirty-seven finding no separation between

the claim	what would kill it
	successful and failed target sites

And the observation this Part records. The authors of the 2024 study reached this volume's central claim from the opposite direction — starting from molecular dynamics rather than from sulfur, and from drug design rather than from the genetic code. They did not set out to say that a notation is insufficient. They set out to make a drug work, and found the notation in the way.

PART ONE HUNDRED AND THIRTEEN · FOUR BANDS, ONE FIELD

Part One Hundred and Thirteen of the evidence volume, sections 1003 to 1015

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

The Preface casts the atoms as a marching band. This Part casts the other three families the same way and puts all four on the field of the 1982 metabolic chart, colored by the same key. Each family turns out to have the same organization — a block that plays, a percussion line that keeps time, specialists who appear once, and a drum major who carries no instrument and is present at every step. Two of the four drum majors are sulfur. And on the chart itself the four letters of the genetic alphabet appear almost nowhere in the anabolic territory, because in the direction that builds, the free base does not exist.

1003. The Figure, Extended ↩

The Preface established one band. There are four families of building block and each has the same shape.

the band	its monomer
the atoms	H · C · N · O · P · S · Se, with the ions and the metals behind them
the nucleotides	the eight — I X G A U O C T
the amino acids	twenty-one in a human

the band	its monomer
the lipids	the acetyl group, two carbons — Part One Hundred and Nine
the carbohydrates	the monosaccharide

Five bands, one figure, and the same four ranks in each.

1004. The Field Is the 1982 Chart ↩

The playing surface is not invented. It is the metabolism wall chart, four sheets, copyright 1982 — the chart Part Forty-Two records being colored atom by atom in a fixed key.

the chart's own key	
oxygen	orange
hydrogen	red
nitrogen	green
phosphorus	purple
carbon	blue
sulfur	yellow

Six atoms. Selenium does not appear on the chart at all, which is the first thing the field tells you about who is on it.

1005. And the Chart Already Told Us Where the Letters Are ↩

Part Forty-Two, section 143. Find every free base drawn on that chart — adenine, guanine, hypoxanthine, xanthine, uracil, thymine, without a sugar and without a phosphate.

They are almost entirely inside the two boxes ruled and titled PURINE CATABOLISM and PYRIMIDINE CATABOLISM.

In the whole anabolic expanse above those boxes the free base is essentially absent, because in de novo purine synthesis the ring is built on top of a ribose phosphate that was there first, and in the pyrimidine branch the free base exists for exactly one step before it is joined to PRPP.

The four letters are not players on that field. They are what is left on it after the show.

1006. The Second Band — the Nucleotides ↩

The block

position	who	why
the largest section	adenosine	it is in ATP, in SAM, in coenzyme A, in PAPS, in NAD and in FAD. Every carrier in this volume is an adenosine conjugate
the signal section	guanosine	GTP drives elongation, ribosome translocation and the cap
the section that carries the marks	cytosine	5-methylcytosine, and the deamination that makes it a mutational hotspot
the most modified player on the field	uracil	made by editing, inserted and deleted by editing, thiolated at the wobble, isomerized to pseudouridine, and the one base that cannot be edited back
the transfer who changed teams	thymine	made from uracil by a sulfur enzyme, and it plays only for DNA

The two who control the tunnel

xanthine	**the purine gate — XMP to GMP**
orotate	the pyrimidine gate — OMP to UMP

Nobody reaches the field except through them, and neither has a letter. This volume's indigo band colors them both, and indigo is the band a human eye can barely separate from its neighbors.

And the one who covers three positions

Inosine reads U, C and A where the others read one codon each. It is manufactured deliberately by an enzyme, it does the work, and it appears in no alphabet.

The drum major

PRPP — phosphoribosyl pyrophosphate. Part Ninety-Seven calls it the door they all come through.

It is not a nucleotide. It has no base. Every purine and every pyrimidine in the body is built on it or salvaged onto it, and it is in none of them. It carries no instrument and it is at the front of every step.

1007. The Third Band — the Amino Acids ↩

The block

position	who	why
the corner section	glycine and proline	opposite residues making the same turn — Part Thirty-Three. Glycine is every third residue in collagen
the two sulfur players	cysteine and methionine	the disulfide and the sulfonium
the largest and rarest	tryptophan	one codon, lowest abundance
the charged rank	Asp · Glu · Lys · Arg · His	the electrostatics

The drum major

Methionine.

it begins every protein ever translated	AUG, the start codon
and in most finished proteins	it has been cut off — N-terminal methionine excision

It leads the band onto the field and then leaves it. Present at the beginning of every performance and absent from most of the record. And it is a sulfur amino acid.

The i-dotter

Selenocysteine, as in the Preface — twenty-five human selenoproteins, one recoded codon, and the only residue with no synthetase of its own.

1008. The Fourth Band — the Lipids ↩

The block

position	who	why
the whole marching block	the acetyl group	two carbons at a time, eight of them to make palmitate
the extender	malonyl-CoA	the three-carbon donor that loses one to drive the condensation
the frame	glycerol	three positions, and the enzyme cuts only one and three
the rigidifier	cholesterol	the plate in the membrane
the sulfur specialists	lipoic acid — an eight-carbon fatty acid with sulfurs at C6 and C8 · sulfoquinovosyl diacylglycerol — an estimated half the sulfur in the biosphere · sulfatide — 4 to 6 percent of myelin lipid	

The drum major

The 4′-phosphopantetheine arm of the acyl carrier protein.

it holds every intermediate from the first two carbons to the last	as a thioester on its terminal sulfhydryl
and it is in none of the product	a thioesterase releases the chain at the end

It carries the entire band across the field and walks off without playing a note. It is the business end of coenzyme A grafted onto a serine, and the atom doing the carrying is a sulfur.

1009. The Fifth Band — the Carbohydrates ↩

The block

position	who	why
the reference	glucose	the standard against which every other sugar is described
the two who joined the nucleotide band	ribose and deoxyribose	and the second was made from the first by a sulfur enzyme — Part Seven
the surface rank	galactose · mannose · fucose · N-acetylglucosamine · N-acetylgalactosamine · sialic acid	the sugars that decide what a cell looks like from outside
the sulfur specialists	sulfoquinovose — the sulfonated sugar of the thylakoid · N-sulfoglucosamine in heparan sulfate, the S–N bond of section 5	

The drum major

UDP — and its relatives.

no sugar is added to any polymer as itself	it arrives as a nucleotide-sugar — UDP-glucose, GDP-mannose, CMP-sialic acid
and the nucleotide	is released at the moment of transfer and is not in the chain

A carbohydrate is assembled by a nucleotide that does not stay. The band that runs the sugars is borrowed from the band that runs the nucleotides.

1010. The Four Drum Majors, Together ↩

the family	who leads it	present at	in the product
nucleotides	PRPP	every purine and pyrimidine, de novo and salvage	no — it has no base
amino acids	methionine	the start of every protein	no — excised from most
lipids	the phosphopantetheine thiol	every elongation cycle	no — released at the end

the family	who leads it	present at	in the product
carbohydrates	UDP and its relatives	every glycosyl transfer	no — released at transfer

Four families, four leaders, and not one of them appears in the finished molecule. Two of the four are sulfur — the methionine and the thiol. A third, PRPP, is the fork this volume has spent a hundred sections on. The fourth is a nucleotide doing a job for a family that is not its own.

1011. What Each Band Cannot Do Without ↩

The percussion rank, from the Preface — the free ions that carry pulse rather than melody.

the family	what it cannot assemble without
nucleotides	magnesium — every polymerase, every ribozyme, and MgATP as the actual substrate
amino acids	magnesium — the tRNA charging reaction runs on MgATP
lipids	magnesium — three of the five CoA biosynthesis steps consume ATP
carbohydrates	magnesium — every kinase in glycolysis

And the specialists at the apex: iron routing electrons, zinc holding shape, molybdenum at one cofactor, manganese making the oxygen.

1012. The Five Bands on One Field ↩

THE ATOMS who everyone is made of\nTHE NUCLEOTIDES who carries the message, and who carries the energy\nTHE AMINO ACIDS who does the catalysis\nTHE LIPIDS who makes the boundary\nTHE SUGARS who makes the surface

The 1982 chart draws all five families on four sheets, and the arrows between them are the metabolism. Colored by the atom key, the sheets show which family is which by the color of its ink before a word is read.

That is the whole reason the chart is in this volume. It is the only document in the working library in which all four monomer families are drawn at once, at a scale where the eye can see the traffic between them.

1013. And the Figure's Limit, Again ↩

A marching band has a drill designer, a score written before the first rehearsal, and a director who knows how the show ends.

Nothing in this volume is explained by design. Every mechanism recorded here is accounted for by chemistry and by selection.

The bands are a way of reading. They carry no argument and decide no question. Every claim in this Part has a section number elsewhere in the volume where the evidence is set out.

1014. What This Part Refuses ↩

the claim	the status
the four families each have a carrier absent from the product	established, and each is cited in its own Part
that this is a designed symmetry	refused. Four families evolved four solutions to the same problem, which is convergence and not a plan
that the drum major role is a real biological category	refused. It is a reading device. The biological categories are activated intermediate, carrier protein and initiator residue, and they are not the same thing as each other
that the 1982 chart is evidence for the framework	refused. It is evidence about where ink falls on a printed sheet, which is what Part Forty-Two says

1015. What This Part Claims ↩

The claims

1	**All four monomer families are assembled through a carrier that is absent from the finished polymer**
2	PRPP carries every nucleotide and has no base
3	Methionine begins every protein and is excised from most
4	The phosphopantetheine thiol carries every fatty acid intermediate and is released at the end
5	Sugars are transferred as nucleotide-sugars and the nucleotide does not stay
6	Two of the four carriers are sulfur
7	On the 1982 chart the free bases sit almost entirely inside the two catabolism boxes
8	Selenium appears nowhere on that chart, which was drawn in 1982
9	Magnesium is required by all four assembly lines

What would refute it

the claim	what would kill it
the carrier pattern	a monomer family assembled by direct addition with no activated carrier
methionine excision	evidence that N-terminal methionine is retained in the majority of mature proteins
the free bases on the chart	a reading of the same chart finding free bases distributed through the anabolic territory
the phosphopantetheine claim	a fatty acid synthase carrying intermediates as oxygen esters

And the observation this Part exists to record. The reason the figure holds across four unrelated chemistries is not that biology was organized like a band. It is that assembling a polymer from a monomer requires the monomer to be carried, activated and released — and a carrier that stayed behind would be part of the product rather than a carrier. The absence is structural. Every one of these four families needed something that would not be in the answer, and two of them reached for sulfur.

PART ONE HUNDRED AND FOURTEEN · SULFUR AND THE PROTEIN

Part One Hundred and Fourteen of the evidence volume, sections 1016 to 1028

Dr. John Allen Berger · NovagonDNA · Naperville, Illinois

Two of the twenty-one residues carry sulfur and a third carries selenium. That is fourteen percent of the alphabet holding the element. Every protein ever made began with a sulfur residue at the front. Every disulfide bridge that holds a shape is two sulfurs finding each other. And the enzyme that joins each amino acid to its transfer RNA — the only covalent junction between the nucleic acid world and the protein world — burns a molecule of ATP to do it.

1016. The Three Residues ↩

residue	what it carries	what it does
cysteine	a thiol — sulfur with a hydrogen on it	makes the disulfide bridge; holds the metal; carries the radical
methionine	a thioether — sulfur between two carbons	begins every protein; becomes the methyl donor
selenocysteine	the same shape with selenium instead	twenty-five human proteins; a recoded stop codon

Three residues out of twenty-one. Section 5 of this volume prints the whole panel and the companion plate colors it.

1017. The First Residue of Every Protein ↩

Translation begins at AUG. AUG is methionine. There is no other start codon in the standard code.

Every protein that has ever been made in any cell of any organism began with a sulfur amino acid at the front.

And in most finished proteins it is gone. An enzyme called methionine aminopeptidase cuts it off once the chain is long enough to fold. The residue that starts the work is not in the record of the work.

Part One Hundred and Thirteen calls methionine the drum major for this reason.

1018. The Bridge ↩

What a disulfide is

Two cysteines, each holding a hydrogen on its sulfur. Take the two hydrogens away and the two sulfurs bond to each other.

$$Cys\text{-}SH \; + \; HS\text{-}Cys \; \rightarrow \; Cys\text{-}S\text{-}S\text{-}Cys \; + \; 2H$$

what it does	staples two parts of a chain together
where it is strong	outside the cell, where conditions favor the bond
where it is broken	inside the cell, which is kept in the opposite condition

The same two residues make a bridge in one compartment and stay apart in the other. Nothing about the sequence changes. The compartment decides.

That is this volume's argument in a protein: identity is written in the letters, and the behavior depends on where the molecule is standing.

1019. And the Bridge Is Why Insulin Is Insulin ↩

the protein	what the disulfides do
insulin	three of them — two joining the A chain to the B chain, one inside the A chain. Cut them and the hormone falls into two useless pieces
antibodies	hold the four chains of the Y together
keratin	the reason hair is hair, and the reason a permanent wave works — the treatment breaks disulfides and remakes them in a new shape

A permanent wave is disulfide chemistry performed in a salon.

1020. The Switch ↩

A thiol can be oxidized part of the way and come back. That makes it a switch rather than a bond.

the state	what it means
thiol, –SH	the resting state
sulfenic acid, –SOH	reversible — the cell can undo it
sulfinic acid, –SO_2H	barely reversible
sulfonic acid, –SO_3H	permanent

One cysteine can sit at four levels of oxidation, and the first step back is easy while the last is not. That is a dial, not a light switch, and no letter in any sequence records which position it is in.

Part Fifty-One of this volume records the sulfenyl-amide switch in the phosphatase enzymes, where this chemistry turns a signal on and off.

1021. The Join ↩

Part Thirty-Two named the aminoacyl-tRNA synthetases as the one covalent junction between nucleic acid and protein. There are twenty of them and each one has to solve the same problem twice.

the job	
pick the right amino acid out of a pool of twenty-one that look similar	
pick the right transfer RNA out of dozens	
join them, using one ATP	

Two of these enzymes have the hardest discrimination problem in the cell, and both cases are sulfur.

1022. The Two Hard Cases, and Both Are Sulfur ↩

Isoleucine against valine

They differ by one methyl group. Isoleucyl-tRNA synthetase gets it wrong about once in a hundred and fifty tries — and then corrects it, in a second active site built only for correcting.

Cysteine against serine

Serine is cysteine with an oxygen where the sulfur is. Same shape, one atom different.

The conjugate pair of Part Two, appearing as a proofreading problem. Sulfur and oxygen are one shell apart and the enzyme has to tell them apart every time it charges a tRNA.

And methionyl-tRNA synthetase has its own version, because homocysteine is methionine one carbon short. It edits that error by forcing the mistake into a ring, which cannot be used.

1023. The Radical ↩

A thiyl radical is a sulfur with an unpaired electron. It is violently reactive and the cell makes one on purpose.

the enzyme	ribonucleotide reductase
what it does	takes an oxygen off a ribose and makes deoxyribose
how it starts	a cysteine loses a hydrogen and becomes a thiyl radical
the consequence	every deoxyribonucleotide in every strand of DNA in every organism was made this way

Part Seven of this volume carries the full account. It belongs here as well, because it is a cysteine doing it.

1024. The Metal Holder ↩

Cysteine is how a protein holds a metal.

the site	the metal	held by
zinc finger	zinc	cysteines and histidines
iron-sulfur cluster	iron	cysteines, and the cluster's own sulfurs
heme, in some proteins	iron	a cysteine underneath
the molybdenum cofactor	molybdenum	sulfurs on the pterin

Part One Hundred and Six placed iron, zinc and molybdenum in the third layer — coordinated, not bonded. Cysteine is what does the coordinating. The metals are held by sulfur.

1025. The Peptide That Is Not in Any Protein ↩

Glutathione

what it is	three amino acids — glutamate, cysteine, glycine
how much	one to ten thousandths of a mole per liter inside a cell — among the most concentrated small molecules there
what it does	keeps the inside of the cell in the condition where disulfides stay open
the working part	the cysteine thiol

It is made by two enzymes, not by a ribosome. It is a peptide with no gene of its own and no codons behind it.

The most abundant thiol in the body is not in the genetic code at all.

1026. What the Notation Loses Here ↩

the molecule	what a sequence records
a free cysteine	C
a cysteine in a disulfide bridge	C
a cysteine oxidized to sulfenic acid	C
a cysteine holding a zinc	C

the molecule	what a sequence records
a cysteine holding an iron-sulfur cluster	C
a cysteine as a thiyl radical	C

Six states. One letter. And the difference between them decides whether a protein is folded, switched on, holding a metal, or making DNA.

1027. What This Part Refuses ↩

the claim	the status
methionine begins every protein and is removed from most	established
disulfides form outside the cell and stay open inside	established, and it is a matter of conditions rather than sequence
cysteine oxidation runs through four levels	established
cysteine coordinates zinc, iron and the metal cofactors	established
that sulfur therefore determines protein folding	refused. Folding is driven mainly by which parts of a chain avoid water. Disulfides lock in a fold that has already happened; they do not choose it
that the two hard proofreading cases being sulfur is more than a coincidence	not established. Two cases is two cases, and the volume says so

1028. What This Part Claims ↩

The claims

1	Three of twenty-one residues carry sulfur or selenium
2	Every protein begins at AUG, which is methionine, and most finished proteins have had it cut off
3	A disulfide bridge is two cysteines joined, and whether it forms depends on the compartment rather than the sequence

1	**Three of twenty-one residues carry sulfur or selenium**
4	Insulin is held together by three of them
5	A cysteine can sit at four oxidation levels, and only the first step back is easy
6	Two of the hardest proofreading problems in translation are sulfur against oxygen and methionine against homocysteine
7	Ribonucleotide reductase starts with a cysteine radical, and made every deoxyribonucleotide that exists
8	Cysteine holds the zinc, the iron and the iron-sulfur cluster
9	Glutathione is the most abundant thiol in a cell and has no gene and no codons

What would refute it

the claim	what would kill it
AUG as the only start	a standard-code organism initiating routinely at a non-methionine codon
the compartment rule for disulfides	measurement showing stable disulfides at normal levels inside the cell
the four oxidation levels	evidence that sulfinic acid is as freely reversible as sulfenic
the six-states-one-letter claim of section 1026	a sequence format in ordinary use that records cysteine state

And the observation this Part exists to record. A protein is described by a string of letters, and the letter C appears in that string whether the residue is idle, bridged, switched, holding a metal, or carrying a radical that is about to build a strand of DNA. The string is the same in all six cases.

PART ONE HUNDRED AND FIFTEEN · SULFUR AND THE FURNACE

Part One Hundred and Fifteen of the evidence volume, sections 1029 to 1041
